The crew then begins their payload operations performing numerous assigned tasks, depending upon the purpose of the mission, such as retrieving satellites from Earth's orbit, servicing orbiting satellites, conducting experiments in space, and studying the Earth and deep space. See Fig. 7.

For deorbit, the orbiter is rotated tail first in the direction of the velocity by the primary reaction control system engines. Then the OMS engines are used to decrease the orbiter's velocity.

During the initial entry sequence, selected primary RCS engines are used to control the orbiter's attitude (pitch, roll, and yaw). As aerodynamic pressure builds up, the orbiter flight control surfaces become active and the primary reaction control system engines are inhibited.

During entry, the thermal protection system covering the entire orbiter provides the protection for the orbiter to survive the extremely high

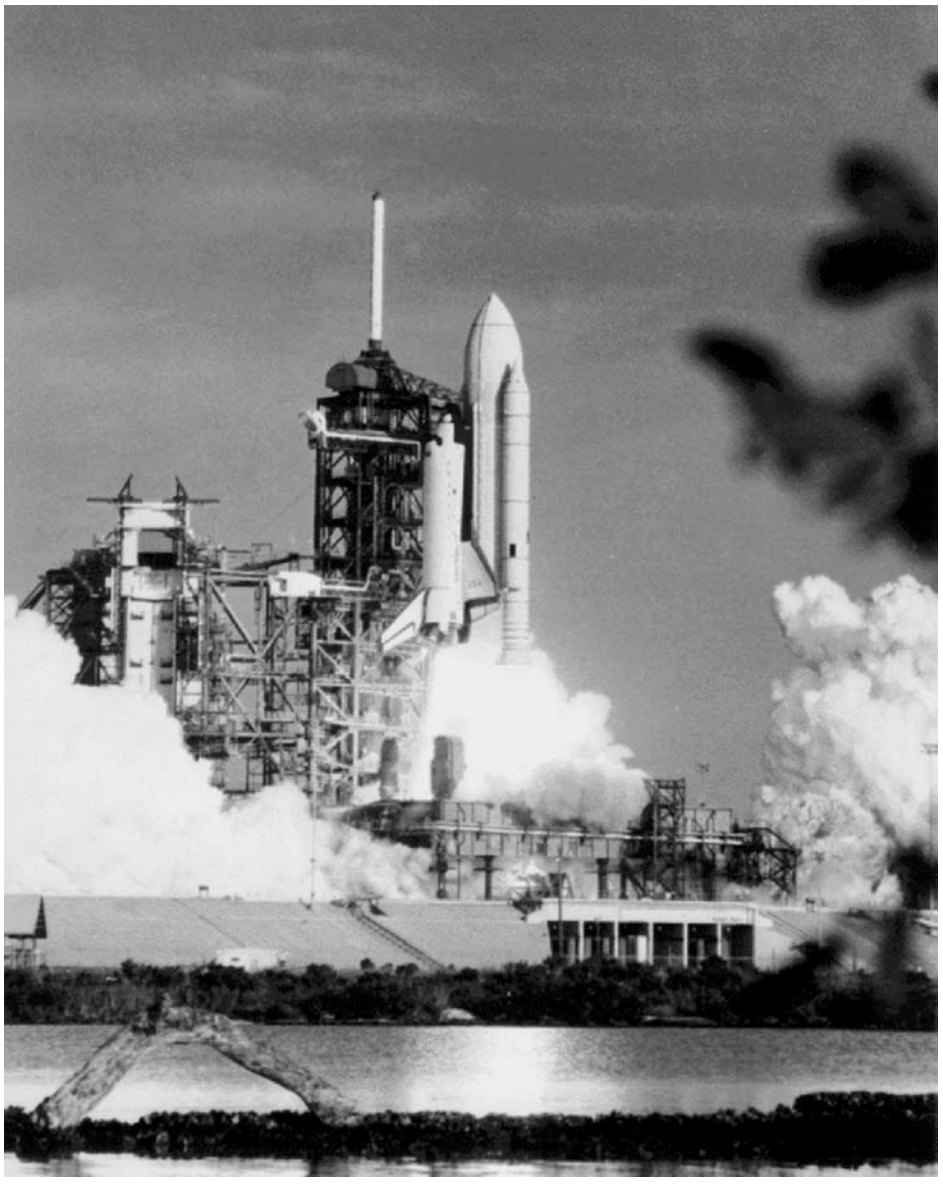

Fig. 5. NASA's re-useable space vehicle, the Space Shuttle, takes off like a rocket, operates in orbit like a spacecraft, then lands like an aircraft. Here it lifts off the launchpad at Kennedy Space Center near Orlando, Florida. At this moment five rockets are firing: the Shuttle's three main engines and two solid rocket boosters. Together they are generating almost seven million pounds of thrust at the moment of lift-off. (*JPL/ NASA*.)

Fig. 6. After lift-off, the solid rocket boosters attached to the sides of the large, reddish, external fuel tank continue to burn for approximately two minutes. When their fuel is spent, they separate from the tank, fall back into the sea, and are retrieved for re-use on subsequent Shuttle missions. The Shuttle's three main engines continue to fire, using half a million gallons of liquid hydrogen and liquid oxygen. Between 8 and 9 minutes into the flight Earth orbit is achieved, the external tank is cast away, and the astronauts use small maneuvering engines to ease the Shuttle into its final orbit. (*JPL/NASA*.)

temperatures encountered during entry. Portions of the orbiter's exterior will reach temperatures of up to 2300 °F (1260 °C). The thermal protection system is reusable (it does not burn off or ablate during entry).

The unpowered orbiter glides to Earth and lands on a runway like an airplane. Nominal touchdown speed varies from 184 to 196 knots (213 to 225 miles per hour). See Fig. 8.

The main landing gear wheels have a braking system for stopping the orbiter on the runway, and the nose wheel is steerable, again similar to a conventional airplane.

Main Engine. The shuttle's main engine, along with two solid rocket boosters, is the most advanced liquid-fueled rocket engine built to date. With variable thrust permitting the engine thrust to be tailored to the mission needs, it can operate effectively at both high and low altitudes. This system can operate up to $7\frac{1}{2}$ hours of accumulated firing time before major maintenance or overhaul is required. It is expected that the main engine will be reusable for up to 55 separate shuttle missions.

Three main engines are mounted on the orbiter aft fuselage in a triangular pattern. The engines are so spaced that they can be gimbaled during flight and, in conjunction with the two solid rocket-boosters, are used to steer the shuttle during flight as well as to provide thrust for launch. Fuel for the engines, liquid hydrogen and liquid oxygen, is carried to be supplied from the tank at a rate of about 45,283 gallons (63,588 liters) per minute of hydrogen and about 16,800 gallons (63,588 liters) per minute of oxygen.

Numerous features have been designed into the engine to satisfy the performance, life, reliability, and maintainability requirements of the shuttle. One feature includes the use of a stage combustion power cycle coupled with high combustion chamber pressures. In the staged combustion cycle, the liquid hydrogen is partially burned at high pressure and relatively low temperature in preburners and then completely combusted at high temperature and pressure in the main combustion chamber before expanding through the high-area ratio nozzle. The rapid mixing of propellants under these conditions is so complete that a combustion efficiency of about 99% is attained. The engine also uses hydrogen fuel to cool all combustion devices in direct contact with high-temperature combustion products, thereby contributing to long engine life.

Each engine has three primary levels of thrust or power: minimum, rated, and full power. Engine thrust, however, can be varied throughout the range from minimum to full power level, depending on mission needs. On some shuttle flights where heavy payloads dictate an extra measure of power, up to full power level thrust can be commanded. This level equals 109% of rated power. During the latter part of ascent, engine thrust is

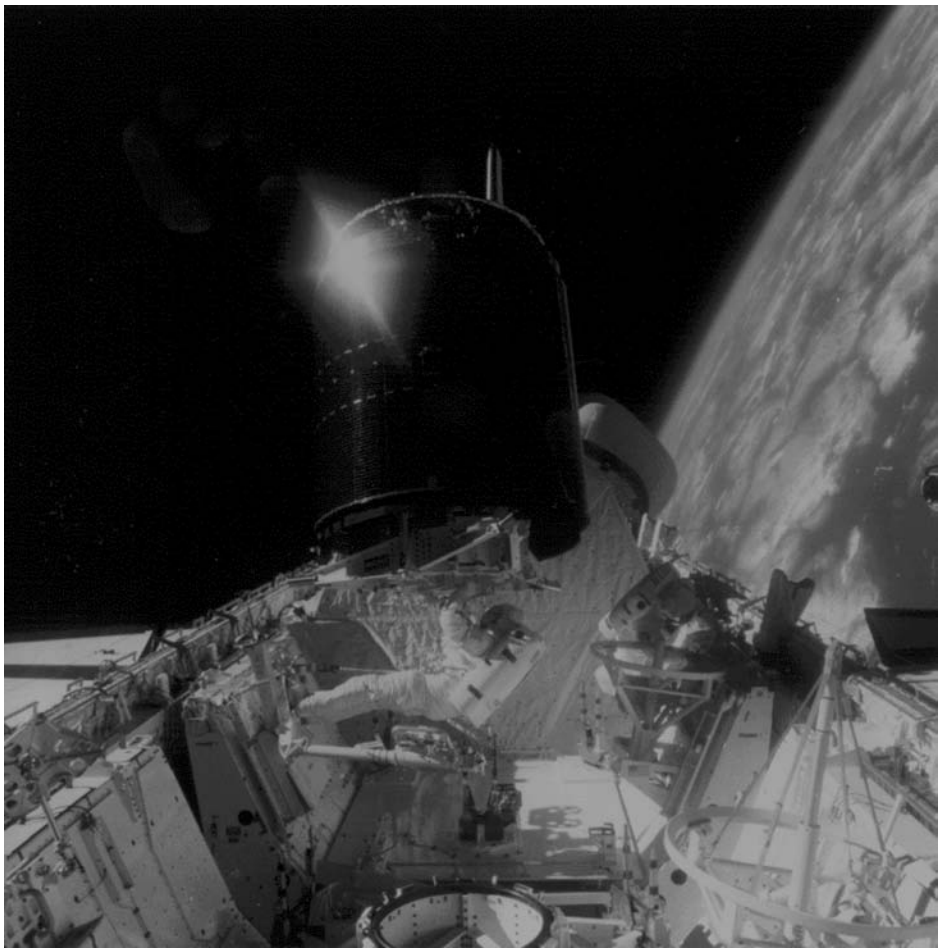

Fig. 7. In this image, a space-suited astronaut prepares a satellite for its release from the Shuttle's cargo bay. The bay, 18.3 meters long and 4.6 meters wide (60 feet by 15 feet), has payload attachment points along its full length, and is adaptable enough to accommodate as many as five unmanned spacecraft of various sizes and shapes in one mission. The cargo bay is equipped also with a 15 meter (50 foot) robot arm for lifting and releasing, or grasping and retrieving satellites in space. (*JPL/NASA*.)

reduced to ensure that an acceleration force of no more than three times that of Earth's gravity is reached. This acceleration level, permitted by the throttleable shuttle engines, is about one-third the acceleration experienced in prior manned space flights and is well under the physical stress limits of non-astronaut scientists who will fly aboard the space shuttle. The lowest throttle setting, the minimum power level, equals 65% of rated power.

Solid Rocket Boosters. Two solid rocket boosters are used for each shuttle flight to provide, along with the orbiter main engines, the initial ascent thrust to lift the shuttle with its payload from the launch pad to an altitude of about 27.5 miles (44 kilometers). Prior to launch, the entire shuttle weight is supported by the two boosters. Each solid rocket booster is made up of six subsystems: the solid rocket motor, structures, thrust vector control, separation, recovery, and electrical and instrumentation subsystems. The overall length of the solid rocket booster is 149.1 feet (45.5 meters). The diameter is 12.2 feet (3.7 meters).

The heart of each booster is the motor, the largest solid rocket motor ever flown to date and the first designed for reuse. The motor is made up of eleven segments joined together to make four loading segments, which are filled with propellant at the manufacturer's site. The segmented design permits ease of fabrication, handling and transportation. The segments are shipped from the manufacturer's site to the launch sites by rail in specially built canisters carried on a flat rail car. At the launch site, they are assembled to make up a complete motor.

Propellant loading of the motor segments is completed in pairs from batches of propellant ingredients to minimize any thrust imbalances between boosters used for a single shuttle flight. Propellant loading, using different internal propellant shapes (cores), is done in such a way that will cause a regressive thrust 55 seconds into the shuttle flight. This prevents overstressing the shuttle vehicle during the critical phase of flight, which is called the period of maximum dynamic pressure. Each motor, when assembled, contains about 1.1 million pounds (.5 million kilograms) of propellant, and at launch develops a thrust of 2.9 million pounds (1.3 million kilograms).

The exhaust nozzle in the aft segment of each motor, in conjunction with the orbiter engines, steers the shuttle during flight. The nozzle can be moved up to 6.65 degrees by the booster's hydraulically operated thrust vector control subsystem. The latter is controlled by the orbiter's guidance and control computer.

Throughout the flight, measurements are taken to verify proper booster performance. The signals are routed to the orbiter for data recording and transmission to the ground. Electrical power for the solid rocket booster subsystems is supplied from the orbiter fuel cells through interconnect cabling from the external tank.

At burnout, the two solid rocket boosters are separated from the external tank by pyrotechnic (explosive) devices, and moved away from the shuttle vehicle by eight separation motors, four housed in the forward nose frustum and four on the aft skirt. Each of the eight separation motors, fired at solid rocket motor burnout, develops a thrust of 22,000 pounds (9,900 kilograms) for a duration of a little more than one-half second, just sufficient to move the boosters away from the still-accelerating orbiter and external tank. Also a part of the system is a device for separating electrical interconnection with the external tank.

The facility for providing the method to control the boosters' final descent velocity and altitude after separation is the recovery subsystem. This system in the forward section of each booster and within the nose cap consists of parachutes and location aids to help in the search and retrieval operations for each expended booster and its parachute.

Following separation and entry into the lower atmosphere at about 15,420 feet (4,700 meters), each booster is slowed by a pilot and drogue parachute, and finally by three main parachutes, each 104 feet

Fig. 8. The return to Earth at the end of a mission is a critical and demanding time for the Shuttle crew. Astronauts slow the craft and ease it into Earth's atmosphere by using small rockets in the craft's nose and tail. Then after re-entry, they steer it like an airplane using rudders and flaps as the craft glides Earthward. Here, after having slowed down from 1,000 to 100 meters per second (3,280 to 328 feet per second), and withstood temperatures of up to 1000 °C (1830 °F), the Space Shuttle *Columbia* touches down at Edwards Air Force Base, thirty busy minutes after having left Earth orbit. (*JPL/ NASA*.)

(31.7 meters) in diameter. Impact with the water is aft end first about 160 miles (257.5 kilometers) downrange, at a speed of about 60 miles (95.5 kilometers) per hour. By entering the water in this way, the air in the hollow boosters is trapped and compressed, causing the boosters to float with the forward end out of the water. At booster impact, the main parachutes are disconnected and the direction finding beacons and lights are actuated to guide recovery craft to the boosters and parachutes. The parachutes are picked up by the recovery craft, and the boosters are towed to shore, where they are disassembled and refurbished. The motor segments are shipped to the manufacturer by rail for refurbishment and reloading for a subsequent shuttle flight. The other systems are refurbished either at the launch site or at the respective manufacturers' locations. The thrust vector control subsystem, structural subsystem, and the electrical subsystems are planned for 20 flights and the recovery subsystem for 10 flights.

The separation system is not planned for reuse. At the launch site, the two boosters are assembled vertically on the launch platform. Following assembly of the boosters, the external tank is attached to the boosters, and finally the orbiter and payload to the external tank, thus making the shuttle ready for checkout and another flight.

External Tank. This tank has two principal roles in the space shuttle program: (1) to contain and deliver quality propellants, liquid hydrogen and liquid oxygen, to the engines; and (2) to serve as the structural backbone of the shuttle during launch operations.

The external tank is composed of essentially two tanks (a large hydrogen tank and a smaller oxygen tank) joined together to form one large propellant storage container that is 154.2 feet (47 meters) in length and 27.5 feet (8.4 meters) in diameter. See Fig. 7. The oxygen tank is the forward portion of the external tank and, when loaded, contains 1,331,783 pounds (603,983 kilograms) of liquid oxygen. By comparison, the oxygen tank has considerably more volume than that of a house with a floor square area of 2,000 square feet (186 square meters). The forward end of the oxygen tank curves to a point to reduce aerodynamic drag and to provide lightning protection for the shuttle vehicle once the shuttle has cleared the launch pad. Prior to launch, the launch tower provides lightning protection.

The liquid hydrogen tank, aft of the oxygen tank, is about 2.5 times larger than the oxygen tank. In this tank is stored approximately 223,814 pounds (101,503 kilograms) of cold liquid hydrogen (approximately −240 °F or −251 °C).

The intertank joins the two tanks and provides a protective compartment to house some of the instrumentation components in the space between the two propellant tanks. For launch, the external tank supports the orbiter and solid rocket boosters at attach points on the tank. Since the thrust is generated by the orbiter main engines and the solid rocket boosters, the external tank must absorb the thrust loads for the shuttle during launch. The intertank takes the major thrust loads from the solid rocket boosters; the orbiter main engine thrust loads are transferred through other attach fittings on the tank.

Much of the outer surface of the tank is protected thermally. Spray-on foam insulation is applied over the forward portion of the oxygen tank, the intertank, and the sides of the hydrogen tank. The foam insulation is required for reducing ice or frost formation on the tank during launch preparation, thus protecting the orbiter insulation from free-falling ice during flight. Additionally, it serves to minimize heat leaks into the tank, which would cause excessive boiling of the liquid propellants, and to prevent condensation and solidification of the air next to the tank.

An ablating material (a substance that *chars away*) is applied to the external tank bulges and projections to protect them from aerodynamic heating during flight through the atmosphere. Sometimes a combination foam and *ablator* is used where both heating and insulation protection are needed. Protection is also required in areas where exhausts of launch engines provide high radiant energy to the tank and where separation motor exhaust plumes may strike the tank.

The external tank, having no electrical power, obtains required electrical energy from the orbiter fuel cells. It does, however, provide the needed cabling to carry power and signals to the external tank electronics and instrumentation components and to the two solid rocket boosters. Fluid controls and valves, except the vent valves, for operation of the engines are located in the orbiter. This is done to minimize throwaway costs inasmuch as the external tank is not reused.

During flight, gases supplied from the three engines pressurize the two tanks. Pressurization is required for structural support of the tank and for operating pressure requirements of the engine pumps. Near the end of the launch phase of the shuttle mission, when the orbiter is just short of orbital velocity, the main engines are cut off. After about ten seconds, the external

tank is severed from its attachment to the orbiter, playing a totally passive role in the separation sequence. Just prior to separation, the external tank tumbling system is activated, opening a valve and venting the oxygen tank through the nose cap. This causes the external tank to pitch away from the orbiter and begin to tumble at a rate that will assure that the tank will break up upon reentry and fall within the designated ocean impact area.

Orbiter Structure. The orbiter structure is divided into nine major sections: the forward fuselage, which consists of upper and lower sections fit around a pressurized crew compartment; wings; midfuselage; payload bay doors; aft fuselage; forward reaction control system; vertical tail; orbital maneuvering system/reaction control system pods; and body flap. The majority of the sections are constructed of conventional aluminum and protected by reusable surface insulation.

The forward fuselage structure is composed of 2024 aluminum alloy skin-stringer panels, frames, and bulkheads. The crew compartment is supported within the forward fuselage at four attachment points, which minimizes thermal conductivity, and is welded to create a pressure-tight vessel. The two major attach points are located at the aft end of the crew compartment at the flight deck floor level. The three-level compartment has a wide hatch for normal passage and hatches in the airlock to permit extravehicular and intravehicular activities. The side hatch can be jettisoned.

Redundant pressure windowpanes are provided in the six forward windshields, the two overhead viewing windows, the two aft viewing windows and the side hatch windows. Approximately 300 penetrations in the pressure shell are sealed with plates and fittings. A large removable panel in the aft bulkhead provides access to the interior of the crew compartment during initial fabrication and assembly and provides for airlock installation and removal.

The crew compartment is configured to accommodate a crew of four on the flight deck and three to four in the middeck. The crew compartment is pressurized to 14.7 psia, plus or minus 0.2 psia, and is maintained at an 80-percent nitrogen and 20-percent oxygen composition that provides a shirtsleeve environment for the flight crew. The crew compartment is designed for 16 psia. The crew compartment's volume with the airlock in the middeck is 2,325 cubic feet (69.7 cubic meters). If the airlock is in the payload bay, the crew compartment's cabin volume is 2,625 cubic feet (78.7 cubic meters). The crew cabin arrangement consists of a flight deck, middeck and lower level equipment bay in a combination of living, working, and storage areas.

The flight deck is the uppermost compartment of the cabin. The commander's and pilot's workstations are positioned side by side in the forward portion of the flight deck. These stations have controls and displays for maintaining autonomous control of the vehicle throughout all mission phases. Directly behind and to the sides of the commander and pilot centerline are the mission specialist seats. The aft flight deck has two overhead and aft viewing windows for viewing orbital operations.

The aft flight deck station also contains displays and controls for executing attitude or translational maneuvers for rendezvous, station keeping, docking, payload deployment and retrieval, payload monitoring, remote manipulator system controls and displays, payload bay door operations and closed-circuit television operations. The aft flight deck is approximately 40 square feet (3.6 square meters). The forward flight deck, which includes the center console and seats, is approximately 24 square feet (2.2 square meters). However, the side console controls and displays add approximately 3.5 square feet more (0.3 square meters).

Directly beneath the flight deck is the mid-deck. Access to the mid-deck is through two interdeck openings, which measure 26 by 28 inches (650 by 700 millimeters). Normally, the right interdeck opening is closed and the left is open. A ladder attached to the left interdeck access allows easy passage in 1-g conditions. The mid-deck provides crew accommodations and contains three avionics equipment bays. The two forward avionics bays utilize the complete width of the cabin and extend into the mid-deck 39 inches (975 millimeters) from the forward bulkhead. The aft bay extends into the mid-deck 39 inches (975 millimeters) from the aft bulkhead on the right side of the airlock. Just forward of the waste management system is the side hatch. The completely stripped mid-deck is approximately 160 square feet (14.4 square meters); the gross mobility area is approximately 100 square feet (9 square meters).

The side hatch in the mid-deck is used for normal crew entrance/exit and may be operated from within the crew cabin mid-deck or externally. It can be jettisoned for emergencies. It is attached to the crew cabin tunnel by hinges, a torque tube and support fittings. The hatch opens outwardly 90 degrees down with the orbiter horizontal or 90 degrees sideways with the orbiter vertical. It is 40 inches (1,000 millimeters) in diameter and has a 10-inch (250 millimeters) clear-view window in the center of the hatch. The window consists of three panes of glass.

Depending on the mission requirements, bunk sleep stations and a galley can be installed in the mid-deck. In addition, three or four seats of the same type as the mission specialists' seats on the flight deck can be installed in the mid-deck. Three seats over the normal three could be installed in the mid-deck for rescue missions if the bunk sleep stations were removed. The waste management system, located in the mid-deck, can also accommodate payloads in the pressurized crew compartment environment. The mid-deck also provides a stowage volume of 140 cubic feet (4 cubic meters). Accommodations are included for dining, sleeping, maintenance, exercising, and data management. On the orbiter centerline, just aft of the forward avionics equipment bay, an opening in the ceiling provides access to the inertial measurement units.

The mid-deck equipment bay below the mid-deck floor houses the major components of the waste management and air revitalization systems, such as pumps, fans, lithium hydroxide, absorbers, heat exchangers, and ducting. This compartment has space for stowing lithium hydroxide canisters and five separate spaces for crew equipment stowage with a volume of 29.9 cubic feet (0.8 cubic meters). Modular stowage lockers are used to store the flight crew's personal gear, mission-necessary equipment, personal hygiene equipment, and experiments. The modular lockers are made of sandwich panels of Kevlar/epoxy and a nonmetallic core. This reduced the lockers' weight by 83 percent compared to all-aluminum lockers, a reduction of approximately 150 pounds (67 kilograms).

Seating for three passengers/researchers, along with the habitability provisions, are located on the lower level or deck. The habitability provisions consist of a galley for food preparation, which includes an oven and hot and cold water dispensers for the preparation of rehydratable freeze-dried foods, an eating area, personal hygiene facilities, and sleeping accommodations.

The wing is constructed of a conventional aluminum alloy, using a corrugated spar web, truss-type ribs and riveted skin-stringer and honeycomb covers. The elevons are constructed of aluminum honeycomb and are split into two segments to minimize hinge binding and interaction with the wing.

The midfuselage is a 60-foot (18-meter) section of primary load-carrying structure between the forward and aft fuselages. It includes the wing carry-through structure and the payload bay doors. The skins consist of integral-machined aluminum panels and aluminum honeycomb sandwich panels. The frames are constructed from a combination of aluminum panels with riveted or machined integral stiffeners and a truss structure center section.

Payload bay doors make up the upper half of the midfuselage and are hinged along the side and split at the top centerline. The doors are graphite epoxy frames and honeycomb panel construction.

The aft fuselage includes a truss-type internal structure of diffusion-bonded elements that transfer the main engine thrust loads to the midfuselage and external tank. The aft fuselage's external surface is of standard construction except for the removable orbital maneuvering system/reaction control system pods, which are constructed of graphite epoxy skins and frames. An aluminum bulkhead shield with reusable insulation at the rear of the orbiter protects the rear portion of the aft fuselage.

The vertical tail, a conventional aluminum alloy structure, is a two-spar, multirib, integrally machined skin assembly. The tail is attached to the aft fuselage by bolted fittings at the two main spars. The rudder/speed brake assembly is divided into upper and lower sections, which are split longitudinally and actuated individually to serve as both rudder and speed brake.

The body flap, which has aluminum honeycomb covers, is attached to the lower aft fuselage by four rotary actuators.

These major structural assemblies are mated and held together by rivets and bolts. The midfuselage is joined to the forward and aft fuselage

primarily by shear ties. The wing is attached to the midfuselage and aft fuselage primarily by shear ties, except in the area of the wing carry-through, where the upper panels are attached with tension bolts. The vertical tail is attached to the aft fuselage with bolts that work in both shear and tension.

The orbiter's exterior is covered with thermal protective materials to protect the spacecraft from solar radiation and the extreme heat of atmospheric reentry. Two types of reusable surface insulation, coated silica tiles and coated flexible sheets, cover the top and sides of the orbiter. The tiles protect the surfaces up to 1200 °F (649 °C); the flexible insulation provides protection up to 700 °F (371 °C). The coating on both types of insulation gives the orbiter a nearly white color and has optical properties that reflect solar radiation. On the bottom of the orbiter and on the leading edge of the tail, a high-temperature reusable surface insulation, made of coated silica tiles, protects the aluminum structure up to 2300 °F (1260 °C). The high-temperature coating is of a glossy black appearance. A reinforced carbon–carbon material is used for the nose cap and the wing leading edges, where the temperatures exceed 2300 °F (1260 °C).

Shuttle Landing Facility (SLF). Orbiter landings at the Kennedy Space Center are made on one of the largest runways in the world. The runway is located 3.2 kilometers (2 miles) northwest of the Vehicle Assembly Building and is 4,572 meters (15,000 feet) long and 91.4 meters (300 feet) wide, about as wide as the length of a football field. It has 305 meters (1000 feet) of paved overruns at each end and the paving thickness is 40.6 cm (15 inches) at the center.

The facility includes a 150 × 168 meters (490 × 550 feet) parking apron and a 3.2 kilometers (2 miles) tow-way connecting it with the Orbiter Processing Facility. Located adjacent to the parking apron is a Landing Aids Control Building (LACB) which supports landing operations and houses operations personnel.

Located at the northeast corner of the parking apron is the Mate/Demate device (MDD) used to raise and lower the orbiter from its 747 carrier aircraft during ferry operations. The open-truss steel structure is equipped with hoists, adapters and movable platforms for access to certain orbiter components and equipment. It also is equipped with lightning protection devices. The MDD is 45.7 meters (150 feet) long, 28.3 meters (93 feet) wide and 32 meters (105 feet) high.

The Shuttle Landing Facility is equipped with a number of navigation and landing aids to assist Shuttle pilots in landing. There are four sophisticated Microwave Scanning Beam Landing System (MSBLS) ground stations, two located at each end of the runway, that provide elevation and directional/distance measurement for landing approaches from the northwest (runway 15) or southeast (runway 33). Equipment onboard the orbiter receives the data from the MSBLS stations and automatically makes any needed adjustments to the glide slope.

A Tactical Air Navigation (TACAN) system, located at mid-field off the east side of the runway, is used by pilots to execute an instrument landing approach to the runway. The TACAN has a range of 483 kilometers (300 miles), and is received by the orbiter when it emerges from the reentry blackout period. The final approach is guided by the MSBLS system.

Visual aids are provided by Precision Approach Path Indicators, known as the PAPI system. They utilize arrays of red and white lights that, when lined up properly by the pilot, will indicate the proper glide slope. A ball/bar light system is used for inner glide slope information on final approach to inform the pilot whether he is on, above or below the glide slope for an orbiter touchdown point marked on the runway.

A Recovery Convoy Staging Area, located just east of the runway about midway along its length, houses trailers, mobile units and specially designed vehicles that are used to "safe" the orbiter immediately after landing for crew egress and transfer of the orbiter to the Orbiter Processing Facility. For information on the Kennedy Space Center facilities see http://science.ksc.nasa.gov/facilities/tour.html.

Orbiter Ground Turnaround. Approximately 160 Space Shuttle launch operations team members support spacecraft recovery operations at the nominal end-of-mission landing site. Ground team members wearing self-contained atmospheric protective ensemble suits that protect them from toxic chemicals approach the spacecraft as soon as it stops rolling. The ground team members take sensor measurements to ensure the atmosphere in the vicinity of the spacecraft is not explosive. In the event of propellant leaks, a wind machine truck carrying a large fan will be moved into the area to create a turbulent airflow that will break up gas concentrations and reduce the potential for an explosion.

A ground support equipment air-conditioning purge unit is attached to the right-hand orbiter T-0 umbilical so cool air can be directed through the orbiter's aft fuselage, payload bay, forward fuselage, wings, vertical stabilizer, and orbital maneuvering system/reaction control system pods to dissipate the heat of entry.

A second ground support equipment ground cooling unit is connected to the left-hand orbiter T-0 umbilical spacecraft Freon Coolant loops to provide cooling for the flight crew and avionics during the postlanding and system checks. The spacecraft fuel cells remain powered up at this time. The flight crew will then exit the spacecraft, and a ground crew will power down the spacecraft.

AT KSC, the orbiter and ground support equipment convoy move from the runway to the Orbiter Processing Facility.

If the spacecraft lands at Edwards Air Force Base, the same procedures and ground support equipment are used as at the KSC after the orbiter has stopped on the runway. The orbiter and ground support equipment convoy move from the runway to the orbiter mate and demate facility at Edwards. After detailed inspection, the spacecraft is prepared to be ferried atop the Shuttle carrier aircraft from Edwards to KSC. For ferrying, a tail cone is installed over the aft section of the orbiter.

In the event of a landing at an alternate site, a crew of about eight team members will move to the landing site to assist the astronaut crew in preparing the orbiter for loading aboard the Shuttle carrier aircraft for transport back to the KSC. For landings outside the United States, personnel at the contingency landing sites will be provided minimum training on safe handling of the orbiter with emphasis on crash rescue training, how tow the orbiter to a safe area, and prevention of propellant conflagration.

Upon its return to the Orbiter Processing Facility (OPF) at KSC, the orbiter is safed (ordnance devices safed), the payload (if any) is removed, and the orbiter payload bay is reconfigured from the previous mission for the next mission. Any required maintenance and inspections are also performed while the orbiter is in the OPF. A payload for the orbiter's next mission may be installed in the orbiter's payload bay in the OPF or may be installed in the payload bay when the orbiter is at the launch pad.

The spacecraft is then towed to the Vehicle Assembly Building and mated to the external tank. The external tank and solid rocket boosters are stacked and mated on the mobile launcher platform while the orbiter is being refurbished. Space Shuttle orbiter connections are made and the integrated vehicle is checked and ordnance is installed.

The mobile launcher platform moves the entire space shuttle system on four crawlers to the launch pad, where connections are made and servicing and checkout activities begin. If the payload was not installed in the OPF, it will be installed at the launch pad followed by prelaunch activities.

Kennedy Space Center Launch Operations has responsibility for all mating, prelaunch testing and launch control ground activities until the Space Shuttle vehicle clears the launch pad tower. Responsibility is then turned over to Mission Control Center-Houston. The Mission Control Center's responsibility includes ascent, on-orbit operations, entry, approach and landing until landing runout completion, at which time the orbiter is handed over to the postlanding operations at the landing site for turnaround and re-launch. At the launch site the SRBs and external tank are processed for launch and the SRBs are recycled for reuse.

Editor's Note. The staff of this encyclopedia is most appreciative of the cooperation extended by National Aeronautics and Space Administration (NASA) for furnishing information for numerous portions of this article.

SPACE STATIONS. Space stations have long been seen as laboratories for learning about the effects of space conditions and as a springboard to the Moon and Mars. These space stations are man-made satellites designed to maintain a fixed orbit around the Earth while providing a platform for research activities in outer space. Crews live on board the space stations and travel back and forth to Earth via a space transportation system (STS). In the United States, the STS is known as the *Space Shuttle*. See also **Space Shuttle**. In Russia, the primary transport system is the *Soyez-TM*.

The first satellites designed as space stations were Russia's *Salyut* and the United States *Skylab*. These were programs of the early 1970s that served as the foundation of today's space station design and development. Long-duration microgravity research began on *Skylab*, and on *Salyut*, has continued on the *Mir Space Station* and will be further expanded and refined on the *International Space Station* (ISS). See also **Microgravity and Materials Processing**; and **Satellites (Scientific and Reconnaissance)**.

The Beginning (1869–1957)

The concept of a staffed outpost in Earth orbit dates from just after the Civil War. In 1869, American writer Edward Everett Hale published a science fiction tale called "The Brick Moon" in the *Atlantic Monthly*. Hale's manned satellite was a navigational aid for ships at sea. Hale proved prophetic. The fictional designers of the *Brick Moon* encountered many of the same problems with redesigns and funding that NASA would with its station more than a century later.

In 1903, Russian schoolteacher Konstantin Tsiolkovsky wrote "Beyond the Planet Earth," a work of fiction based on sound science. In it, he described orbiting space stations where humans would learn to live in space. Tsiolkovsky believed these would lead to self-contained space settlements and expeditions to the moon, Mars, and the asteroids. Tsiolkovsky wrote about rocketry and space travel until his death in 1935, inspiring generations of Russian space engineers.

In 1923, Hermann Oberth, a Romanian, coined the term "space station." Oberth's station was the starting point for flights to the Moon and Mars. Herman Noordung, an Austrian published the first space station blueprint in 1928. Like today's *International Space Station* (ISS), it had modules with different functions. Both men wrote that space station parts would be launched into space by rockets.

In 1926, American Robert H. Goddard made a major breakthrough by launching the first liquid-fueled rocket, setting the stage for the large, powerful rockets needed to launch space station parts into orbit. Rocketry advanced rapidly during World War II, especially in Germany, where the ideas of Oberth and Noordung had great influence. The German V-2 rocket, a missile with a range of about 300 miles (483 kilometers), became a prototype for both U.S. and Russian rockets after the war. See also **Goddard, Robert H**.

In 1945, renowned German rocket engineer Wernher Von Braun came to the U.S. to build rockets for the U.S. Army. In the 1950s, he worked with *Collier's* magazine and Walt Disney Studios to produce articles and documentaries on spaceflight. In them, he described a wheel-shaped space station reached by reusable winged spacecraft. Von Braun saw the station as an Earth-observation post, a laboratory, an observatory, and a springboard for Moon and Mars flights. See also **Von Braun, Werner (1912–1977)**.

Soviet engineers began work on large rockets in the 1930s. In May 1995, work began on the Baikonur launch site in central Asia. In August 1957, the world's first intercontinental ballistic missile lifted off from Baikonur on a test flight, followed by the launch of *Sputnik 1*, the world's first artificial satellite, on October 4, 1957. This triggered the Cold War competition between the U.S. and Soviet Union in space, which characterized the early years of the Space Age — competition replaced today by cooperation in the International Space Station Program. In response to *Sputnik*, the U.S. established the National Aeronautics and Space Administration (NASA) in 1958 and started its first man-in-space program, Project Mercury, in 1959.

Apollo and Space Stations (1958–1973)

Project Mercury had hardly begun when NASA and the Congress looked beyond it, to space stations and a permanent human presence in space. Space stations were seen as the next step after humans reached orbit. In 1959, a NASA committee recommended that a space station be established before a trip to the Moon, and the U.S. House of Representatives Space Committee declared a space station a logical follow-on to Project Mercury.

In April 1961, the Soviet Union launched the first human, Yuri Gagarin, into space in the *Vostok 1* spacecraft. President John F. Kennedy reviewed many options for a response to prove that the U.S. would not yield space to the Soviet Union, including a space station, but a man on the Moon won out. Getting to the Moon required so much work that the U.S. and Soviet Union were starting the race about even. In addition, the Moon landing was an unequivocal achievement, while a space station could take many different forms.

Space station studies continued within NASA and the aerospace industry, aided by the heightened interest in spaceflight attending Apollo. In 1964, seeds were planted for *Skylab*, a post-Apollo first-generation space station. Wernher von Braun, who became the first director of NASA's Marshall Space Flight Center, was instrumental in *Skylab's* development.

By 1968, a space station was NASA's leading candidate for a post-Apollo goal. In 1969, the year *Apollo 11* landed on the Moon, the agency proposed a 100-person permanent space station, with assembly completion scheduled for 1975. The station, called Space Base, was to be a laboratory for scientific and industrial experiments. Space Base was envisioned as home port for nuclear-powered tugs designed to carry people and supplies to an outpost on the Moon.

NASA realized that the cost of shipping supplies to a space station using expendable rockets would quickly exceed the station's construction cost. The agency also foresaw the need to be able to return things from a space station. A reusable spacecraft was the obvious solution. In 1968, NASA first called such a spacecraft a space shuttle.

First-Generation Stations (1964–1977)

First-generation space stations had one docking port and could not be resupplied or refueled. The stations were launched unmanned and later occupied by crews. There were two types: *Almaz* military stations and *Salyut* civilian stations. To confuse Western observers the Soviets called both kinds *Salyut*.

The *Almaz* military station program was the first approved. When proposed in 1964, it had three parts: the *Almaz* military surveillance space station, Transport Logistics Spacecraft for delivering soldier-cosmonauts and cargo, and Proton rockets for launching both. All of these spacecraft were built, but none was used as originally planned.

Soviet engineers completed several *Almaz* station hulls by 1970. The Soviet leadership ordered *Almaz* hulls transferred to a crash program to launch a civilian space station. Work on the Transport Logistics Spacecraft was deferred, and the *Soyuz* spacecraft originally built for the Soviet manned Moon program was reapplied to ferry crews to space stations. *Salyut 1*, the first space station in history, reached orbit unmanned atop a Proton rocket on April 19, 1971. The *Salyut 1* weighed 18,600 kilograms (41,000 pounds) and was approximately 14.5 meters (47.4 feet) in length. It had an interior space of 99 cubic meters (3,500 cubic feet) with 7 experimental workstations.

The early first-generation stations were plagued by failures. The crew of *Soyuz 10*, the first spacecraft sent to *Salyut 1*, was unable to enter the station because of a docking mechanism problem. The *Soyuz 11* crew lived aboard *Salyut 1* for three weeks, but died during return to Earth because the air escaped from their *Soyuz* spacecraft. Then, three first-generation stations failed to reach orbit or broke up in orbit before crews could reach them. The second failed station was *Salyut 2*, the first *Almaz* military station to fly.

The Soviets recovered rapidly from these failures. *Salyut 3* (1974–1975), *Salyut 4* 1974–1977), see Fig. 1, and *Salyut 5* (1976–1977) supported a total of five crews. In addition to military surveillance and scientific and industrial experiments, the cosmonauts performed engineering tests to help develop the second-generation space stations. See **Second-Generation Space Stations (1977–1985)** discussed later in this article.

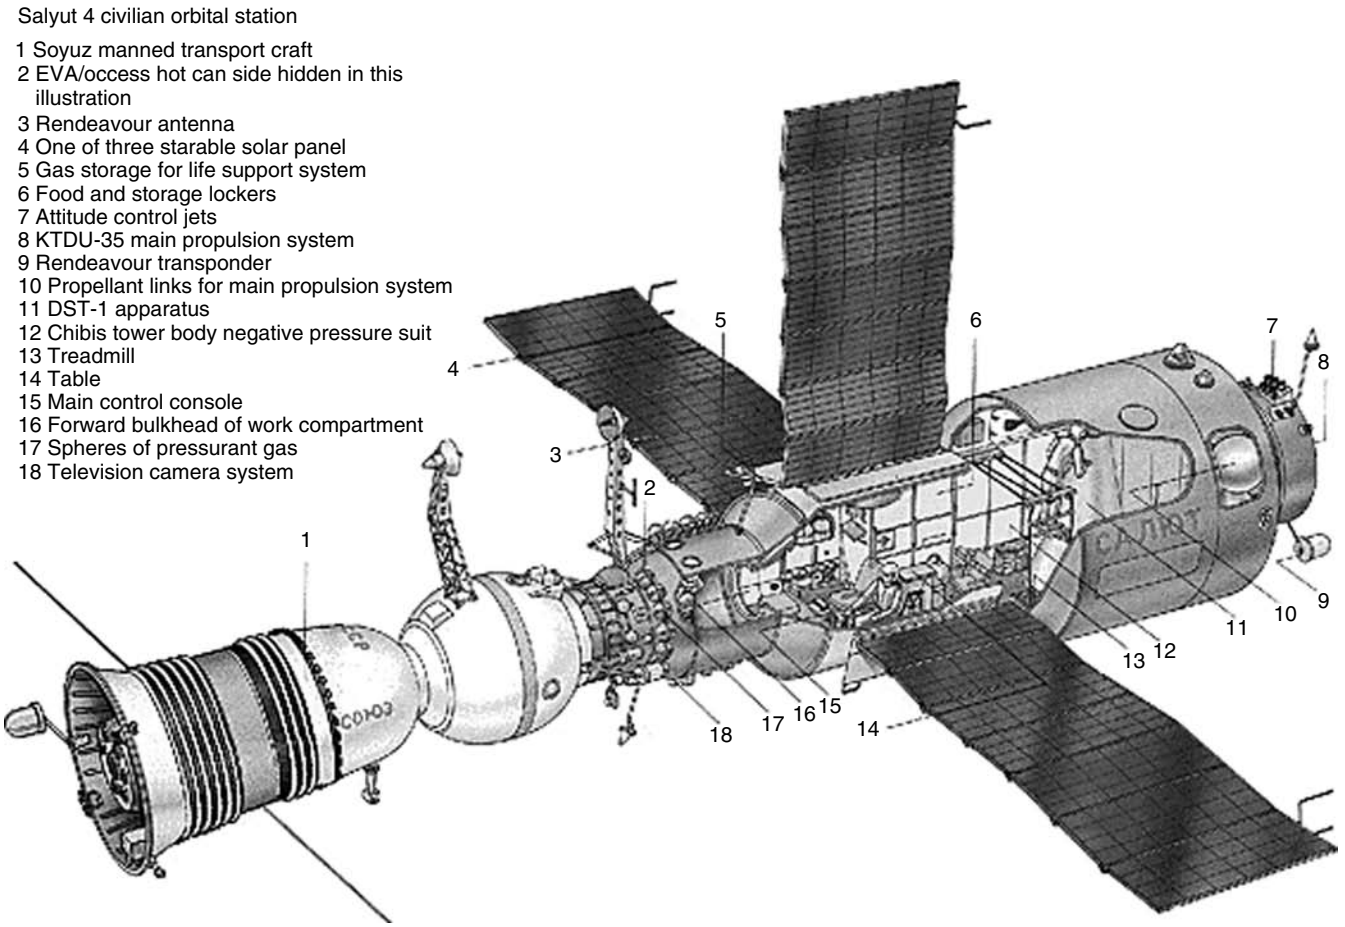

Fig. 1. Diagram of *Salyut 4*, December 1974–February 1977, in the *Salyut* series of early space stations. The instrumentation included optical sensors, which were mounted on the outside of the station together with the X-ray detectors, and power supply and measurement units, which were inside the station. (*NASA*.)

Skylab (1973–1974)

The *Skylab* space station was launched May 14, 1973, from the NASA Kennedy Space Center by a huge *Saturn V* launch vehicle, the moon rocket of the Apollo Space Program. See Figs. 2 and 3. Sixty-three seconds after liftoff, the meteoroid shield — designed also to shade *Skylab's* workshop — deployed inadvertently. It was torn from the space station by atmospheric drag. This event and its effects started a ten-day period in which *Skylab* was beset with problems that had to be conquered before the space station would be safe and habitable for the three manned periods of its planned eight-month mission.

When the meteoroid shield ripped loose, it disturbed the mounting of workshop solar array "wing" two and caused it to partially deploy. The exhaust plume of the second stage retro-rockets impacted the partially deployed solar array and literally blew it into space. Also, a strap of debris from the meteoroid shield overlapped solar array "wing" number one such that when the programmed deployment signal occurred, wing number one was held in a slightly opened position where it was able to generate virtually no power.

In the meantime, the space station had achieved a near-circular orbit at the desired altitude of 435 kilometers (270 miles). All other major functions including payload shroud jettison, deployment of the Apollo Telescope Mount (*Skylab's* solar observatory) and its solar arrays, and pressurization of the space station occurred as planned.

Scientists, engineers, astronauts, and management personnel at the NASA Marshall Space Flight Center and elsewhere worked throughout the first ten-day period of *Skylab's* flight to devise the means for its rescue. Simultaneously, *Skylab*, seriously overheating, was maneuvered through varying nose-up attitudes that would best maintain an acceptable "holding" condition. During that ten-day period and for some time thereafter, the space station operated on less than half of its designed electrical system, in the partially nose-up attitudes, was generating power at reduced efficiency. The optimum condition that maintained the most favorable balance between *Skylab* temperatures and its power generation capability occurred at approximately 50 degrees nose-up.

Skylab's achievements are a summary of the accomplishments of many ground-based persons as well as its three separate crews who were launched in *Apollo*-type command modules by Saturn IB vehicles on May 25, July 28, and November 16, 1973. In *Skylab*, both the man-hours in space and the man-hours spent in performance of extravehicular activities (EVA) under microgravity conditions exceeded the combined totals of all of the world's previous space flights up to that time.

By deploying the parasol-type sun shield through *Skylab's* solar scientific airlock and later releasing workshop solar array wing number one during EVA, the first crew made the remainder of the mission possible. The second crew, also during EVA, erected another sun shield, a twin-pole device.

The effectiveness of *Skylab* crews exceeded expectations, especially in their ability to perform complex repair tasks. They demonstrated excellent mobility, both internal and external to the space station, showing humans to be a positive asset in conducting research from space. By selecting and photographing targets of opportunity on the Sun, and by evaluating weather conditions on Earth and recommending Earth Resources opportunities, crewmen were instrumental in attaining extremely high quality solar and Earth oriented data.

All three crews demonstrated technical skills for scientific, operational, and maintenance functions. Their manual control of the space station, their fine pointing of experiments, and their reasoning and judgment throughout the manned periods were highly effective.

The capability to conduct longer manned missions was conclusively demonstrated in *Skylab*, first by the crew returning from the 28 day mission and, more forcefully, by the good health and physical condition of the second and third *Skylab* crews who stayed in weightless space for 59 and 84 days respectively. Also, resupply of space vehicles was attempted for the first time in *Skylab* and was proven to be effective.

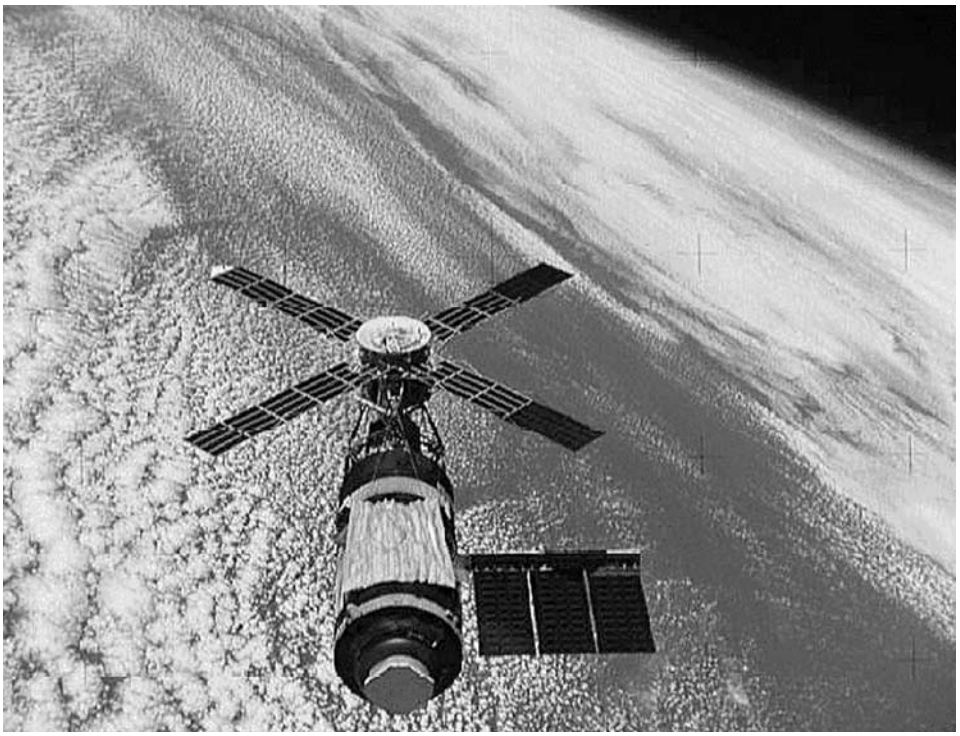

Fig. 2. An overhead view of the *Skylab* space station cluster in Earth orbit as photographed from the *Skylab 4* Command and Service Modules (CSM) during the final fly-around by the CSM before returning home. The space station is contrasted against a cloud-covered Earth. Note the solar shield, which was deployed by the second crew of *Skylab* and from which a micrometeoroid shield has been missing since the cluster was launched on May 14, 1973. The OWS solar panel on the left side was also lost on workshop launch day. (*NASA*.)

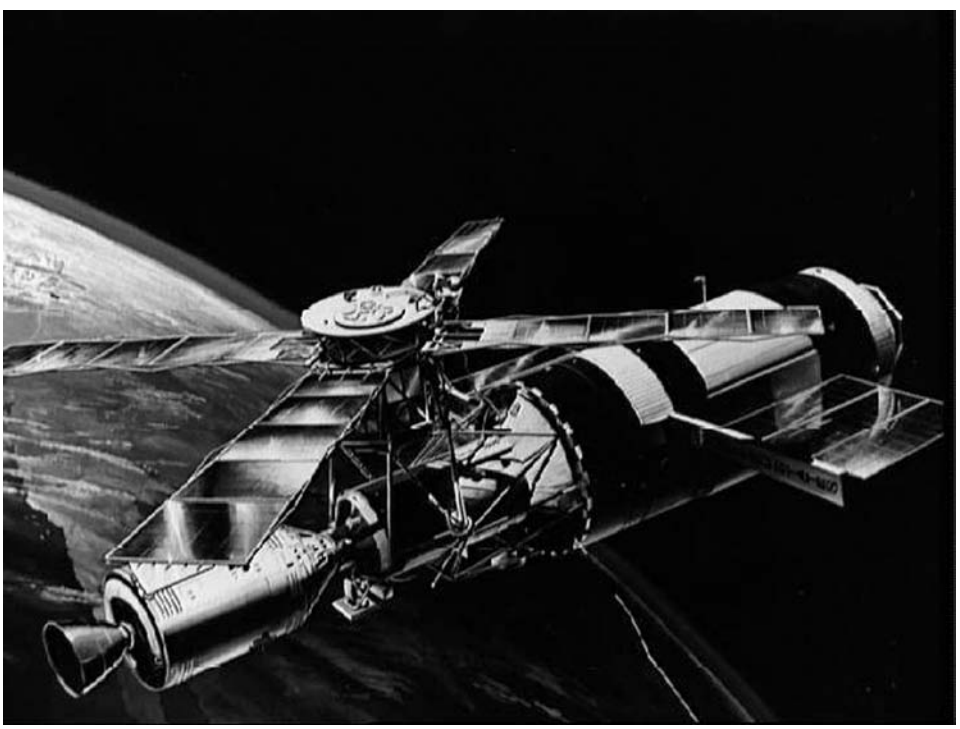

Fig. 3. A Martin Marietta artist's concept of the *Skylab* space station cluster in Earth's orbit. The cluster is composed of the Apollo Command/Service Module, Orbital Workshop, Apollo Telescope Mount (ATM), Multiple Docking Adapter, and Airlock Module. In this concept, a member of the three-man astronaut crew is working atop the ATM in the zero gravity of space. Note the arrays of solar cell panels that turn sunlight into electric power for the space station. (*NASA*.)

During their time in space, all three crews exceeded the operational and experimental requirements placed upon them by the premission flight plan and schedule. In addition, the third crew performed a number of sightings of Comet Kohoutek which were not initially scheduled.

Following the final manned phase of the *Skylab* mission in February 1974, ground controllers performed some engineering tests of certain *Skylab* systems — tests that ground personnel were reluctant to do while men were aboard. Results from these tests helped to determine causes of failures during the mission and to obtain data on long term degradation of space systems.

Upon completion of the engineering tests, *Skylab* was positioned into a stable attitude and systems were shut down. It was expected that *Skylab*

would remain in orbit eight to ten years. However, in the fall of 1977, it was determined that *Skylab* was no longer in a stable attitude as a result of greater than predicted solar activity.

On July 11, 1979, *Skylab* impacted the Earth surface. The debris dispersion area stretched from the Southeastern Indian Ocean across a sparsely populated section of Western Australia.

Second-Generation Stations (1977–1985)

With the second-generation stations, the Soviet space station program evolved from short-duration to long-duration stays. Like the first-generation stations, they were launched unmanned and their crews arrived later in *Soyuz* spacecraft. Second-generation stations had two docking ports. This permitted refueling and resupply by automated *Progress* freighters derived from *Soyuz*. *Progress* docked automatically at the aft port, and was then opened and unloaded by cosmonauts on the station. Transfer of fuel to the station took place automatically under supervision from the ground.

A second docking port also meant long-duration resident crews could receive visitors. Visiting crews often included cosmonaut-researchers from Soviet bloc countries or countries sympathetic to the Soviet Union. Vladimir Remek of Czechoslovakia, the first space traveler not from the U.S. or the Soviet Union, visited *Salyut 6* in 1978.

Visiting crews relieved the monotony of a long stay in space. They often traded their *Soyuz* spacecraft for the one already docked at the station because *Soyuz* had only a limited lifetime in orbit. Lifetime was gradually extended from 60–90 days for the *Soyuz Ferry* to more than 180 days for the *Soyuz-T*M.

Salyut 6 Key Facts:

- Civilian space station from 1977–1982.
- The station received 16 cosmonaut crews, including six long-duration crews. The longest stay time for a *Salyut 6* crew was 185 days. The first *Salyut 6* long-duration crew stayed in orbit for 96 days, beating the 84-day world record for space endurance established in 1974 by the last *Skylab* crew.
- The station hosted cosmonauts from Hungary, Poland, Romania, Cuba, Mongolia, Vietnam, and East Germany.
- Twelve *Progress* freighters delivered more than 20 tons of equipment, supplies, and fuel.
- An experimental transport logistics spacecraft called *Cosmos 1267* docked with *Salyut 6* in 1982. The transport logistics spacecraft was originally designed for the *Almaz* program. *Cosmos 1267* proved that large modules could dock automatically with space stations, a major step toward the multimodular *Mir* station and the International Space Station.

Salyut 7 Key Facts:

- Civilian space station from 1982–1991.
- *Salyut* 7, a near twin of *Salyut* 6, was home to 10 cosmonaut crews, including six long-duration crews. The longest stay time was 237 days.
- Cosmonauts from France and India worked aboard the station, as did the first female space traveler since 1963.
- Thirteen *Progress* freighters delivered more than 25 tons of equipment, supplies, and fuel to *Salyut* 7.
- Two experimental transport logistics spacecraft, *Cosmos 1443* and *Cosmos 1686*, docked with *Salyut 7*. *Cosmos 1686* was a transitional vehicle, a transport logistics spacecraft redesigned to serve as an experimental space station module.
- *Salyut 7* was abandoned in 1986 and reentered Earth's atmosphere over Argentina in 1991.

Third-Generation Station: *Mir* (1986–2001)

The *Mir* Space Station was a manned space station of Russian design that had been in orbit for 15 years. The *Mir* Space Station was designed as a successor to the *Salyut* series and was highly successful. It was comprised of a docking module and 6 research modules, each with a specific design and purpose, which were launched independently and assembled together in space. See Figs. 4 and 5 for illustrations of the configuration. Figure 6 is a close-up view of the *Mir* Space Station as seen from the Space Shuttle.

The core module, *Mir*, which means "Peace" or "Village" in Russian, was the first element of the complex launched from Baikonur Cosmodrome in Kazakhstan, central Asia, on February 20, 1986 at an inclination of 51.6 degrees to the equator. The *Mir* complex developed over the next 10 years with the additions of the component modules: *Kvant-1, Kvant-2, Kristall, Spektr,* the *Docking Module*, and *Piroda*. *Mir* had two axial docking ports, fore and aft, for *Soyuz-TM* manned transports and automated, unmanned *Progress-M* supply ships, plus four radial berthing ports for expansion modules. Manned operations began on March 15, 1986 and there had been near continuous manned operations on *Mir* until 2001.

The *Mir* Space Station, a civilian, third-generation permanent space station, was owned by the Russian Space Agency. The Russian Space Agency (RKA) was formed after the breakup of the former Soviet Union when the existing Soviet space program was eliminated. The RKA uses the technology and launch sites that formerly belonged to the Soviet space program. Centralized control of Russia's civilian space program, including all manned and unmanned nonmilitary space flights falls under the jurisdiction of the RKA. The RKA employs about 300 people, and for much of the work, hires outside contractors. Energia Rocket and Space Complex is the prime contractor used by the RKA. Energia operated the *Mir* Space Station and also owns and operates the Mission Control Center in Kaliningrad. The military counterpart of the RKA is the Military Space Forces (VKS). The RKA and VKS share control of facilities such as the Baikonur Cosmodrome and the Gagarin Cosmonaut Training Center.

Mir Modules

The *Mir* core module contained the space station control center, the crew's living quarters, and power and life support equipment. The core module was 13.1 meters (43.2 feet) long with a maximum diameter of 4.1 meters (13.5 feet). It weighed 20,900 kilograms (46,000 pounds) and had a volume of 90 cubic meters (3,200 cubic feet). See Fig. 7. The module was comprised of two distinct zones, one for living and one for operations. Familiar spatial orientation was used in the living area for the comfort of the crew. The floors were carpeted in dark green, the walls were painted a light green, and the ceilings were painted white and fitted with fluorescent lighting. Although up and down have no meaning in the near total absence of gravity, the design served to provide a semblance of normalcy for the crew.

The crew's living area had a galley with cooking elements, refrigerator, dining table and trash receptacle; a bathroom for personal hygiene with sink, shower, and toilet; and the crew's cabins. Each crewmember had his/her own cabin with a sleeping bag, chair, mirror, and porthole. Also inside this module were medical monitoring equipment and a bicycle ergometer for exercise. In addition, the living area was equipped with a ham radio operation and a video tape recorder with a library of tapes for entertainment and instruction.

The operations area provided the control center for the entire *Mir* complex. The crew was able to monitor and command core systems, the piloting station, and science equipment and facilities from this central operations area. The multiple docking ports of the transfer compartment allowed for the addition of secondary station modules or transport craft. The intermediate compartment was a pressurized tunnel 1.8 meters (6 feet) in diameter that connects the working module to the aft docking port. Main engine and fuel tanks were located in the non-pressurized assembly compartment.

Kvant-1 **("Quantum-1")**, the astrophysics module, was launched on March 31, 1987. See Fig. 8. *Kvant-1* was 5.8 meters (19.1 feet) long with a maximum diameter of 4.1 meters (13.5 feet). *Kvant-1* weighed 11,050 kilograms (24,300 pounds) and had a volume of 40 cubic meters (1,440 cubic feet). *Kvant-1* was successfully docked after several attempts when the cosmonauts on board *Mir*, Yuri Romanenko and Alexander Laveikin, engaged in a spacewalk to remove a plastic bag from the docking port that was preventing a solid connection. *Kvant-1* was located on the aft docking port of the *Mir* core and had its own passive-docking unit that is used by *Progress-M* and *Soyuz-TM* spacecraft. It contained the equipment necessary to gather information and conduct research into the physics of active galaxies, quasars, neutron stars, and other astrophysical phenomena by measuring electromagnetic spectra and x-ray emissions. *Kvant-1* also contained control and life support equipment for the station. Part of the module was a pressurized area for working and living, while

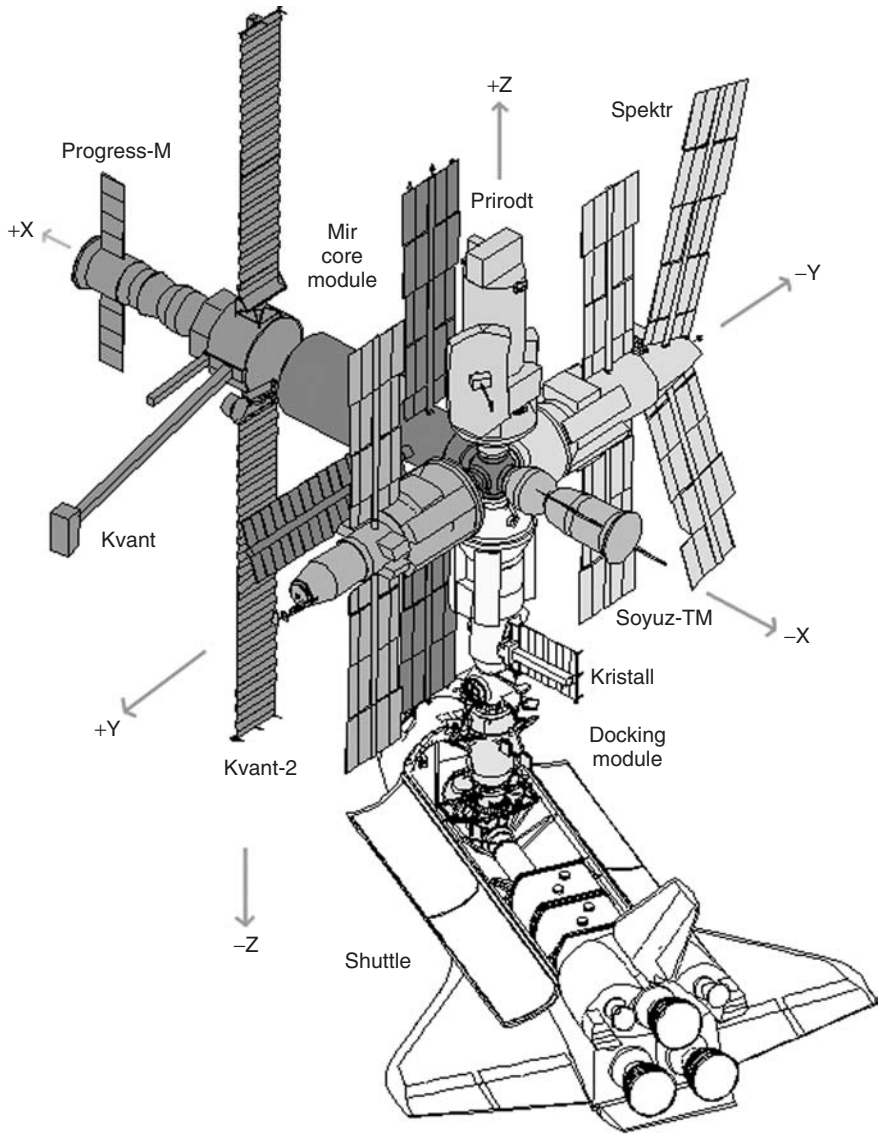

Fig. 4. *Mir* Space Station configuration with shuttle docked and module components labeled. (*NASA*.)

the rest was nonpressurized space for equipment. It had gyrostabilizers that could change the station attitude without propulsive fuel.

***Kvant-2*, ("Quantum-2")**, the second module that was added to the *Mir* core, was the Scientific and Airlock module, which was launched on December 6, 1989. See Fig. 9. *Kvant-2* was 13.7 meters (45.2 feet) long with a maximum diameter of 4.3 meters (14.2 feet). *Kvant-2* weighed 18,500 kilograms (40,700 pounds) and had a volume of 61.3 cubic meters (2,200 cubic feet). This module was originally developed as a logistical transport spacecraft for the Soviet Union's *Almaz* military space station program. *Kvant-2* included Earth observation photographic equipment, scientific equipment for biotechnology research, life support equipment, as well as shower and washing facilities. Two solar panels were attached to the exterior of the module. It was also equipped with an EVA airlock. The airlock allowed access to the outside of *Mir*, which enabled the crewmembers to conduct experiments on the effects of space exposure on electronics and construction materials. Although the airlock included a manned maneuvering unit similar to one tested on American shuttle flights in the 1980s, it had not been utilized. It was tested twice in February 1990 and never used again.

Kristall ("Crystal") was the third module added to the *Mir* core. See Fig. 10. Launched on May 31, 1990, *Kristall* was 13.7 meters (45.2 feet) long and had a maximum diameter of 4.3 meters (14.2 feet). *Kristall* weighed 19,650 kilograms (43,230 pounds) and had a volume of 60.8 cubic meters (2,180 cubic feet). It contained technological research equipment that produced semiconductors and other high-tech materials that benefit from the low gravity environment of space. It was used primarily to develop biological and materials processing technology in the space environment, but it also contained a greenhouse to cultivate plants in zero gravity. *Kristall* was equipped with a *Shuttle* docking port.

***Spektr* ("Spectrum")** was the fourth module to join *Mir* and was launched in May 1995. See Fig. 11. *Spektr* was 13 meters (42.9 feet) long with a maximum diameter of 4.3 meters (14.2 feet). It weighed 19,640 kilograms (43,200 pounds) and had a volume of 61.9 cubic meters (2,200 cubic feet). This module was designed for scientific research specifically related to Earth observation. The module included equipment for atmospheric and surface research, as well as detectors to study the x-ray and gamma-ray background outside the station. *Spektr* served as the living quarters for American astronauts staying on *Mir* as part of the joint Russian-American program. The module also had 4 solar panels, which before June 1997 generated nearly half of the station's electrical power. The collision of a *Progress* cargo vessel with the *Spektr* module on June 25, 1997 resulted in the loss of that module when the hull was punctured, depressurizing the module, and the solar panels were damaged. To view the damaged solar array panels, see Figs. 12 and 13.

The Docking Module, the next component module added to *Mir,* was delivered and installed by the shuttle *Atlantis* mission STS-74 in November 1995. The *Docking* module, attached to the aft end of the *Kristall* module, made it possible for the space shuttle to dock more easily with *Mir.* On a prior mission, STS-71 in June 1995, the shuttle docked with the *Kristall*

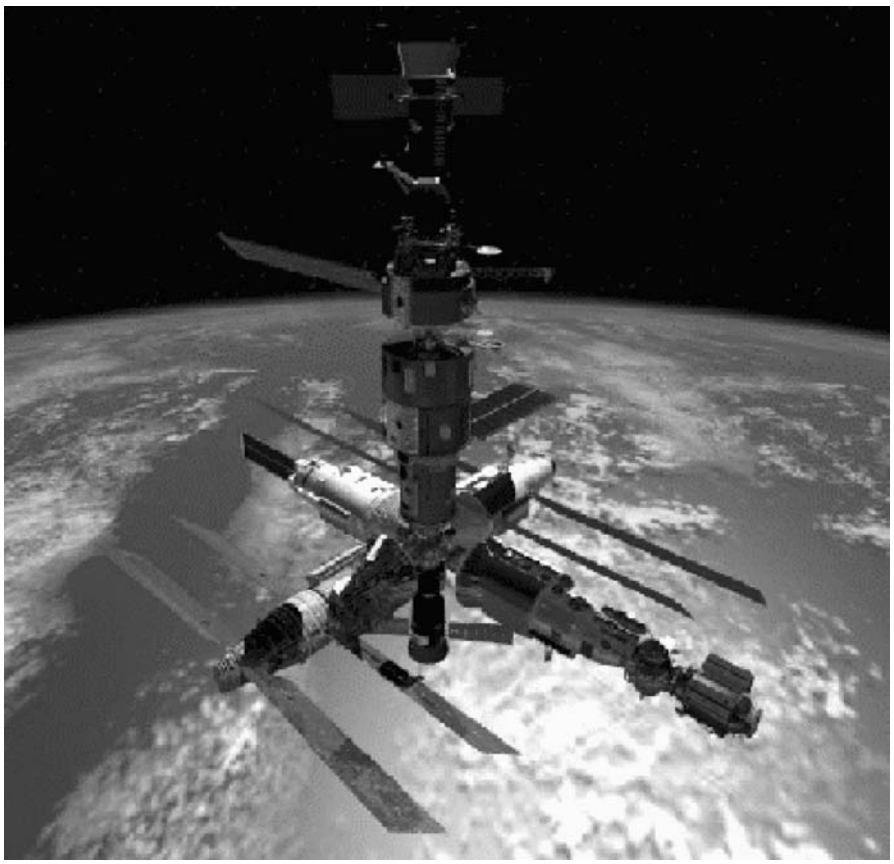

Fig. 5. The *Mir* Space Station, once completed, had a mass of more than 100 tons (90.7 tonnes). It consists of seven modules launched separately and brought together in space over a period of 10 years. *Mir* measures more than 107 feet (32.6 meters) long with docked *Progress-M* and *Soyuz-TM* spacecraft, and is about 90 feet (27.4 meters) wide across its modules. (*NASA*.)

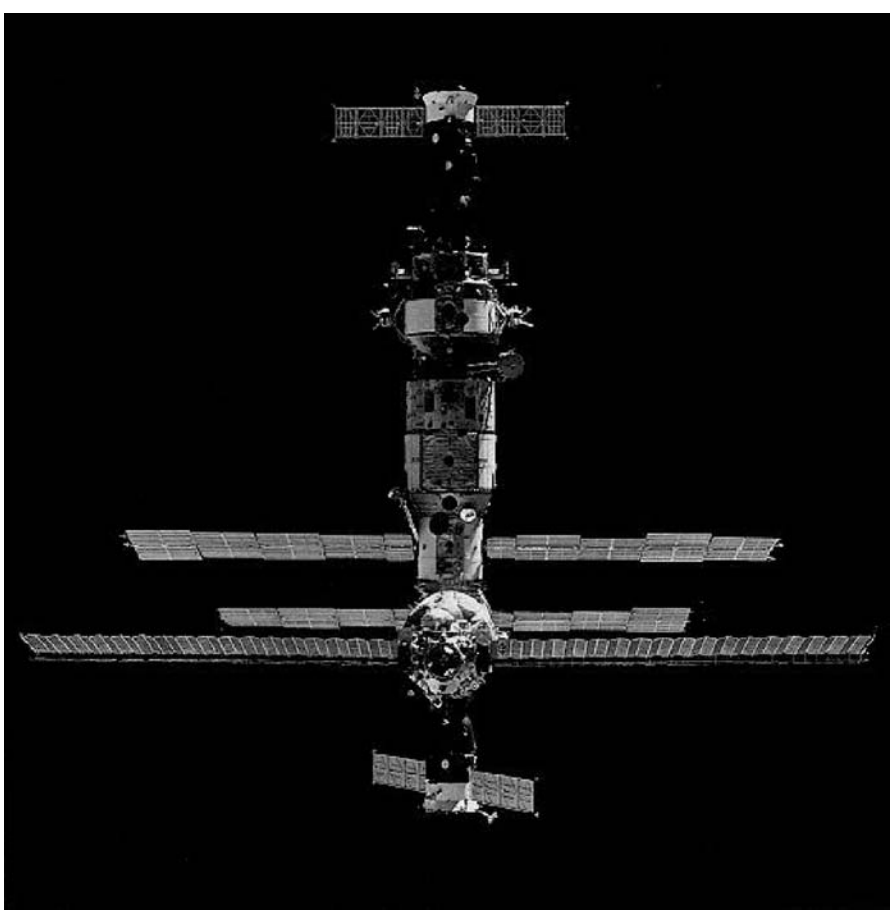

Fig. 6. The *Mir* Space Station in a close-up view as seen from the Space Shuttle *Atlantis*. (*NASA*.)

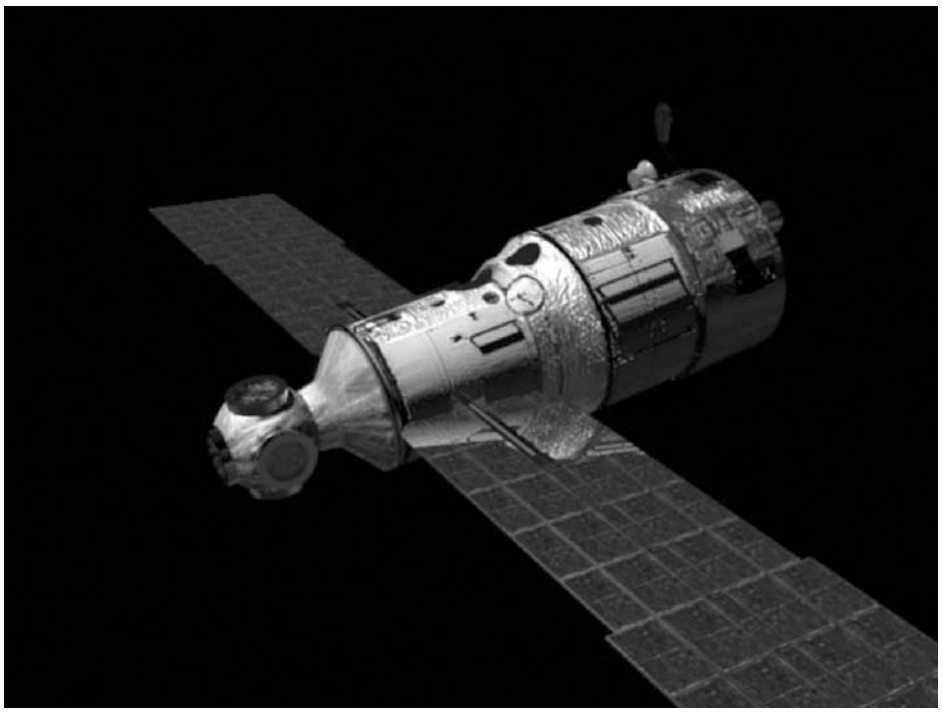

Fig. 7. The 20.4-ton (18.5 tonnes) *Mir* Core Module was launched in February 1986. (*NASA*.)

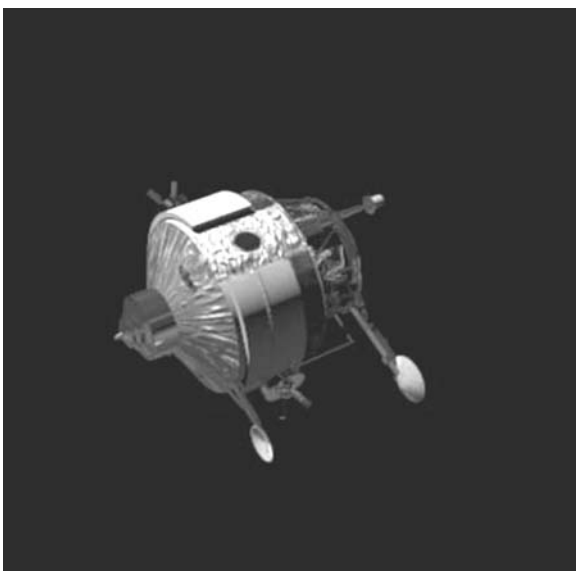

Fig. 8. *Kvant-1*, a small 11-ton (10 tonnes) module, was added to the *Mir* core's aft port in 1987. It contains astrophysics instruments, life support and attitude control equipment. (*NASA*.)

module on *Mir*. However, to make that docking possible, the *Kristall* configuration had to be changed to give the shuttle enough clearance to dock without bumping into any of the solar arrays in the vicinity. Russian cosmonauts had to perform a spacewalk to move the *Kristall* module from a radial axis to a longitudinal axis, relative to *Mir*. After the shuttle departed, *Kristall* was moved back to its original location. Modules for *Mir's* radial berthing ports first dock at the front port. Each module carried a manipulator arm that locks into a socket on *Mir*. The arm pivots the module into place at the proper radial port.

***Priroda* ("Nature")** was the final component module, which was launched in April 1996, completing the assembly of research components in the *Mir* space station complex. See Fig. 14. *Priroda* was 13 meters (42.9 feet) long and has a maximum diameter of 4.3 meters (14.2 feet). It weighed 19,700 kilograms (43,300 pounds) and had a volume of 66 cubic meters (2,370 cubic feet). The module carried Earth observing equipment as well as experiments and other equipment for the joint American-Russian missions on *Mir* (including more than a ton of materials for American astronaut Shannon Lucid, who was on the station when *Priroda* arrived.) It contained active, passive, and infra-red radiometers, a synthetic aperture radar, and several types of spectrometers used for measuring ozone and aerosol concentrations in the atmosphere. The Earth remote-sensing mission of *Priroda* was multifold. It was designed to study the atmosphere and oceans, and in particular, the environmental impact of human activities and pollution. It was also designed to conduct geological surveys that can be used to locate mineral resources and water reserves and study the effects of erosion on crops and forests. It was enabled to receive and relay information from "emergency buoys" located in seismically active areas, around nuclear power plants, and other zones, as part of an emergency warning system.

Soyuz-TM module was used to transport crews and cargo to and from the *Mir* Space Station. In addition, it served as a lifeboat and shelter should an emergency situation occur that would require the crew to abandon *Mir*. The *Soyuz-TM* was 7 meters (23.1 feet) in length and had a maximum diameter of 2.7 meters (8.9 feet). It weighed 7,100 kilograms (15,600 pounds) and had a volume of 10 cubic meters (360 cubic feet). It was made up-of three compartments: the orbital module, the descent module and the instrumentation module. *Soyuz* was first launched in 1963, and was a two-stage rocket that could deliver a payload of over 15,000 pounds into Low-Earth Orbit at a 51.6-degree inclination. This rocket is the primary launcher used for manned Russian space flights and nearly half of all Russian space missions (manned and unmanned) are launched using the *Soyuz* vehicle. The *Soyuz* rocket is also used to deploy low-altitude reconnaissance satellites.

Progress-M Cargo Transport was an unmanned cargo and resupply vehicle used to send science equipment and data, food supplies and crew mail to and from *Mir*. The *Progress-M Transport* is 7 meters (23.1 feet) in length with a maximum diameter of 2.7 meters (8.9 feet). It weighed 7,200 kilograms (15,800 pounds) and had a volume of 7.6 cubic meters (270 cubic feet). After the *Progress* spacecraft has docked and been unloaded, it remained in place for use as a trash storage site. Once the spacecraft was full and shortly before the arrival of the new *Progress* spacecraft, it undocked. Early trash-filled *Progress* ships were deorbited and allowed to burn up in the Earth's atmosphere. Later *Progress-M* freighters were improved and returned to Earth carrying primarily trash, but occasionally with materials for analysis as well. See Fig. 15 for a view of the *Mir* configuration with both *Soyuz* and *Progress* transports docked.

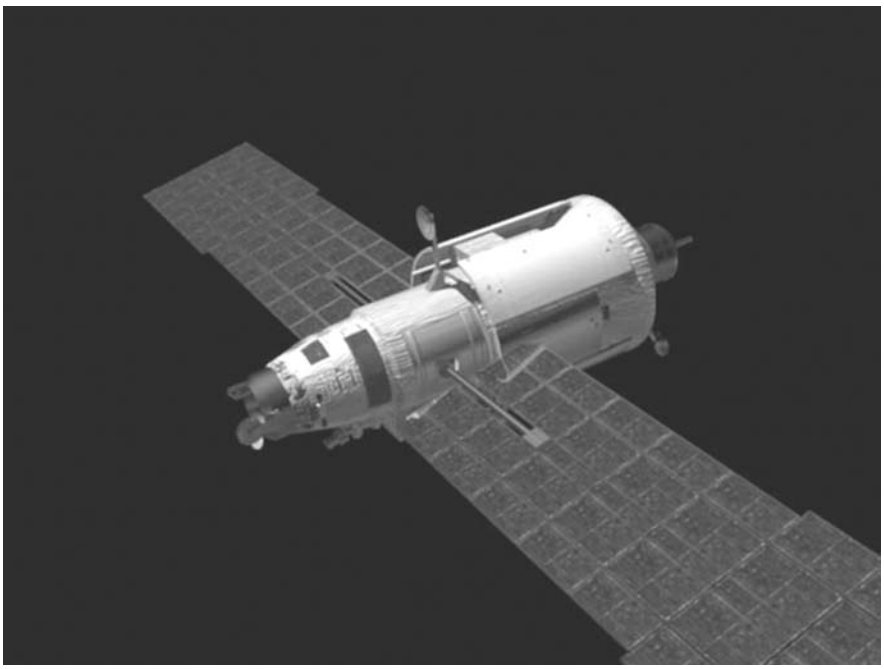

Fig. 9. *Kvant-2*, added in 1989, carries an EVA airlock, solar arrays, and life support equipment as well as the provisions for personal hygiene care, water and oxygen. The 19.6-ton (17.8 tonnes) module is based on the transport logistics spacecraft originally intended for Russia's Almaz military space station program of the early 1970s. (*NASA*.)

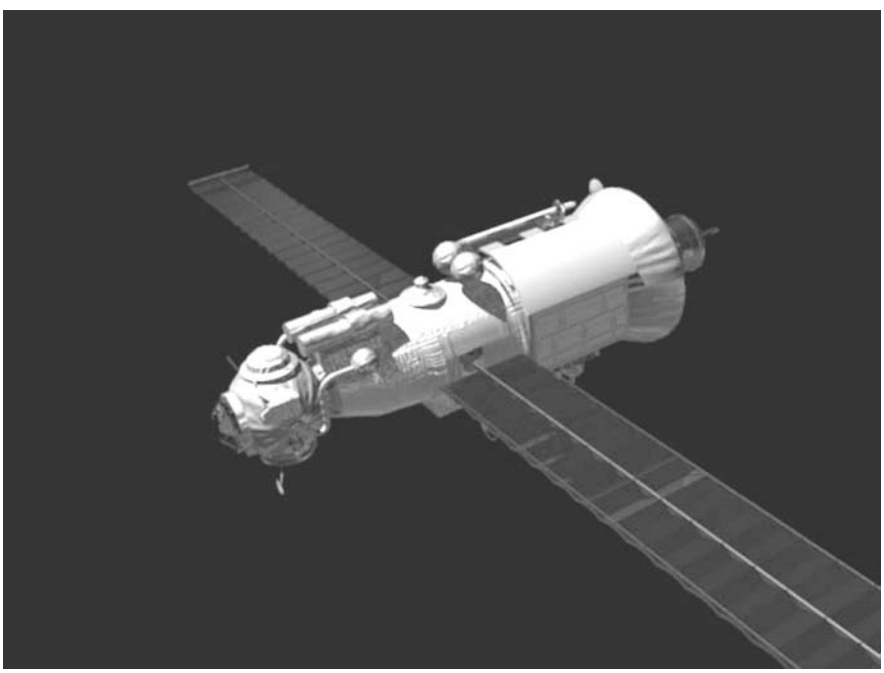

Fig. 10. *Kristall* added in 1990, carries scientific equipment, retractable solar arrays, and a docking node equipped with a special androgynous docking mechanism designed to receive spacecraft weighing up to 100 tons (90.7 tonnes). Originally, the Russian Buran shuttle, which made one unmanned orbital test flight in 1988, would have docked with *Mir* using the androgynous unit. Space Shuttle *Atlantis* used the androgynous unit to dock with *Mir* for the first time on the STS-71 mission in July 1995. On STS-74, in November 1995, *Atlantis* permanently attached a Docking Module to *Kristall's* androgynous docking unit. The Docking Module improved clearance between *Atlantis* and *Mir*'s solar arrays on subsequent docking flights. The 19.6-ton (17.8 tonnes) *Kristall* module is based on the transport logistics spacecraft originally designed to carry Soviet soldier-cosmonauts to the Almaz military space stations. (*NASA*.)

Mir Key Facts

- An important goal of the *Mir* program was to maintain a permanent human presence in space. Except for two brief periods (July 1986–February 1987; April–September 1989), Russian cosmonauts had lived aboard *Mir* continuously for the past 12 years, demonstrating proven experience in space station operations.
- Dr. Valeri Polyakov arrived on *Mir* on *Soyuz-TM 18* in January 1994 and returned to Earth on *Soyuz-TM* 20 on March 21, 1995. He lived in orbit for more than 438 days, a world record.
- Cosmonaut-researchers from Afghanistan, Austria, Britain, Bulgaria, the European Space Agency, France, Germany, Japan, Kazakhstan, and Syria visited *Mir*. European and French cosmonauts lived on *Mir* for as long as a month. U.S. astronauts have spent up to 5 months on the station.
- More than 40 *Progress* and *Progress-M* freighters have delivered more than 100 tons of supplies and fuel to *Mir*. The improved *Progress-M* occasionally carried a capsule for returning to Earth a small quantity of experiment results and industrial products from the station. Occasionally cargo came back to Earth with cosmonauts in *Soyuz-TM* capsules.

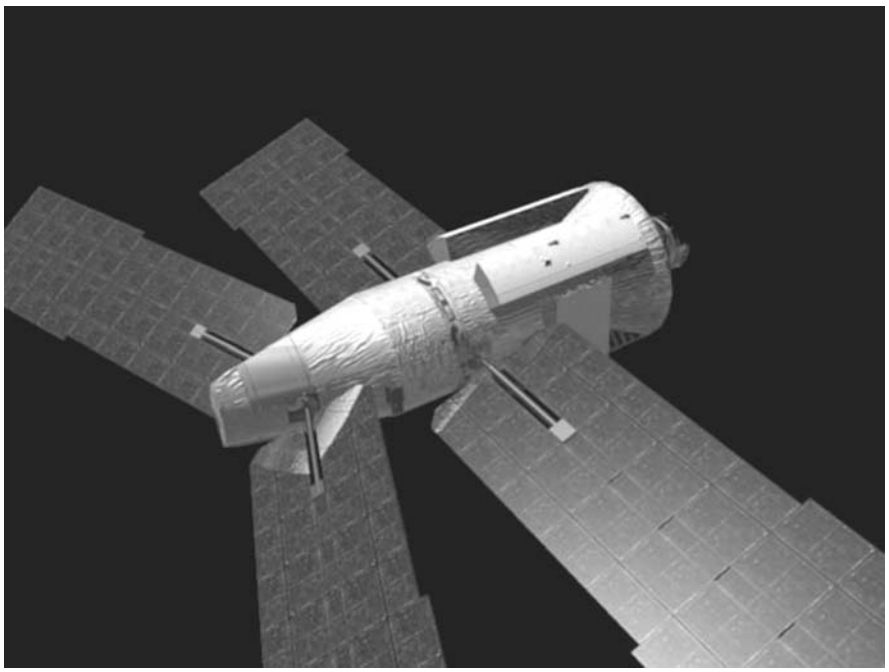

Fig. 11. *Spektr* was launched on a Russian Proton rocket from the Baikonur launch center in central Asia on May 20, 1995. The module was berthed at the radial port opposite *Kvant 2* after *Kristall* was moved out of the way. *Spektr* carries four solar arrays and scientific equipment, including more than 1600 pounds (726 kilograms) of U.S. equipment. The focus of scientific study for this module is Earth observation, specifically natural resources and atmosphere. The equipment onboard is supplied by both Russia and the United States. (*NASA*.)

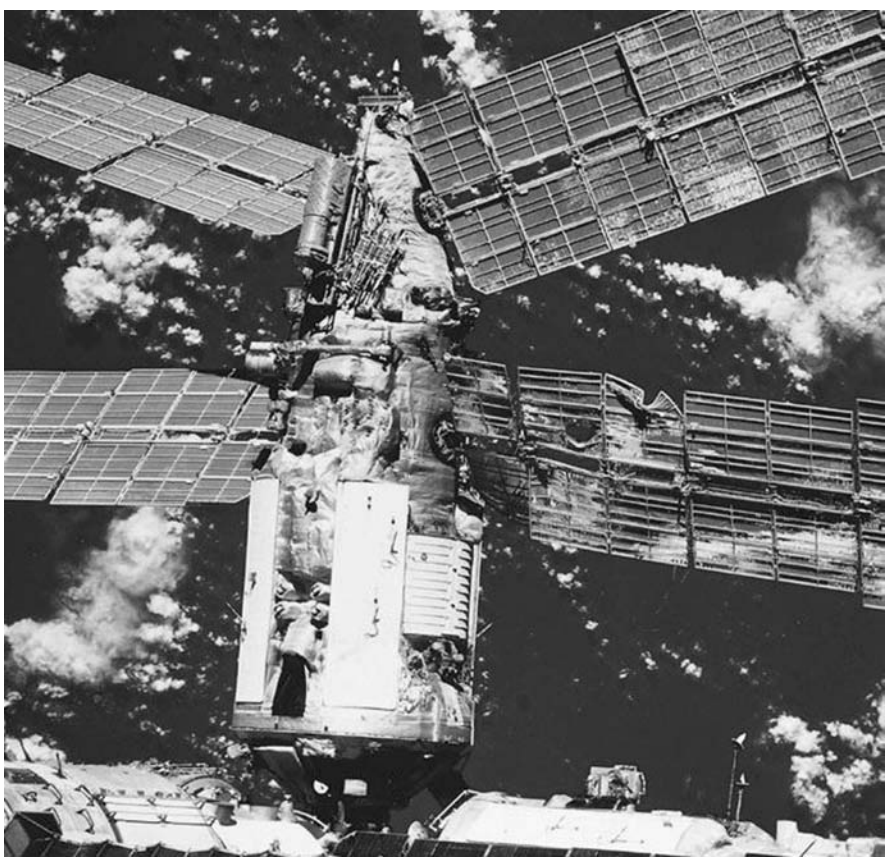

Fig. 12. View of the damage to the solar array panel on *Spektr*, and the module body, the result of a collision with a *Progress* cargo ship. (*NASA*.)

- Beginning with STS-71, the shuttle had returned to Earth more industrial products and experiment samples than would be possible using the *Progress-M* capsules or *Soyuz-TM*. In addition, the shuttle could be used to return components from *Mir's* exterior, such as solar arrays, for studying the effects of long exposure to space conditions — a capability not available with *Progress-M* and *Soyuz-TM*.
- Important lessons from *Mir* operations and *Shuttle–Mir* operations and research are being incorporated into the *International Space Station* design and planning.
- *Mir* had docked with 31 spacecraft.
- *Mir* had docked with 64 cargo vessels.
- *Mir* docked with the space shuttle 9 times.

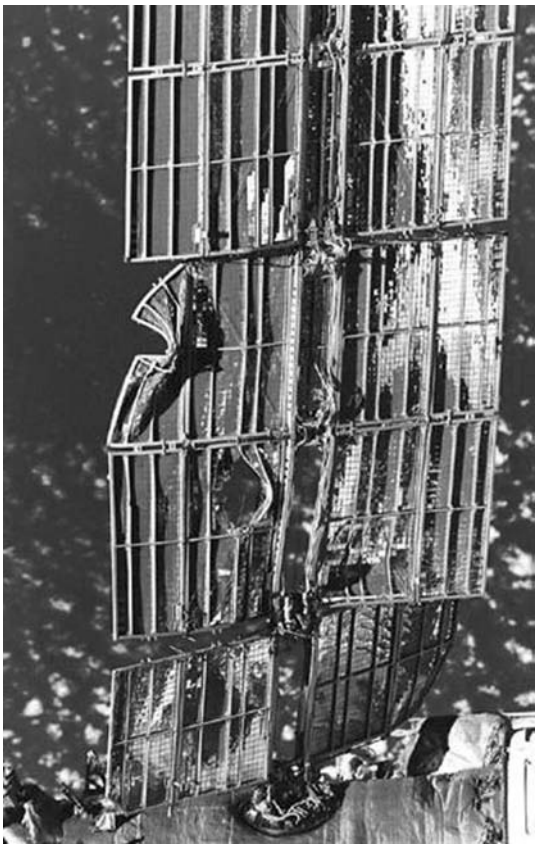

Fig. 13. Close-up view of the damaged solar array panel on *Spektr* as seen from the *Soyuz* transport. (*NASA*.)

- There were 17 space expeditions to *Mir*.
- There were 28 long-term crews on board *Mir*.
- 125 cosmonauts/astronauts from 12 different countries visited *Mir*.

For a complete list of *Mir* highlights, see the following website: http://www.satobs.org/mir.html

Born in the Cold War, *Mir's* ultimate legacy is that it taught the two-superpower enemies, the USSR and the USA, to co-operate in space. *Mir* showed man how to live and work in space and how to overcome unforeseen problems and survive potentially fatal situations. In terms of science, *Mir* returned very little but in no way does that diminish its achievements. It was mankind's first true long-term home in space and many will lament its passing.

Mir celebrated 15 years in space in 2001–10 years longer than the original projected lifespan of the station. But on 23 March the final command was sent to the pride of the Russian space program. The final stages of reentry all went according to plan and were a triumph for Russian ground controllers.

Since 1978-present spacecraft, including several previous space stations, have been safely brought to Earth in the South Pacific and *Mir* was no exception. At 0530GMT the disintegrating remains, which had split into approximately nine to twelve pieces, passed over Japan. The 25 tonnes (27.6 tons) of wreckage finally streaked across the sky and hit the intended target area in the South Pacific, 5,800 kilometers (3,600 miles) off the eastern coast of Australia, at about 0600GMT.

Mir/Shuttle Program (1994–1998)

On June 17, 1992 in Washington DC, George Bush, the President of the United States, and Boris Yeltsin, President of the Russian Federation, signed the "Agreement between the United States of America and the Russian Federation Concerning Cooperation in the Exploration and Use of Outer Space for Peaceful Purposes." This agreement states that one of the areas of cooperation will include a "Space Shuttle and *Mir* Space Station mission involving the participation of U.S. astronauts and Russian Cosmonauts." At this Washington meeting the leaders further agreed to flight's of Russian cosmonauts on the Shuttle in 1993, flight of an U.S. astronaut on a long-duration mission on *Mir* in 1994, and a docking mission between the Shuttle and the *Mir* in 1995. This was the beginning of the Phase 1 (*Mir*/Shuttle) Program).

On October 5, 1992, in Moscow, Daniel Goldin, Administrator of NASA, and Yuri Koptev, Director General of RSA, signed the "Implementing Agreement between the National Aeronautics and Space Administration of the United States of America and the Russian Space Agency of the

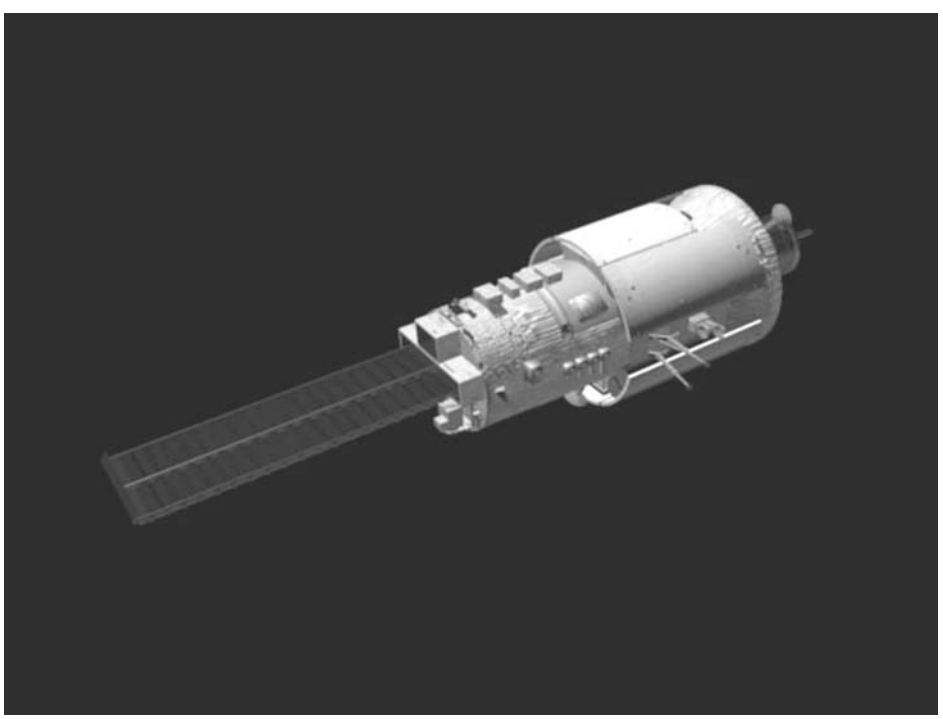

Fig. 14. *Piroda*, the last science module to be added to the *Mir*, launched from Baikonur on April 23, 1996, and docked to the space station as scheduled on April 26. Its primary purpose is to add Earth remote sensing capability to *Mir*. It also contains the hardware and supplies for several joint U.S.-Russian science experiments. (*NASA*.)

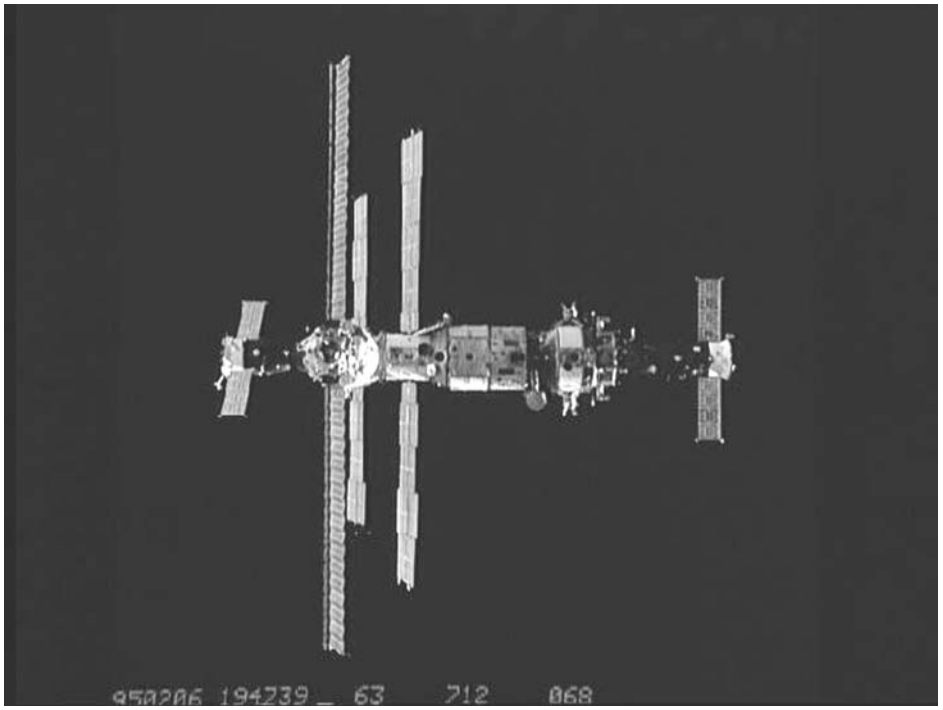

Fig. 15. Russia's *Mir* space station during rendezvous operations with the Space Shuttle *Discovery*. Docked at the bottom (nearest portion where longest solar array panel is visible) is a *Soyuz* vehicle. On the opposite end is a Progress spacecraft. (*NASA*.)

Russian Federation on Human Space Flight Cooperation." This agreement further outlined details of cooperation that included:

- A Russian cosmonaut flying on the Shuttle mission STS-60 as a mission specialist.
- A U.S. astronaut launching on a *Soyuz*, flying more than 90 days on the *Mir*, and returning on a Shuttle.
- Russian cosmonauts on *Mir* being "changed out" via the Shuttle on the same flight that would return the U.S. astronaut.
- The evaluation of and possible contract for the Russian Androgynous Peripheral Docking Assembly developed by NPO Energia for use on the Shuttle.

This program was called the *Mir*-Shuttle Program.

Later, the American side proposed expansion of the joint program: It would include up to 10 dockings of the Shuttle with *Mir*; and would increase the presence of American astronauts on *Mir* to up to two years; and deliver up to two tons of hardware on board the Russian *Spektr* and *Priroda modules*. Separate flights of up to six months were proposed for American astronauts on board *Mir*. In June, a contract was concluded for work between RSA and NASA. This program was called *Mir*-NASA. The work performed for the *Mir*-Shuttle and *Mir*-NASA program are considered as Phase 1 of the preparation for the creation of the *International Space Station*.

The Phase 1 Program became a formal stand-alone program on the NASA side on October 6, 1994, which included 11 space shuttle flights over a four-year period. See Fig. 16. The United States and Russia combined their existing assets, primarily U.S. space shuttle orbiters and the Russian Space Station *Mir*, in a joint operation of the program, which lasted from 1994–1998. The goal of the Shuttle–*Mir*, a complicated interlocking program, was to build joint space experience, which would be necessary to complete the International Space Station (ISS), and to begin joint scientific research. A significant challenge of the program was to incorporate the diverse and unique working styles and philosophies of the U.S. and Russian space agencies and their international partners.

Four major science objectives were established at the beginning of the Shuttle-*Mir* Program, International Space Station, Phase I. They were:

- To get engineering and operational experience in a research program on a long-duration space platform. (The most recent U.S. experience had been aboard *Skylab* in the 1970s. Tremendous knowledge and experience was gained on *Mir*, and many of the lessons are applicable to the *International Space Station* program.)
- To learn more about *Mir* and the microgravity environment in general for conducting research programs in various disciplines.
- To use *Mir* as a test bed for space station technologies.
- To learn how to do space walks with Russian counterparts and systems. (One Phase 1 EVA was planned initially. Three were performed.)

NASA astronauts underwent specialized training before living aboard *Mir*. As a prerequisite for the assignment, they had to acquire cosmonaut certification training. They also learned to speak Russian and attained proficiency with the experiments they would perform and the work they would have to do. The first American, Norman Thagard, to live aboard *Mir* reported feelings of loneliness and isolation, and steps were taken to prevent that happening to his successors.

Shuttle-*Mir*, International Space Station, Phase 1 served as a four-year prologue to station assembly in Phases 2 and 3. NASA and its international partners found that Phase 1 was invaluable in learning about all aspects of living and working in low-Earth orbit. For the list of long-duration flight missions that took place during the Shuttle-*Mir* Program, see Table 1.

International Space Station

The International Space Station Program has been in the planning stages since 1984, when President Ronald Reagan called for a space station in his State of the Union address. He said that the space station program was to include participation by U.S. allies.

With the presidential mandate in place, NASA set up the Space Station Program Office in April 1984, and issued a Request for Proposal to U.S. industry in September 1984. In April 1985, NASA let contracts on four work packages, each involving a different mix of contractors and managed by a separate NASA field center. (This was consolidated into three work packages in 1991.)

This marked the start of Space Station Phase B development, which aimed at defining the station's shape. By March 1986, the baseline design was the dual keel, a rectangular framework with a truss across the middle for holding the station's living and working modules and solar arrays.

By the spring of 1985, Japan, Canada, and the European Space Agency each signed a bilateral memorandum of understanding with the U.S. for participation in the space station project. In May 1985, NASA held the first space station international user workshop in Copenhagen, Denmark.

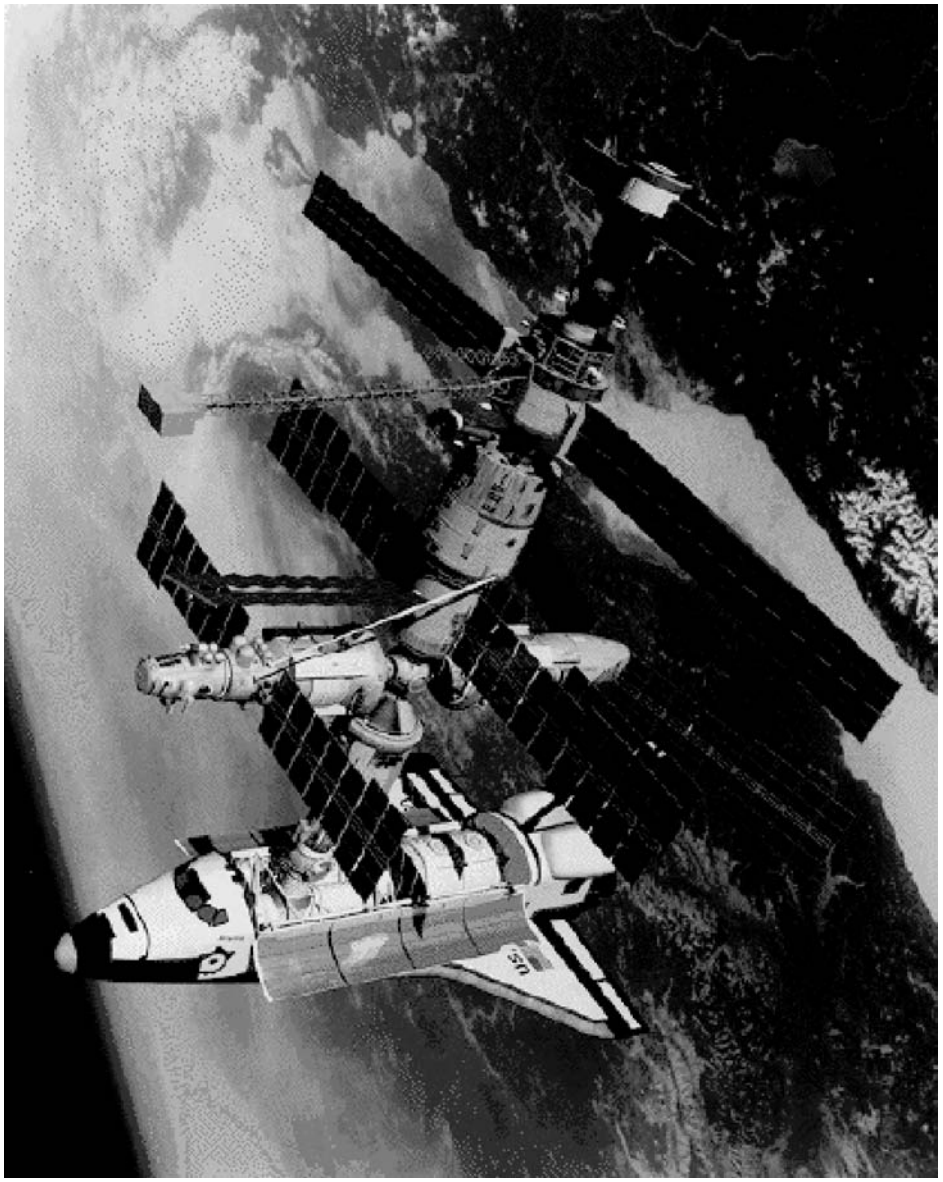

Fig. 16. Shuttle docked with *Mir*. (*NASA*.)

By mid-1986, the partners reached agreement on their respective hardware contributions. Canada would build a remote manipulator system similar to the one it had built for the space shuttle, while Japan and Europe would each contribute laboratory modules. Formal agreements were signed in September 1988. These partners' contributions remain generally unchanged for the *International Space Station*.

In 1987, the dual keel configuration was revised to take into account a reduced space shuttle flight rate in the wake of the *Challenger* accident. The revised baseline had a single truss with the built-in option to upgrade to the dual keel design. The need for a space station lifeboat, called the assured crew return vehicle, was also identified.

In 1988, Reagan gave the station a name–*Freedom*. Space Station *Freedom's* design underwent modifications with each annual budget cycle as Congress called for its cost to be reduced. The truss was shortened and the U.S. Habitation and Laboratory modules reduced in size. The truss was to be launched in sections with subsystems already in place. Despite the redesigns, NASA and contractors produced a substantial amount of hardware. In 1992, in moves presaging the current increased cooperation between the U.S. and Russia, the U.S. agreed to buy Russian *Soyuz* vehicles to serve as Freedom's lifeboats (these are now known as *Soyuz* crew transfer vehicles) and the Shuttle-*Mir* Program got its start. See **Shuttle-*Mir* Program** described early in this article.

In 1993, President William Clinton called for the station to be redesigned once again to reduce costs and include more international involvement. To stimulate innovation, teams from different NASA centers competed to develop three distinct station redesign options. The White House selected the option dubbed Alpha. In its new form, the station uses 75 percent of the hardware designs originally intended for the *Freedom* program. After the Russians agreed to supply major hardware elements, many originally intended for their *Mir 2* space station program, the station became known as the *International Space Station*. Russian participation reduces the station's cost to the U.S. while permitting expansion to basic operational capability much earlier than *Freedom*. This provides new opportunities to all the station partners by permitting early scientific research.

The program's management was also redesigned. Johnson Space Center became lead center for the space station program, and Boeing became prime contractor. NASA and Boeing teams are housed together at JSC to increase efficiency through improved communications.

The first phase of the International Space Station Program, the Shuttle-*Mir* Program, kicked off in February 1994 with STS-60, when Sergei Krikalev became the first Russian astronaut to fly on a shuttle. See **Shuttle-Mir Program** and Table 1.

The *International Space Station* (ISS) will be a permanent research platform in space, a laboratory orbiting the Earth. The *International Space Station* is the single largest international aerospace project ever undertaken by humankind. Assembly of the *International Space Station* involves complex on-orbit operations and hardware/software integration

TABLE 1. TIMELINE OF SHUTTLE-*MIR* (1994–1998)

Mission	Duration	Highlights
STS-60	February 3–11, 1994	The first shuttle flight of 1994 marked the first flight of a Russian cosmonaut, Sergei Krikalev, onboard the U.S. space shuttle. Part of an international agreement on human space flight, the mission also was the second flight of the Spacehab pressurized module and marked the 100th "Get Away Special" payload to fly in space.
STS-63	February 3–11, 1995	Referred to as the "near *Mir*" mission, STS-63 had special importance as a dress rehearsal for the missions that would rendezvous and dock with *Mir*. With Cosmonaut Vladimir Titov aboard, *Discovery* rendezvoused with Mir, closed to within 37 feet (11.3 meters) then backed off to 400 feet (122 meters) and performed a fly-around, but did not dock. Docking equipment was tested for future missions, and communications procedures between the two mission control centers were validated.
Mir 18	March 14–July 7, 1995	Norman Thagard was the first American astronaut to train in Russia, the first to launch into space aboard a *Soyuz TM-21* (with cosmonauts Vladimir Dezhurov and Gennady Strekalov), and the first to complete a residency aboard *Mir*, setting an American space endurance record of 115 days in orbit. During that time, the *Spektr* science module was launched to *Mir*, with more than 1,500 pounds of research equipment from the U.S. and other countries. Thagard returned to Earth with the space shuttle mission STS-71, the first shuttle flight to dock with *Mir*.
STS-71	June 27–July 7, 1995	STS-71 marked the 100th U.S. human space launch; the first docking of the space shuttle with *Mir*; the largest combined spacecraft ever in orbit; and the first shuttle changeout of a *Mir* crew, Cosmonauts Anatoly Soloyev and Nikolai Budarin, and returned Dezhurov, Strekalov and Thagard to Earth.
STS-74	November 12–20, 1994	STS-74 marked the second docking of the U.S. space shuttle to Russian Space Station *Mir* and illustrated the international flavor of the space station effort. The mission's primary payload was the Russian-built Docking Module (DM), designed to become a permanent extension on *Mir* to afford better clearances for Shuttle-*Mir* linkups. Unlike the STS-71 crew exchange flight, this second docking focused on delivery of equipment to *Mir*.
STS-76	March 22–31, 1996	STS-76 was the third docking between a U.S. space shuttle and the Russian Space Station *Mir* and was highlighted by the transfer to *Mir* of astronaut Shannon Lucid. Lucid became the first American woman to live on the station and commenced a continuous U.S. presence in space for the next two years. Her 188-day stay eclipsed the long-duration U.S. spaceflight record set by the first American *Mir* astronaut, Norman Thagard. STS-76 also marked the first flight of the Spacehab pressurized module to support Shuttle-*Mir* dockings. Spacehab primarily served as a stowage area for supplies and equipment.
STS-79	August 16–26, 1996	STS-79 brought back to Earth U.S. astronaut Shannon Lucid after her 188 days in space, a new U.S. spaceflight record and a world record for a woman. Astronaut John Blaha succeeded Lucid on *Mir*, joining *Mir*-22 commander Valeri Korzun and flight engineer Alexander Kaleri. The mission conducted the first U.S. Shuttle-Mir crew exchange, the fourth Shuttle-Mir docking, and the first flight of the Spacehab Double Module configuration.
STS-81	January 12–22, 1997	STS-81 replaced U.S. astronaut John Blaha with Jerry Linenger, after Blaha's 118-day stay aboard Russian Space Station *Mir*. It transferred the most materials to date, during this fifth of nine dockings. *Atlantis* also returned the first plants to complete a life cycle in space — a crop of wheat planted by Shannon Lucid and grown from seed to seed. During Linenger's stay aboard, the fire of February 1997 occurred, offering new challenges and new information. Linenger conducted the first spacewalk by an U.S. astronaut outside *Mir* wearing a Russian spacesuit.
STS-84	May 15–24, 1997	STS-84 delivered U.S. Astronaut Michael Foale to *Mir* and brought back to Earth astronaut Jerry Linenger, who had spent 123 days on *Mir* and who was, at that time, second behind Shannon Lucid for most time spent on-orbit by an American. One of the first items transferred to *Mir* was an Electron oxygen-generating unit, especially important after the Feb. 23, 1997 fire that had occurred on *Mir*.
STS-86	September 25–October 6, 1997	STS-86 performed the seventh Shuttle-*Mir* docking and continued the presence of a U.S. astronaut onboard *Mir*, by transferring the sixth U.S. *Mir* astronaut David Wolf, in exchange for Michael Foale, who returned to Earth after 145 days in space. Crewmembers Titov and Parazynski conducted the first joint U.S.-Russian extravehicular activity during a shuttle mission, and the first in which a Russian wore a U.S. spacesuit. During the 5-hour spacewalk on October 1, 1997, the pair affixed a 121-pound (54.9 kilogram) Solar Array Cap to the Docking Module, for a future attempt by *Mir* crew members to seal off the suspected leak in *Spektr's* hull. Parazynski and Titov also retrieved four Mir Environmental Effects Payloads (MEEPs) from the outside of Mir and tested several components of the Simplified Aid for EVA Rescue (SAFER) jetpacks.
STS-89	January 22–31, 1998	STS-89 delivered Cosmonaut Salizhan Sharipov to *Mir* and replaced U.S. Mir astronaut David Wolf with Andy Thomas, after Wolf had spent 119 days onboard Mir and a total of 128 days on-orbit. *Endeavor* was the first orbiter after *Atlantis* to dock with *Mir*.
STS-91	June 2–12, 1998	STS-91 closed out the Shuttle-*Mir* Program, when it brought back to Earth U.S. *Mir* astronaut Andy Thomas, after he had spent 130 days on *Mir*. The transfer wrapped up a total of 907 days spent by seven U.S. astronauts aboard the Russian space station. When the hatches closed for undocking at 9:07 a.m. EDT June 8 and the spacecraft separated at 12:01 p.m. EDT that day, the final Shuttle-*Mir* docking mission was concluded and Phase 1 of the International Space Station (ISS) program came to an end.

For more information on the Shuttle-*Mir* Program timeline see http://spaceflight.nasa.gov/history/shuttle-mir/history/h-timeline.htm.

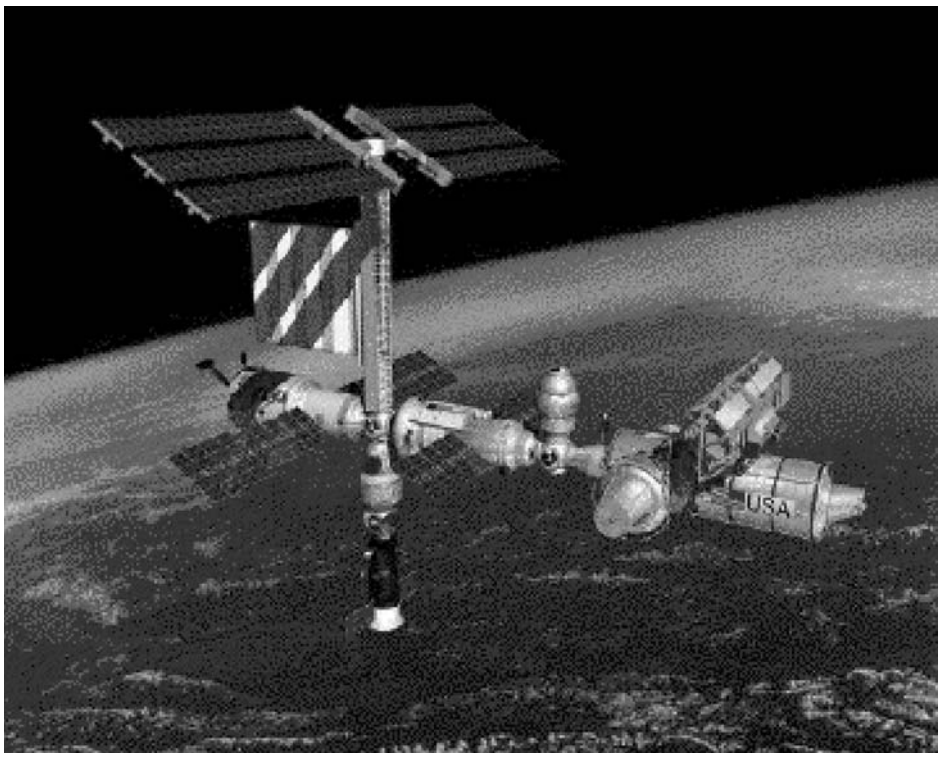

Fig. 17. An early conceptualization of the *International Space Station*, which will be a permanent research platform in space, a laboratory orbiting the Earth. (*NASA*.)

tasks that are unprecedented in space history. Drawing upon the scientific and technological expertise of 16 nations: the United States, Canada, Japan, Russia, 11 member nations of the European Space Agency (ESA), and Brazil, enabling scientists from around the globe to perform long-duration research in the unique environment of microgravity. See Fig. 17.

More than four times as large as the Russian *Mir* space station, the completed *International Space Station* will have a mass (weight) of about 1 million pounds (453,592 kilograms). The ISS inclination will be approximately 51.6 degrees to the equator. The operating altitude is 220 nautical miles average (407 kilometers) because of orbital decay and the reboost schedule. There are 19 scheduled reboost flights during the assembly phase. The wingspan width is 356 feet (108.5 meters) and the length is 290 feet (88.4 meters). Power generated by the completed station will be about 110 kilowatts with 46 kilowatts dedicated to scientific research. This power will be generated by 4 photovoltaic modules, each with 2 arrays measuring 34.1 meters by 11.2 meters (112 feet by 39 feet). The atmosphere inside will be 14.7 psi (101.36 kilopascals) the same as Earth. Total pressurized volume of the completed station will be approximately 43,000 cubic feet (1,218 m^3) in 6 laboratories.

The pressurized living and working space aboard the completed ISS will be about the size of three average American homes. It giant solar arrays will generate the electricity needed to power about 50 average American homes. Inside the ISS its weightless environment will be maintained at "shirt sleeve" temperatures.

Six main laboratories will house research facilities, which include:

- Two U.S. — a laboratory module called "Destiny" and a Centrifuge Accommodations Module (CAM).
- One European Space Agency (ESA) laboratory named "Columbus."
- One Japanese Experiment Module named "Kibo."
- Two Russian Research Modules.

Researchers in government agencies, commercial enterprises, and scientific institutions will utilize the space station state-of-the-art laboratory facilities. The highly advanced data computing capabilities of the *International Space Station* will enable researchers to continuously operate multiple experiments. Scientists will be able to monitor and conduct their experiments from computer terminals in laboratories all over the world. With the exception of the centrifuge, all laboratory facilities will be designed to fit into a standard payload rack, called an "International Standard Payload Rack" (ISPR). See Fig. 18.

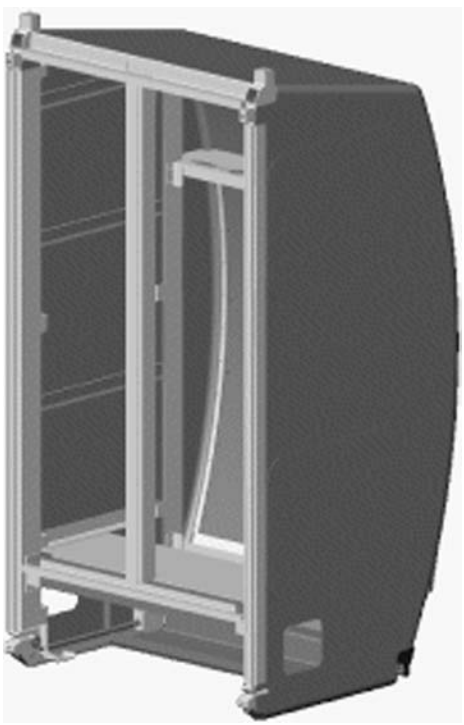

Fig. 18. The standard payload rack, called an International Standard Payload Rack (ISPR) will allow payloads to be easily changed out as needed and will allow facilities and payloads developed by one partner to fit into rack space supplied by another. (*NASA*.)

The central girder, called the truss, will connect the modules and four giant solar arrays making the ISS larger than a football field. The Canadian-built Remote Manipulator System, a 55-foot robot arm and a grappling mechanism called the Special Purpose Dexterous Manipulator (SPDM) will

move along the truss on a mobile base transporter to perform assembly and maintenance work.

External sites for mounting experiments intended for looking down to Earth and out into space or for direct exposure to space are provided at four locations on the truss structure, along with 10 on the Japanese *Kibo* Module's back porch and 4 on the ESA *Columbus* Module exposed facility. These external experiment sites vary as to the number of payloads that can be accommodated.

A three-person Russian Soyuz capsule provides emergency crew return.

A variety of vehicles will be visiting the ISS to ferry crew and supplies to and from Earth. Crew exchanges will be accomplished with the Space Shuttle and *Soyuz*. Russian Progress spacecraft, Japanese H-II Transfer Vehicle, and Europe's Autonomous Transfer Vehicle (ATV) will provide resupply and reboost.

Responsibility for the planning and operations of the *International Space Station* is divided among the partners. NASA has the overall integration role for systems and payload operations. The Space Station Control Center (SSCC) in Houston is responsible for crew safety, rendezvous and docking, and systems such as life support, propulsion, communications, and power. The Payload Operations Integration Center (POIC) in Huntsville is responsible for integrated payload operations and is the focal point for the science planning and operations that will occur around the world.

The other partners' control centers work with the SSCC and POIC to keep the ISS running smoothly and to ensure that specific goals and program objectives are being met. The Space Station Information and Promotion Center (SSIPC, Japan), Attached Pressurized Module Control Center (APM-CC, Europe), and Mission Control Center-Moscow (MCC-M, Russia) are all responsible for planning and operating the payloads and systems that reside within their respective modules.

Progress to Date

The *International Space Station* and its crew of three are orbiting the Earth at an altitude of over 230 miles (373 kilometers) and at a speed exceeding 17,000 mph (27,358 km/h).

Operational Progress. A new chapter in human space flight history unfolded with the launch of the first permanent occupants of the new *International Space Station* (ISS), the Expedition One crew. Liftoff occurred October 31, 2000 aboard a Russian *Soyuz* rocket from the Baikonur Cosmodrome in Kazakhstan. U.S. astronaut, Bill Shepherd, Russian cosomonauts, Yuri Gidzenko as *Soyuz* Commander and Sergei Krikalev as Flight Engineer, docked with the ISS on November 2, 2000 to begin a pioneering four-month mission to prepare the facility for future scientific research. The Expedition One crewmembers returned to Earth March 21, 2001 aboard the Space Shuttle *Discovery*.

On March 8, 2001 *Discovery* STS-102 delivered the second resident crew Expedition Two. Relieving a crew that transformed the *International Space Station* into a home, the second station crew opened the research outpost for business, beginning scientific work while continuing the growth in size and sophistication.

The mission of the station's Expedition Two crew, Commander Yury Usachev and Flight Engineers Jim Voss and Susan Helms, was highlighted by the arrival of the complex's first major experiments; the installation and checkout of a Canadian-developed station robotic arm; and the installation and initial space walks from a new station airlock designed for both U.S. and Russian spacesuits.

The Expedition Two crew worked with 18 different scientific experiments. The research included studies of the human body in space, space radiation, observations of the Earth, crystal growth in weightlessness and plant growth in space.

When Usachev, Voss, and Helms handed off their assignments to the Expedition Three crew, during space shuttle mission STS-105 on August 12, 2001 the station had reached a significant plateau of self-reliance: able to sustain and maintain itself for long periods and capable of ongoing research activities.

On August 22, 2001 the Expedition Three crew, Commander Frank Culbertson, Pilot Vladimir Dezhurov, and Flight Engineer Mikhail Tyurin, assumed command of a four-month expedition, which was highlighted by the extension of scientific research and the addition of a new Russian docking port to the expanding complex.

Expedition Three science focused on the effects of space flight on bone and muscle mass during extended stays in space and how such phenomena may relate to similar conditions on Earth. Additional experiments in the fields of human life sciences, biotechnology, education, and video technology were conducted.

The Expedition Three crewmembers returned to Earth December 17, 2001 aboard the Space Shuttle *Endeavor*.

On December 5, 2001 the Expedition Four crew, Commander Yury I. Onufrienko, Flight Engineers Daniel W. Bursch and Carl E. Walz, assumed command of a four- month expedition. The number of science investigations aboard the *International Space Station* will almost double during Expedition Four, and new equipment will make the research outpost even more productive.

With the successful installation of Quest the Airlock, in July 2001, the ISS has completed it Phase II Assembly milestone and is now a fully functioning operational facility. Key operational systems activated and confirmed include the following:

- Life-support systems needed to maintain a "shirt-sleeve" environment for the crew.
- Power systems needed to generate, store, and distribute renewable electricity from the solar arrays.
- Flight control systems needed to maintain a stable orbiting platform.
- Voice systems needed to communicate among the orbiting modules and with ground control data systems for commanding and monitoring ISS health and status.
- Airlock and space suit systems needed to conduct spacewalks without the Space Shuttle present.

Mission Control Center-Houston (MCC-H) has assumed responsibility from MCC-Moscow as the lead ISS Control Center.

Development and Assembly Progress

Each International Partner has made contributions to the ISS configuration on orbit:

- *Destiny*, the U.S. Laboratory, the most complex and capable piece of the ISS.
- Russia's Zvezda Service Module.
- NASA-developed Neutron Detector in the U.S. Lab, *Kibo*, Japan's Experiment Module and principal contribution, continues on schedule for a 2004 launch.
- European Space Agency's (ESA's) data management equipment on the Service Module. The Columbus Module, ESA's principal contribution, is scheduled for a 2005 launch.
- Canada's robotic arm was delivered to orbit in April of 2001.
- In addition, two of the three U.S.-owned, Italian-built Multi-Purpose Logistics Modules have been delivered and are making logistics flights to and from the ISS.

Approximately 75 percent of all U.S. flight hardware has been delivered to Kennedy Space Center for deployed to orbit.

More than 46 space flights over five years and at least three space vehicles — the Space Shuttle, the Russian *Soyuz* rocket and the Russian Proton rocket — will deliver the various space station components to Earth orbit. Assembly of the more than 100 components, will require a combination of human space walks and robot technologies.

ISS Elements Launched to Date

Sixteen flights, which includes 12 space shuttle missions, have already occurred in the *International Space Station* era:

- November 20, 1998, ISS Mission 1A/R, the *Zarya* Control Module (Functional Cargo Block — FGB) was launched into orbit aboard a Russian Proton rocket.
- December 4, 1998, ISS Mission 2A Space Shuttle *Endeavor* (STS-88) attached the *Unity module* and two Pressurized Mating Adapters to *Zarya*.
- May 27, 1999, ISS Mission 2A.1 Space Shuttle *Discovery* (STS-96). For flight 2A.1 the double SPACEHAB module carried internal and resupply

cargo for station outfitting. The STS-96 Shuttle Discovery flight will go into the books as the first docking of a shuttle with the *International Space Station*.

- May 19, 2000, ISS Mission 2A.2a Space Shuttle *Atlantis* (STS-101) prepared the station for the arrival of the *Zvezda* Service Module. Installed four new batteries, 10 new smoke detectors and four new cooling fans on the *Zarya* module; Installed the final parts of the Strela crane on Pressurized Mating Adapter 1; Removed and replaced the early communications system antenna; Installed handrails on Node 1 (*Unity module*).
- July 12, 2000, ISS Mission 1R attached the *Zvezda* Service Module. The Service Module is the primary Russian station contribution and an early station living quarters. It provides life support system functions to all early elements.
- September 8, 2000, ISS Mission 2A.2a Space Shuttle *Atlantis* (STS-106). The crew spent five days, 9 hours and 21 minutes inside the *International Space Station*. The seven crewmembers completed a long checklist aimed at making the station a home for its first residents.
- October 11, 2000, ISS Mission 3A, Space Shuttle *Discovery* (STS-92) attached the Integrated Truss Structure (ITS) Z1, Pressurized Mating Adapter 3 (PMA 3), Ku-band Communications System and the Control Moment Gyros (CMGs).
- October 31, 2000, ISS Mission 2R (*Soyuz*) Test Flight and Assembly. Provides Russian assured crew return capability without the space shuttle present. The initial three-person crew (Expedition One) establishes first human presence on the space station.
- Nov. 30, 2000, ISS Mission 4A, Space Shuttle *Endeavor* (STS-97) attached the first set of U.S. solar arrays and batteries, called the "Photovoltaic (PV) Module," radiators, and the P6 Truss.
- February 7, 2001, ISS Mission 5A, Space Shuttle *Atlantis* (STS-98) attached the U.S. *Destiny* Laboratory Module.
- March 8, 2001, ISS Mission 5A.1, Space Shuttle *Discovery* (STS-102) delivered the second resident crew and attached *Leonardo*, the Multi-Purpose Logistics Module (MPLM).
- April 19, 2001, ISS Mission 6A, Space Shuttle *Endeavor* (STS-100) delivers the Canada's Robot Arm (Canadarm2), the station's mechanical arm, which is needed to perform assembly operations on later flights. Attached the *Raffaello* the Italian-built Multi-Purpose Logistics Module (MPLM) which carries six system racks and two storage racks for the U.S. Lab.
- July 12, 2001, ISS Mission 7A, Space Shuttle *Atlantis* (STS-104) delivered the Joint Airlock, enabling spacewalks without the Space Shuttle present.
- August 10, 2001, ISS Mission 7A.1 Space Shuttle *Discovery* (STS-105) delivered the Expedition Three crew and attached the *Leonardo* Multi-Purpose Logistics Module, transferred supplies and equipment to the station.
- September 14, 2001, ISS Mission 4R (*Soyuz*) attached the Docking Compartment 1 (DC-1) and Strela Boom. These provide additional egress and ingress location for Russian-based space walks and a *Soyuz* docking port.
- December 5, 2001, ISS Mission UF1, Space Shuttle *Endeavor* (STS-108) attached the *Raffaello* Multi-Purpose Logistics Module to the station so that about 2.7 metric tons (3 tons) of equipment and supplies could be unloaded. The crew later returned *Raffaello* to *Endeavour's* payload bay for the trip home. Expedition Four crew delivered.

International Space Station elements scheduled for launched over the next 5 years are shown in Table 2.

For a view of the *International Space Station*, assembled complete, in its most current configuration design, along with the components labeled by country of origin, see Fig. 19.

International Space Station Modules and Components

Zarya Control Module: The *Zarya Control Module*, also known by the technical term Functional Cargo Block and the Russian acronym (FGB), was the first component launched for the *International Space Station*. This module was designed to provide the station's initial propulsion and power. The 19,323-kilogram (42,600-pound) pressurized module was launched on a Russian Proton rocket November 20, 1998.

The U.S.-funded and Russian-built *Zarya*, which means "Sunrise" when translated to English, is a U.S. component of the station although it was built and launched by Russia. The module was built by the Khrunichev State Research and Production Space Center, which is also known as KhSC, in Moscow under a subcontract to The Boeing Company for NASA. Only weeks after *Zarya* reached orbit, Space Shuttle *Endeavor* made a rendezvous and attached a U.S.-built connecting module called *Node 1*, or *Unity*. The *Zarya* module provided orientation control, communications and electrical power attached to the passive *Node 1* while the station awaited launch of the third component, a Russian-provided crew living quarters and early station core known as the *Zvezda Service Module*. The Service Module enhanced or replaced many functions of *Zarya*. Later in the station assembly sequence, the *Zarya module* will be used primarily for its storage capacity and external fuel tanks.

The *Zarya module* is 12.6 meters (41.2 feet) long and 4.1 meters (13.5 feet wide) at its widest point. See Fig. 20. It has an operational lifetime of at least 15 years. Its solar arrays and six nickel–cadmium batteries can provide an average of 3 kilowatts of electrical power. Using the Russian Kurs system, the *Zarya* performed an automated and remotely piloted rendezvous and docking with the Service Module in orbit. Its side docking ports will accommodate Russian *Soyuz* piloted spacecraft and unpiloted *Progress* resupply spacecraft. See Figs. 21 and 22. Each of the two solar arrays is 10.7 meters (35 feet) long and 3.4 meters (11 feet) wide.

TABLE 2. *INTERNATIONAL SPACE STATION* PROPOSED SCHEDULE FOR UPCOMING MISSIONS

Mission	Launch Date	Launch Vehicle	Elements
8A	04/04/2002	Shuttle *Atlantis*	Central Truss Segment (ITS S0) and Mobile Transporter (MT)
UF-2	05/02/2002	Shuttle *Endeavor*	*Multipurpose Logistics Module* (MPLM) with payload racks. The Mobile Base System is installed on the Mobile Transporter to complete the *Canadian Mobile Servicing System* (MSS).
9A	08/01/2002	Space Shuttle	First right-side Truss segment (ITSS1) with radiators; Crew and Equipment Translation Aid (CETA) Cart A.
11A	09/06/2002	Space Shuttle	First left-side truss segment (ITSP1); Crew and Equipment Translation Aid (CETA) Cart B.
12A	01/2003	Space Shuttle	Second left-side truss segment (ITS P3/P4); Second set of Solar arrays and batteries (Photovoltaic Module).
12A.1	04/2003	Space Shuttle	Third left-side truss segment (ITSP5), logistics and supplies
13A	05/2003	Space Shuttle	Second right-side truss segment (ITS S3/S4); The Mobile Base System is installed on the Mobile Transporter to complete the Canadian Mobile Servicing System, or MSS. Third set of U.S. Solar arrays and batteries (Photovoltaic Module).

TABLE 2. (*Continued*)

Mission	Launch Date	Launch Vehicle	Elements
15A	11/2003	Space Shuttle	Fourth and final set of U.S. solar arrays delivered along with fourth starboard truss segment, the S6 Truss.
3R	TBD	Russian Proton Rocket	Universal Docking Module.
5R	TBD	Russian *Soyuz* Rocket	Docking Compartment 2 (DC2).
10A	02/2004	Space Shuttle	The second of three station connecting modules, *Node 2*, attaches to end of U.S. Lab and provides attach locations for the Japanese laboratory, European laboratory, the *Centrifuge Accommodation Module* and later *Multipurpose Logistics Modules*.
9A.1	04/2004	Space Shuttle	Russian provided Science Power Platform (SPP) with four solar arrays and European Robotic Arm, or ERA, which is a second station mechanical arm that will be used to maintain the SPP.
1J/A	08/2004	Space Shuttle	Japanese Experiment Module Experiment Logistics Module (JEMELM PS) and two additional solar arrays for the Russian Science Power Platform, or SPP.
1J	09/2004	Space Shuttle	The primary Japanese contribution, the Japanese Experiment Module, or JEM, laboratory (*Kibo*), is delivered and begins use and a Japanese robotic arm attached to the Japanese Experiment Module is delivered.
UF-3	01/2005	Space Shuttle	Multipurpose Logistics Module (MPLM) and *EXPRESS Pallet*.
1E	02/2005	Space Shuttle	The European Space Agency's primary contribution to the station, the Columbus Orbital Facility laboratory (*Columbus Module*).
UF-4	05/2005	Space Shuttle	Spacelab Pallet carrying "Canada Hand" (Special Purpose Dexterous Manipulator) and Alpha Magnetic Spectrometer experiment to be attached to station truss site.
2J/A	06/2005	Space Shuttle	The Japanese "back porch," the Exposed Facility, for Japanese laboratory along with external experiments carried in a Japanese exterior logistics carrier.
UF-5	09/2005	Space Shuttle	*Multipurpose Logistics Module* and *EXPRESS Pallet*.
UF-6	TBD	Space Shuttle	*Multipurpose Logistics Module* (MPLM) and Batteries; *EXPRESS Pallet*.
14A	TBD	Space Shuttle	*Cupola* with eight windows provides station crew with direct viewing capability for some robotics operations, space walks and experiments and Science Power Platform (SPP) Solar Arrays; Zvezda Micrometeroid and Orbital Debris Shields (MMOD); MT/CETA Rails.
16A	TBD	Space Shuttle	U.S. *Habitation Module* to enhance crew accommodations and provide for a station crew with as many as seven members.
17A	TBD	Space Shuttle	*Multipurpose Logistics Module*; Destiny racks; Common Berthing Mechanism — an interface between the Crew Return Vehicle and U.S. Node 3.
18A	TBD	Space Shuttle	X-38 Crew Return Vehicle is attached to the station provides additional seven-person crew return capability, added to already existing three-person *Soyuz* crew return capability.
20A	TBD	Space Shuttle	U.S. Node 3. Node 3 provides attachment points for the U.S. Habitation Module, Crew Return Vehicle, pressurized mating adapter and any future station additions.
8R	TBD	Russian *Soyuz* Rocket	First of two Russian laboratories providing experiment and research facilities (Research Module 1).
9R	TBD	Russian Proton Rocket	*Docking and Stowage Module* (DSM). Provides additional on-orbit stowage and *Soyuz* docking location
10R	TBD	Russian *Soyuz* Rocket	Second Russian laboratory to house experiments and research facilities (Research Module 2).
19A	TBD	Space Shuttle	*Multipurpose Logistics Module* (MPLM)
UF-7	TBD	Space Shuttle	*Centrifuge Accommodation Module* (CAM), completes the complement of station laboratory facilities providing a facility to control gravity for research activities. The CAM attaches to *Node 2*.

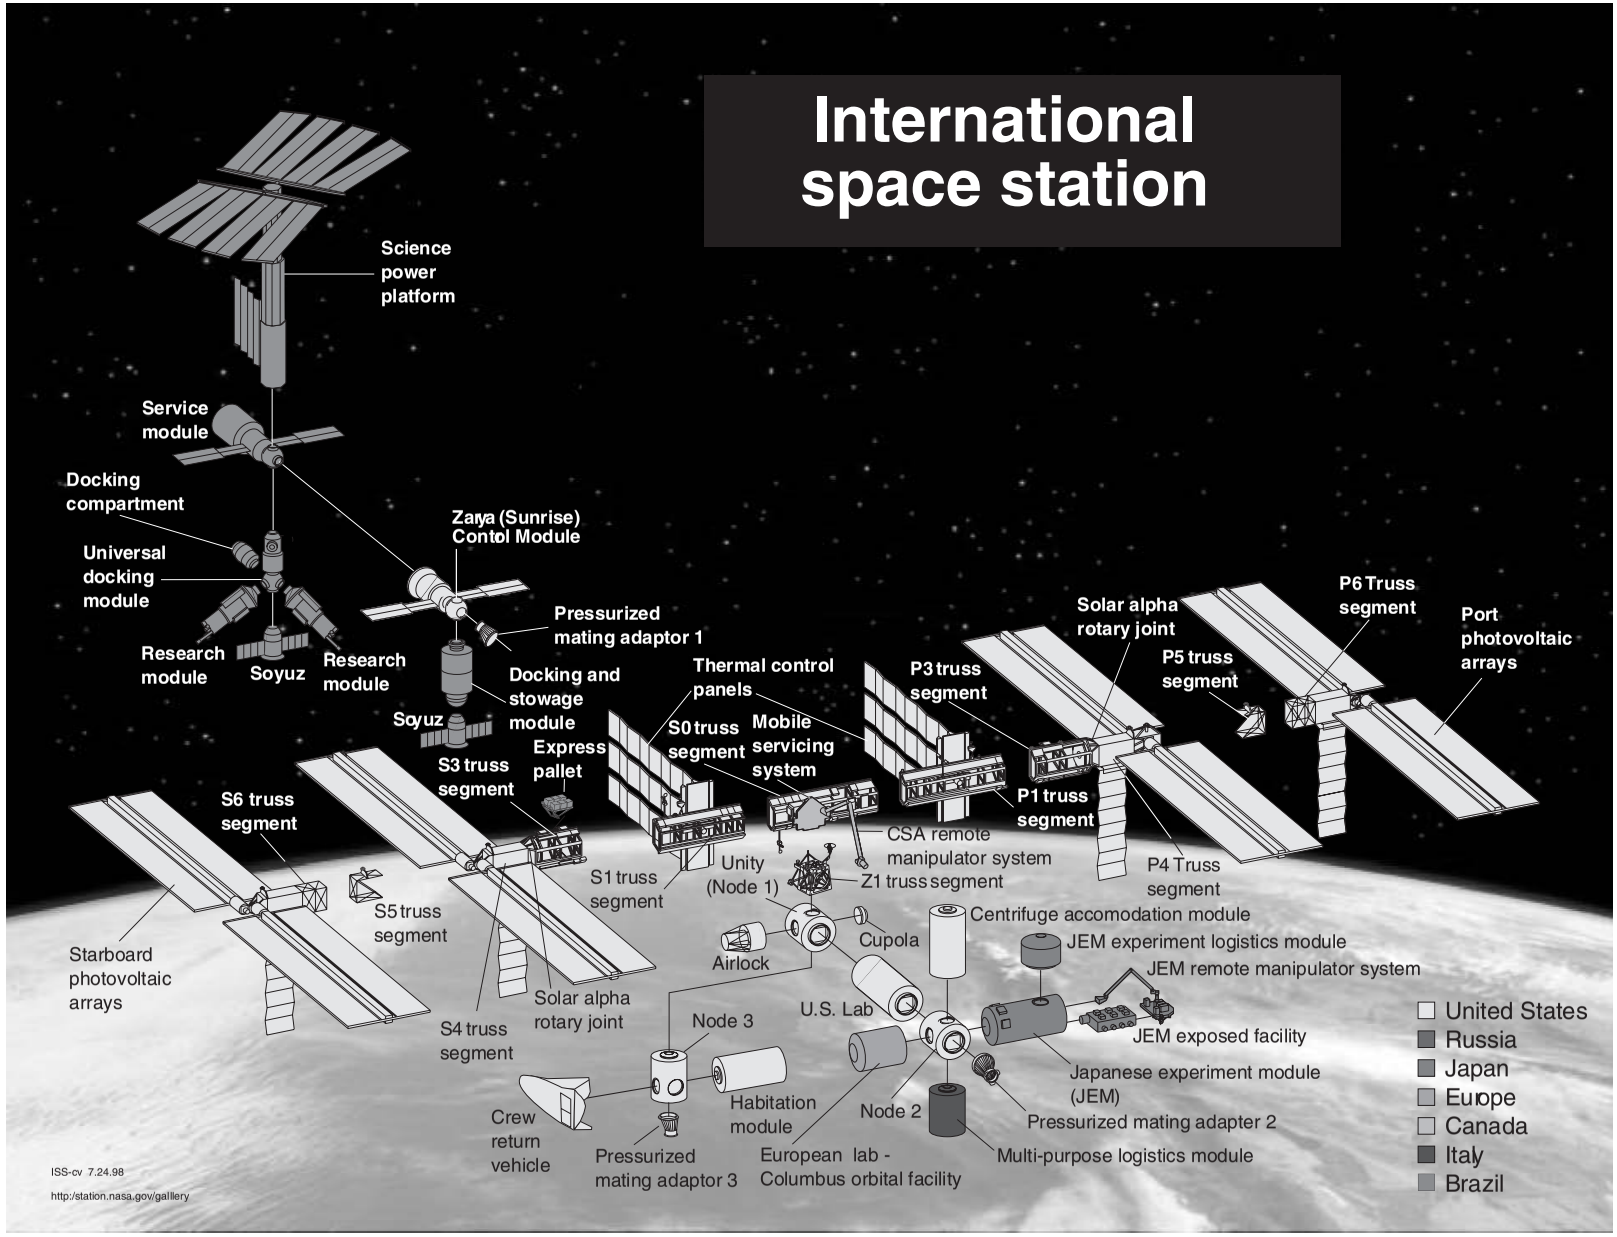

Fig. 19. Source for a component view of the International Space Station with each element identified by its name and ownership at assembly complete. (Rev. D) (*NASA*.)

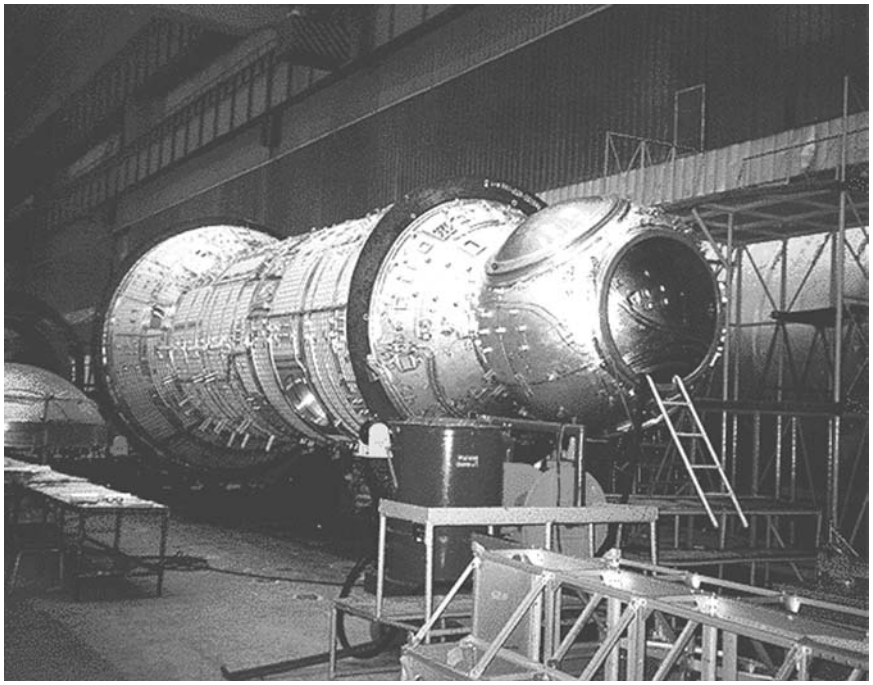

Fig. 20. The *Zarya* module, also known as the Functional Cargo Block, of the *International Space Station* in Khrunichev's manufacturing facility in Moscow. (*NASA*.)

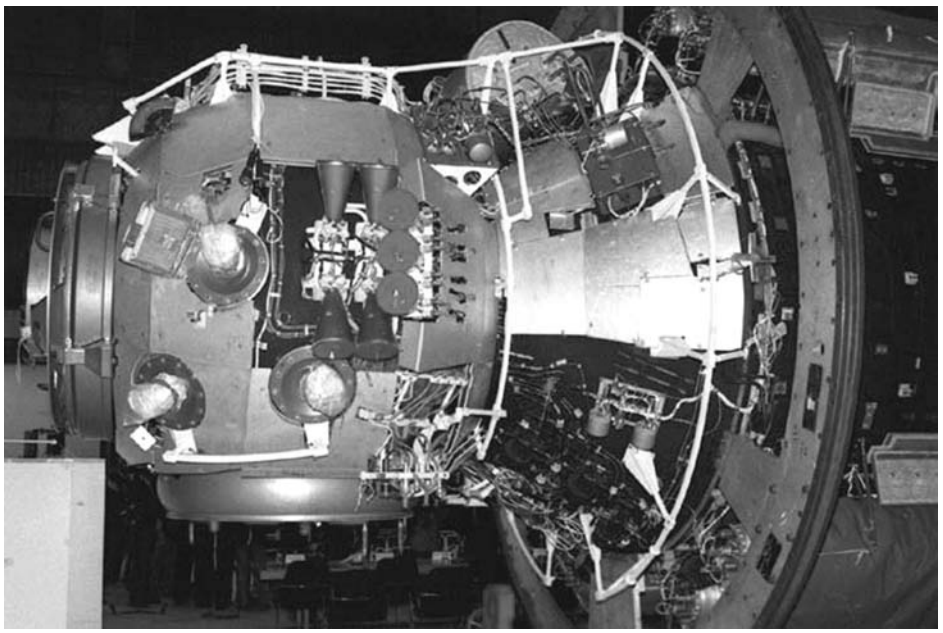

Fig. 21. Two docking ports on the control module, or Functional Cargo Block (Russian acronym FGB), are shown in this view as the module is prepared for shipment from its Moscow factory to the launch site in Kazakstan in January 1998. (*NASA*.)

The module's 16 fuel tanks combined can hold more than 5.4 metric tons (6 tons) of propellant. The attitude control system for the module includes 24 large steering jets and 12 small steering jets. Two large engines are available for reboosting the spacecraft and making major orbital changes.

Construction of the *Zarya* module began at KhSC in December 1994. It was shipped to the Baikonur Cosmodrome, Kazakhstan, launch site to begin launch preparations in January 1998. The three-stage proton rocket launched the module into a 220.4- by 339.6-kilometer (137- by 211-statute mile) orbit. See Fig. 23. During launch, the module's systems were in an idle mode to conserve battery power. After reaching the initial elliptical orbit and separating from the Proton's third stage, a set of preprogrammed commands automatically activated the module's systems and deployed the solar arrays and communications antennas. After several days of operational tests, the module was commanded to fire its engines and circularize its orbit at an altitude of about 386.2 kilometers (240 statute miles), the orbit at which *Endeavor* made rendezvous and captured the spacecraft to attach it to the U.S.-built *Unity Connecting Module*.

Unity Connecting Module: The first U.S.-built component of the *International Space Station*, a six-sided connecting module and passageway, or node, named *Unity*, was the primary cargo of Space Shuttle mission STS-88, launched on December 4, 1998 as the first mission dedicated to assembly of the station.

Now permanently attached to the *Zarya control module* in orbit, the *Unity connecting module* lays a foundation for all future U.S. *International Space Station* modules. *Unity* has six berthing ports, one on each side, one of which already is attached to *Zarya*. Future U.S. station modules and station components will attach to the remaining five ports. Built by the Boeing Company at a manufacturing facility at the Marshall Space Flight Center in Huntsville, Alabama, *Unity* is the first of three such connecting modules that will be built for the station. Sometimes referred to as *Node 1*,

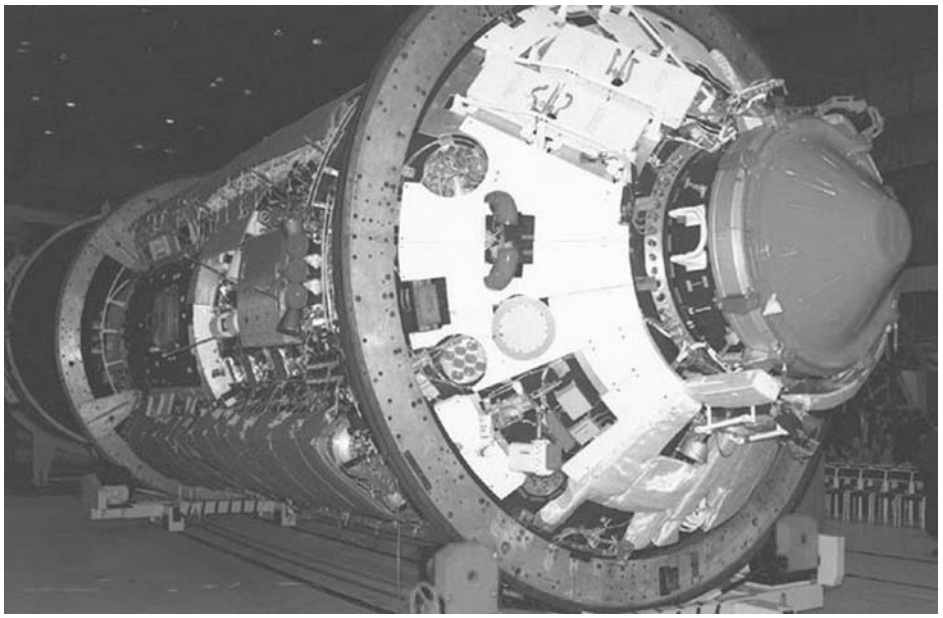

Fig. 22. The aft docking port on the control module, or Functional Cargo Block (Russian acronym FGB), is seen in this view as the module is prepared for shipment from its Moscow factory to the launch site in Kazakstan in January 1998. (*NASA*.)

the *Unity module* measures 15 feet (4.6 meters) in diameter and 18 feet (5.5 meters) long. Including mating adapters attached at each end, as is currently the case in orbit, the overall component measures about 34 feet (10.4 meters) long. See Fig. 24.

Essential space station resources such as fluids, environmental control and life support systems, electrical and data systems are routed through *Unity* to supply work and living areas of the station. More than 50,000 mechanical items, 216 lines to carry fluids and gases, and 121 internal and external electrical cables using six miles of wire were installed in the *Unity node*. *Unity* is made of aluminum. See Fig. 25.

The remote power control modules (RPCM's) that are contained in the Unity node were also designed and developed by NASA Glenn Research Center. Each of the 12 small metal containers is filled with "circuit breakers" that provide switching and protection in case of a short circuit during construction of the ISS or during operation of the completed station. They can be controlled by astronauts via laptop computers or by ground personnel.

Two conical docking adapters were attached to each end of *Unity* prior to its launch aboard *Endeavor*. The adapters, called *pressurized mating adapters* (PMAs), allow the docking systems used by the Space Shuttle and by Russian modules to attach to the node's hatches and berthing mechanisms. One of the conical adapters now permanently attaches *Unity* to *Zarya*, while the other provides a Shuttle docking port. *Unity* and the two mating adapters weigh about 25,600 pounds (11,600 kilograms). Attached to the exterior of the mating adapter that permanently attaches *Unity* to *Zarya* are computers, or multiplexer-demultiplexers (MDMs), which provide early command and control of *Unity*. *Unity* also is outfitted with an early communications system that allows data, voice and low data rate video with Mission Control, Houston, to supplement Russian communications systems during the early station assembly activities.

The two remaining station connecting modules, or nodes, are being built by the European Space Agency (ESA) for NASA in Italy by Alenia Aerospazio. Nodes 2 and 3 will be slightly longer than the *Unity node*, measuring almost 21 feet (6.4 meters) long, and each will hold eight standard space station equipment racks in addition to six berthing ports. ESA is building the two additional nodes as partial payment for the launch of the ESA *Columbus laboratory module* and other equipment on the Space Shuttle. *Unity* holds four equipment racks.

Zvezda Service Module: The *Zvezda Service Module* was the first fully Russian contribution to the *International Space Station* and will serve as the early cornerstone for the first human habitation of the station. The *Zvezda Service Module* a unpiloted component was launched on July 12, 2000 as the third station component to reach orbit, docking by remote control with the already orbiting *Zarya Control Module* and *Unity Connecting Module* at an altitude of about 250 statute miles.

Fig. 23. *Zarya*, the first component of the *International Space Station* (ISS) launched flawlessly at 1:40 a.m. (EST) on November 20, 1998, from Kazahkstan. Atop a Russian Proton rocket, the *Zarya Module* was lifted into orbit from the Baikonur Cosmodrome in Kazahkstan. (*NASA*.)

The 42,000-pound (19,100-kilogram) module, similar in layout to the core module of Russia's *Mir* Space Station, will provide the early station living quarters; life support system; electrical power distribution; data processing system; flight control system; and propulsion system. It also

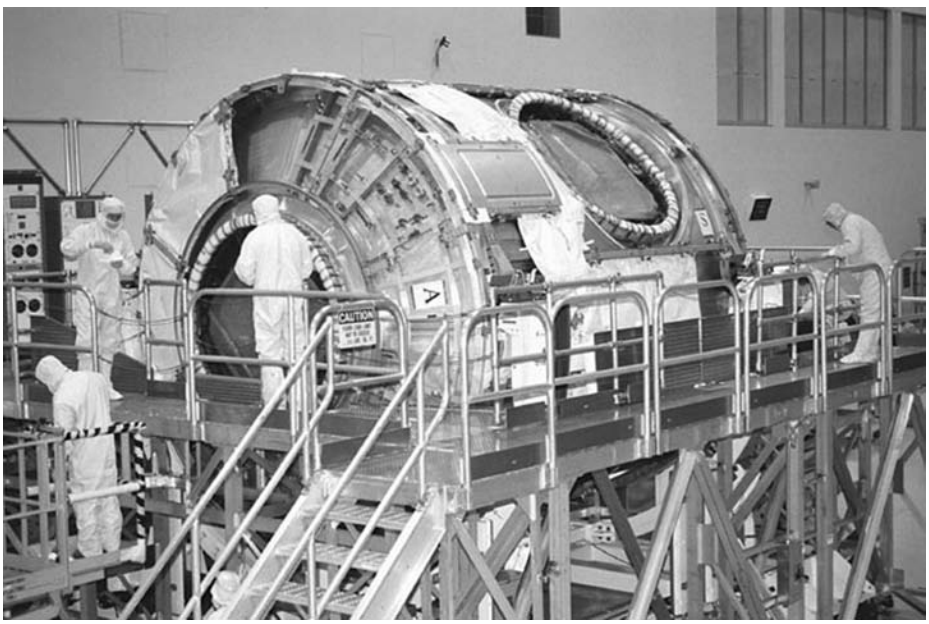

Fig. 24. A close-up view of the Node 1 in its work stand in the Space Station Processing Facility at Kennedy Space Center shows two of its six hatches that will serve as docking ports. (*NASA*.)

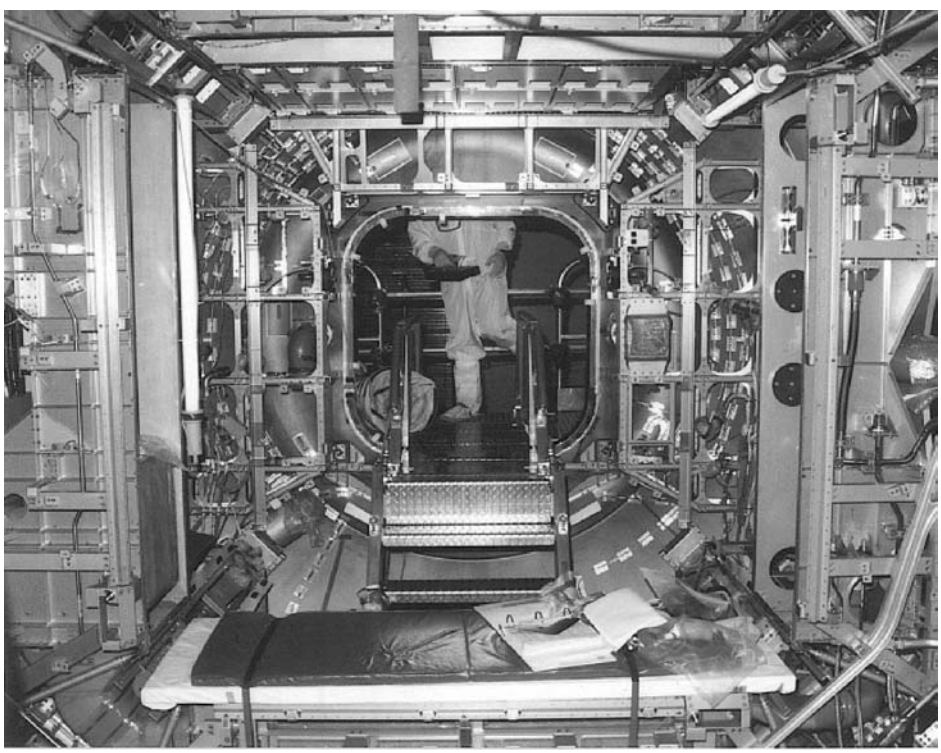

Fig. 25. The interior of the first U.S. module to be launched to the *International Space Station*, a connecting module called *Node 1*, is shown as it neared the completion of manufacturing in the spring of 1997. The node was shipped from the Boeing manufacturing facility at the Marshall Space Flight Center in Huntsville, Alabama, to the Kennedy Space Center, Florida. (*NASA*.)

will provide a communications system that includes remote command capabilities from ground flight controllers. See Fig. 26.

Although many of these systems will be supplemented or replaced by later U.S. station components, the Service Module will always remain the structural and functional center of the Russian segment of the International Space Station.

The module has a wingspan of 97.5 feet (29.9 meters) from tip to tip of the solar arrays, and 43 feet (13.1 meters) long from end to end. The Service Module contains three pressurized compartments: a small, spherical Transfer Compartment at the forward end; the long, cylindrical main Work Compartment; and the small, cylindrical Transfer Chamber at the aft end. An unpressurized Assembly Compartment is wrapped around the exterior of the Transfer Chamber at the aft of the module. The Assembly Compartment holds external equipment such as propellant tanks, thrusters and communications antennas.

The Service Module includes four docking ports, one in the aft Transfer Chamber and three in the spherical forward Transfer Compartment–one facing forward, one facing up and one facing down. See Fig. 27. The aft docking port has a probe and cone docking mechanism to allow dockings by the *Progress* resupply spacecraft and *Soyuz* piloted spacecraft. It is also outfitted with an automated rendezvous and docking system. The forward docking ports have hybrid docking mechanisms to allow docking with the *Zarya* using the forward-facing port; with a Russian Science Power Platform to be delivered later in the station's assembly using the up-facing

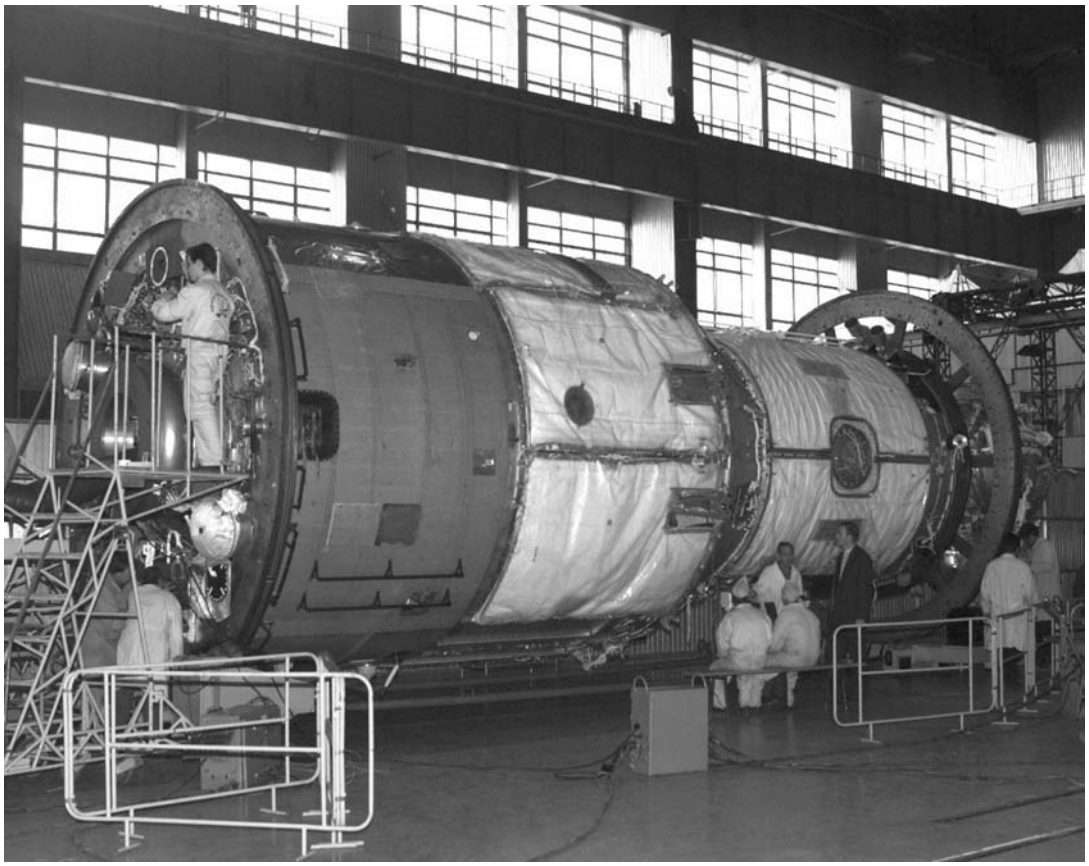

Fig. 26. Starboard side of the *Zvezda Service Module* exterior. The aft end is to the left. (*NASA*.)

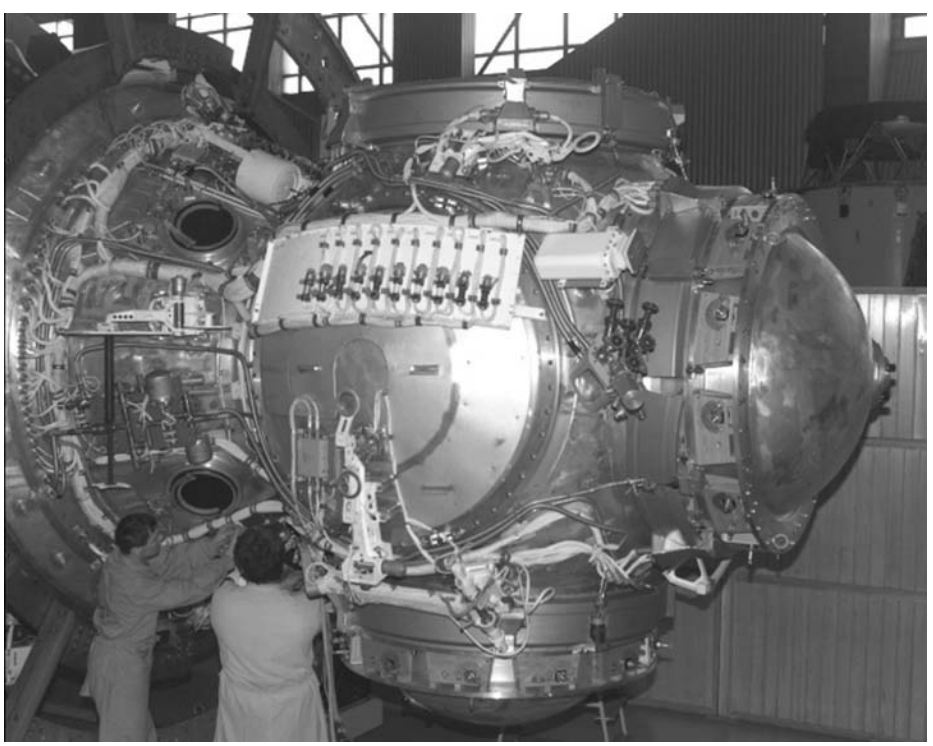

Fig. 27. Transfer compartment on the forward section of the *Zvezda Service Module*. (*NASA*.)

port; and with a Russian Universal Docking Module to be delivered later in assembly using the down-facing port.

Living accommodations on the Service Module include personal sleeping quarters for the crew; a toilet and hygiene facilities; a galley with a refrigerator-freezer; and a table for securing meals while eating. The module has a total of 14 windows, including three 9-inch (22.9-centimeter) diameter windows in the forward Transfer Compartment for viewing docking activities; one large 16-inch (40.4-centimeter) diameter window in the Working Compartment; an individual window in each crew compartment; and additional windows positioned for Earth and intramodule observations. Exercise equipment will include a NASA-provided treadmill and a stationary bicycle. The crew's wastewater and condensation water will be

recycled for use in oxygen-generating devices on the module, but it is not planned to be recycled for use as drinking water. Spacewalks using Russian Orlan-M spacesuits can be performed from the Service Module by using the Transfer Compartment as an airlock. The module also provides data, voice and television communications with Mission Control Centers in Moscow and in Houston.

Z1 Integrated Truss Structure: The *Z1 Truss* was the first permanent latticework structure for the space station, very much like a girder, setting the stage for the future addition of the station's major trusses or backbones. The *Z*1 fixture also serves as the platform on which the huge U.S. solar arrays were mounted on the following shuttle assembly flight, STS-97. It includes power distribution components, four flat discs that will be used to control the station's attitude, communications equipment, temperature control system hardware, space walk/extravehicular aids and power, data and coolant connections. See Fig. 28.

The crew of shuttle mission STS-92 attached the *Z1 Truss* to the station on October 14, 2000.

P6 Integrated Truss Structure: During shuttle mission STS-97, Space Shuttle *Endeavor* delivered the first set of U.S.-provided solar arrays and batteries, called the *P6 Photovoltaic Module*. They were temporarily installed on the *P6 Integrated Truss Structure* on the *Z1 Truss* until it can be relocated to its permanent location on the *P5 Truss* during a later assembly mission. See **Photovoltaic Cell**.

The *P6 Integrated Truss Structure* contains three discrete elements: the Photovoltaic Array Assembly, the Integrated Equipment Assembly, and the Long Spacer.

The *P*6 has four primary functions: the conversion or generation, storage, regulation and distribution of electrical power for the space station. The station derives its power from the conversion of solar energy into electrical power. The *Photovoltaic Power Module* performs this energy conversion.

The *P6 Integrated Truss Structure* was installed on Sunday, December 3, 2000.

Photovoltaic Module: Electrical power is the most critical resource for the *International Space Station* (ISS) because it allows the crew to live comfortably, to safely operate the station, and to perform scientific experiments. So, whether it is used to power the life support system, run a furnace that makes crystals, manage a computerized data network, or operate a centrifuge, electricity is essential. Since the only readily available source of energy for spacecraft is sunlight, NASA Glenn Research Center has pioneered, and continues to develop, technologies to efficiently convert solar energy to electrical power. One method of harnessing this energy, called *photovoltaics*, uses purified silicon solar cells to directly convert light to electricity. Large numbers of cells are assembled in arrays to produce high power levels.

However, a spacecraft orbiting the Earth is not always in direct sunlight. Therefore, the ISS relies on nickel-hydrogen rechargeable batteries to provide continuous power during the "eclipse" part of the orbit. The batteries ensure that the station is never without power to sustain life-support systems and experiments. During the sunlit part of the orbit, the batteries are recharged. The process of collecting sunlight, converting it to electricity, and managing and distributing this electricity builds up excess heat that can damage spacecraft equipment. This heat must be eliminated for reliable operation of the Space Station in orbit. The ISS power system uses radiators to dissipate the heat away from the spacecraft. The radiators are shaded from sunlight and aligned toward the cold void of deep space.

The power management and distribution subsystem disburses power at 160 volts of direct current (abbreviated as "dc") around the station through a series of switches. These switches have built-in microprocessors that are controlled by software and are connected to a computer network running throughout the station. To meet operational requirements, dc-to-dc converter units step down and condition the voltage from 160 to 120 volts

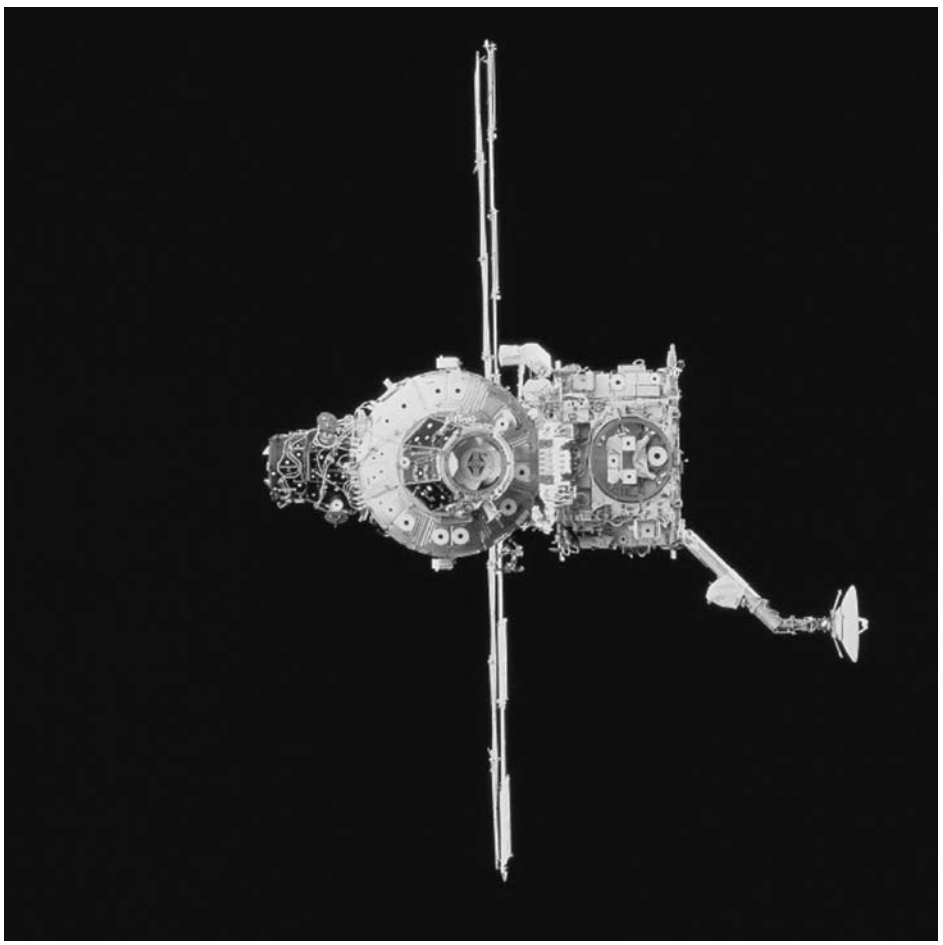

Fig. 28. Not long after separation of the Space Shuttle *Discovery* from the *International Space Station* (ISS), a crewmember onboard the shuttle was able to use a 70 mm handheld camera to grab this "edge-on" image of the station, featuring its newest additions. Backdropped against the blackness of space, the *Z1 Truss* structure and its antenna, as well as the new pressurized mating adapter (PMA-3), are visible in the foreground. (*NASA*.)

dc to form a secondary power system to service the loads. The converters also isolate the secondary system from the primary system and maintain uniform power quality throughout the station.

The NASA Glenn Research Center has decades of experience in designing, building, and testing space power systems. Therefore, it became the NASA Center initially responsible for designing the Space Station power system — the largest power system ever constructed in space. Engineers at Glenn combined state-of-the-art electrical designs with complex computer-aided analyses.

The *International Space Station's* electrical power system (EPS) will use eight "photovoltaic solar arrays" to convert sunlight to electricity. Each of the eight solar arrays will be 112 feet (34.1 meters) long by 39 feet (11.9 meters) wide. With all eight arrays installed, the complete Space Station is large enough to cover a football field. See Fig. 29.

Because the Space Station needs very high power levels, the solar arrays will require more than 250,000 silicon solar cells. NASA has developed a method of mounting the solar arrays on a "blanket" that can be folded like an accordion for delivery to space. Once in orbit, astronauts will deploy the blankets to their full size. Gimbals will be used to rotate the arrays so that they face the Sun to provide maximum power to the Space Station.

The complete power system, consisting of U.S. and Russian hardware, will generate 110 kW (kilowatts) total power, about as much as 55 houses would typically use. Approximately 46 kW will be available for research activities.

Radiator System: The ISS radiator system maintains the temperatures of systems and components. It was tested at the NASA Glenn Space Power Facility (SPF) at Glenn's Plum Brook Station in Sandusky, Ohio. This facility is the world's largest space environment simulation chamber 100 feet (30.5 meters) in diameter by 122 (37.2 meters) in height and is used to ground-test large space-bound hardware. It can simulate the severe conditions of space such as vacuum, low temperatures, and unfiltered sunlight.

The radiator system on the ISS consists of seven panels each about 6 by 12 feet (1.8 by 3.7 meters) designed to deploy in orbit from a 2-foot (0.6 meter) high stowed position to a 50-foot (15.2 meter) long extended position. The first round of tests confirmed that the deployment mechanism would operate properly in the cold void of space. The next phase of tests used a NASA Glenn-designed and assembled ammonia flow system to evaluate radiator performance. The ammonia collects heat from the Space Station's electronic equipment and module cooling components and transfers it to the radiator panels to be dissipated into space. Ammonia was selected because it was found to be the best heat transport fluid that meets all of NASA's thermal performance and safety requirements (i.e., toxicity, flammability, freeze temperature, stability, cost, and successful commercial and industrial use).

Destiny Laboratory Module: The *Destiny Laboratory Module* is the centerpiece of the *International Space Station*, where unprecedented science experiments will be performed in the near-zero gravity of space.

The 28-foot (8.5-meter) long, 14-foot (4.3-meter) diameter laboratory weighs 31,000 pounds (14, 100 kilograms) and cost approximately $1.4 billion. It is the most sophisticated and versatile space laboratory ever built and eventually will house an additional 18 racks for crew support and scientific research that can be removed and replaced periodically as experiment operations warrant. This versatility will allow researchers from around the world to conduct experiments in the unique microgravity environment of space as never before.

Destiny will provide many more functions of the station in addition to serving as the platform for experiment operations. It was launched with five system racks already installed. They include two avionics racks, two thermal control system racks and an atmosphere revitalization system rack. Each is capable of being tilted downward to provide access to the area behind.

The two avionics racks house equipment controlling the Communications and Tracking, Environmental Control and Life Support System, Thermal Control System, Command and Data Handling, and the Electrical Power System. These racks manage the audio equipment, video switching, and the computer switching boxes, called *Multiplexer/Demultiplexers*, which provide computer control of lab systems.

There are two thermal control system racks that circulate chilled water to cool other racks and the cabin air. One is a "low temperature" system, with water chilled to about 4 °C (39.2 °F). The low temperature system provides cooling to selected racks. The 'moderate temperature' system, with water chilled to about 17 °C (62.6 °F), cools selected racks and the cabin air.

The atmosphere revitalization (AR) rack provides for carbon dioxide removal, trace contaminant control, and monitoring of the cabin air. On orbit, the AR rack was moved from its launch location to its operational location during lab outfitting.

Additionally, the lab controls the function of the gyroscopes, called *Control Moment Gyros* (CMGs). These were preintegrated into the *Z1 Truss* launched on STS-92 in the fall of 2000 and were activated during STS-98. The four CMGs are electrically powered and provide attitude control of the station. At least two are required to provide attitude control without the need for supplementary control using the thrusters on *Zvezda* or *Zarya*.

The lab has three cylindrical sections and two endcones with hatches that will be mated to other station components. See Fig. 30. A 50.9-centimeter (20-inch) diameter window is located on one side of the center module segment. This pressurized module is designed to accommodate pressurized payloads. It has a capacity of 24 rack locations. Payload racks will occupy 13 locations specially designed to support experiments.

An exterior waffle pattern strengthens the hull of the lab. The exterior is covered by a debris shield blanket made of a material similar to that used

Fig. 29. The *International Space Station* is shown with its eight "photovoltaic solar arrays" installed. These solar arrays will convert sunlight to electricity. (*NASA*.)

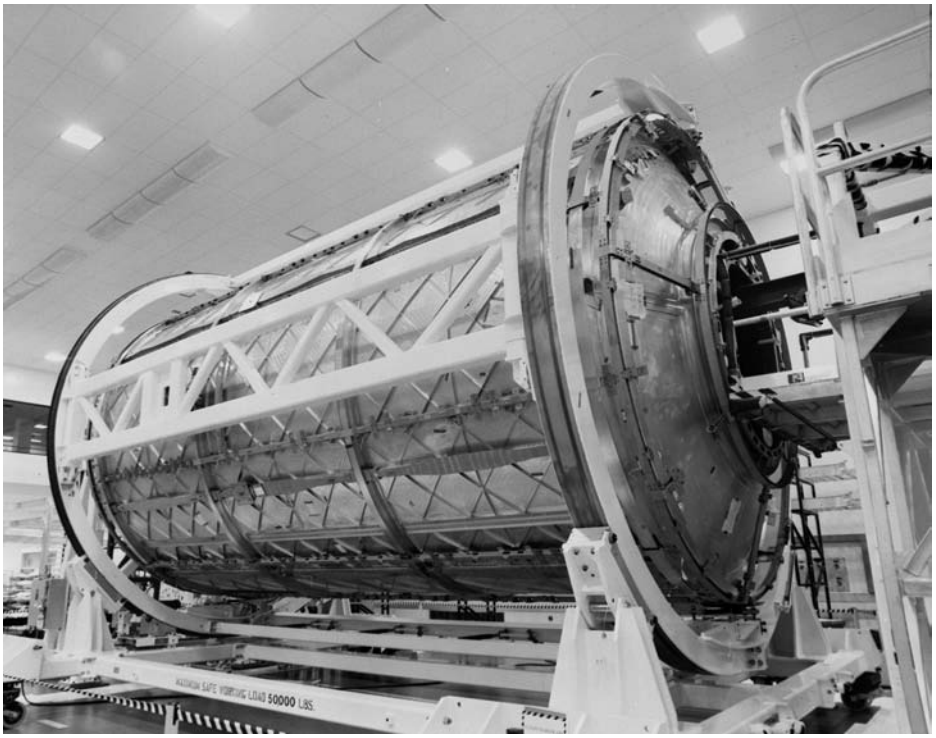

Fig. 30. The U.S. *Destiny* Laboratory module for the *International Space Station* is shown under construction in the fall of 1997 at the Marshall Space Flight Center station manufacturing facility in Huntsville, Al. (*NASA*.)

in bulletproof vests on Earth. A thin aluminum debris shield is placed over the blanket for additional protection.

Destiny was launched into space aboard shuttle mission STS-98, station assembly flight 5A, on February 7, 2001.

Multi-Purpose Logistics Modules: The three *Multi-Purpose Logistics Modules*, which were built by the Italian Space Agency (ASI), are pressurized modules that serve as the *International Space Station's* "moving vans," carrying laboratory racks filled with equipment, experiments and supplies to and from the station aboard the space shuttle.

The unpiloted, reusable Logistics Modules function as both a cargo carrier and a space station module when they are flown. Mounted in the space shuttle's cargo bay for launch and landing they are berthed to the station using the shuttle's robotic arm after the shuttle has docked. While berthed to the station, racks of equipment are unloaded from the module and then old racks and equipment may be reloaded to be taken back to Earth. The Logistics Module is then detached from the station and positioned back into the shuttle's cargo bay for the trip home. When in the cargo bay, the cargo module is independent of the shuttle cabin, and there is no passageway for shuttle crewmembers to travel from the shuttle cabin to the module.

In order to function as an attached station module as well as a cargo transport, the Logistics Modules also include components that provide some life support, fire detection and suppression, electrical distribution and computer functions. Eventually, the modules also will carry refrigerator freezers for transporting experiment samples and food to and from the station. Although built in Italy, the logistics modules, technically known as *Multi-Purpose Logistics Modules* or MPLMs, are owned by the U.S. and provided in exchange for Italian access to U.S. research time on the station.

The first MPLM, named *Leonardo*, was launched on the space shuttle *Discovery* mission STS-102 on March 8, 2001. See Fig. 31. On that flight, *Leonardo* was filled with equipment and supplies to outfit the U.S. *Destiny Laboratory Module*, which was carried to the station on STS-98. The second module, named *Raffaello*, was launched on space shuttle *Endeavor* (STS-100) on April 19, 2001. *Leonardo* flew a second time on the shuttle *Discovery* mission (STS-105) and will fly for a third time on STS-111 scheduled for April 2002. *Raffaello* flew for the second time on the space shuttle *Endeavor* mission (STS-108) December 5, 2001.

Construction of ASI's *Leonardo* module began in April 1996 at the Alenia Aerospazio factory in Turin, Italy. *Leonardo* was delivered to Kennedy from Italy in August 1998 by a special Beluga cargo aircraft. The cylindrical module is approximately 6.4 meters (21 feet) long and 4.6 meters (15 feet) in diameter, weighing almost 4.1 metric tons (4.5 tons). It can carry up to 9.1 metric tons (10 tons) of cargo packed into 16 standard space station equipment racks. Of the 16 racks the module can carry, five can be furnished with power, data and fluid to support a refrigerator freezer. *Raffaello* arrived at Kennedy in August 1999. The third module, named *Donatello*, was delivered to Kennedy on February 1, 2001.

The Italian Space Agency chose the names of the modules because they denote some of the great talents in Italian history. Leonardo da Vinci, an extraordinary inventor-scientist, civil engineer, architect, artist and military planner and weapons designer. Donato di Niccolo di Betto Bardi, one of the greatest sculptors of all time and one of the founders of modern sculpture; and Raffaello Sanzio, an artist whose work stands alone for its visual achievement of human grandeur, both in clarity of form and ease of composition.

Space Station *Remote Manipulator System* (SSRMS): Canada is contributing an essential component of the *International Space Station*, the *Mobile Servicing System*. This robotic system will play a key role in space station assembly and maintenance: moving equipment and supplies around the station, supporting astronauts working in space, and servicing instruments and other payloads attached to the space station. Astronauts will receive robotics training to enable them to perform these functions with the arm.

The Mobile Servicing System, which is also known as the MSS, has three parts:

- *Canadarm 2*: Launched on the space shuttle *Edneavour* mission STS-100 on April 19, 2001, the next generation Canadarm is a bigger, better, smarter version of the space shuttle's robotic arm. The robotic arm is essential to the continued assembly or the space station as the outpost grows beyond the reach of the shuttle's arm. It is 17.6 meters (57.7 feet) long when fully extended and has seven motorized joints. This arm is capable of handling large payloads and assisting with docking the space shuttle. The Space Station *Remote Manipulator System*, or SSRMS, is self-relocatable with a Latching End Effector, so it can be attached to complementary ports spread throughout the station's exterior surfaces. See Fig. 32.

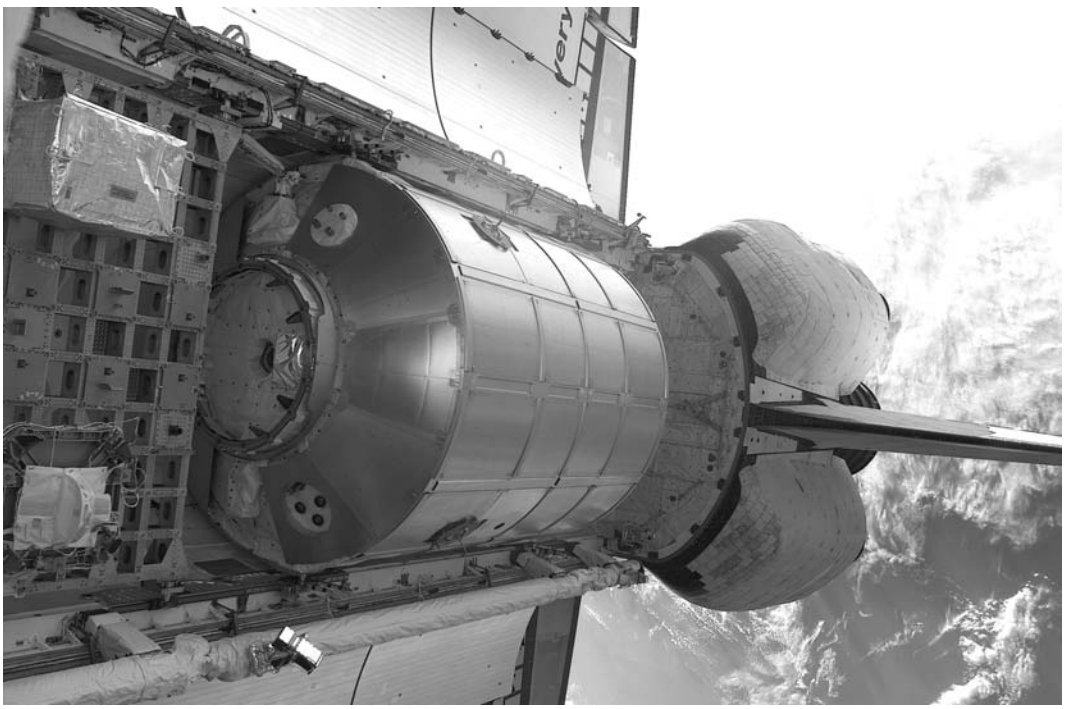

Fig. 31. The *Leonardo Multi Purpose Logistics Module* rests in *Discovery's* payload bay in this view taken from the station by a crewmember using a digital still camera. (*NASA*.)

Fig. 32. Astronaut Chris A. Hadfield, STS-100 mission specialist representing the Canadian Space Agency (CSA), stands on one Canadian-built robot arm to work with another one. Called *Canadarm2*, the newest addition to the *International Space Station* (ISS) was ferried up to the orbital outpost by the STS-100 crew. Hadfield's feet are secured on a special foot restraint attached to the end of the Remote Manipulator System (RMS) arm, which represents one of the standard shuttle components for the majority of the 100-plus STS missions thus far. The picture was recorded with a digital still camera. (*NASA*.)

- *Mobile Base System*: A work platform that moves along rails covering the length of the space station, the *Mobile Base System*, or MBS, will provide lateral mobility for the Canadarm as it traverses the main trusses. The *Mobile Base System* is scheduled for ISS Mission UF-2 (STS-111) April 2002.
- *Special Purpose Dexterous Manipulator*: The Special Purpose Dexterous Manipulator, or Canada Hand, is a smaller two-armed robot capable of handling the delicate assembly tasks currently handled by astronauts during space walks. The *Special Purpose Dexterous Manipulator* is scheduled for ISS Mission UF-4, May 2005.

Joint Airlock: The space shuttle Atlantis delivered the *Joint Airlock* to the *International Space Station* on the STS-104 Mission July 12, 2001, giving station crewmembers the ability to conduct spacewalks using either U.S. or Russian suits. The airlock also will vent less precious air into space than the shuttle airlock.

The airlock is a critical space station element because of design differences between American and Russian spacesuits. American suits will not fit through Russian-designed airlocks. During a series of integration tests, the Russian suits were connected to the airlock to assure that they worked together. The airlock is specially designed to accommodate both suits, providing a chamber where astronauts from every nation can suit up for spacewalks to conduct science experiments and perform maintenance outside the station. See Fig. 33.

The airlock serves two key purposes: to keep air from escaping when the hatch to space is opened and to regulate the air pressure before an

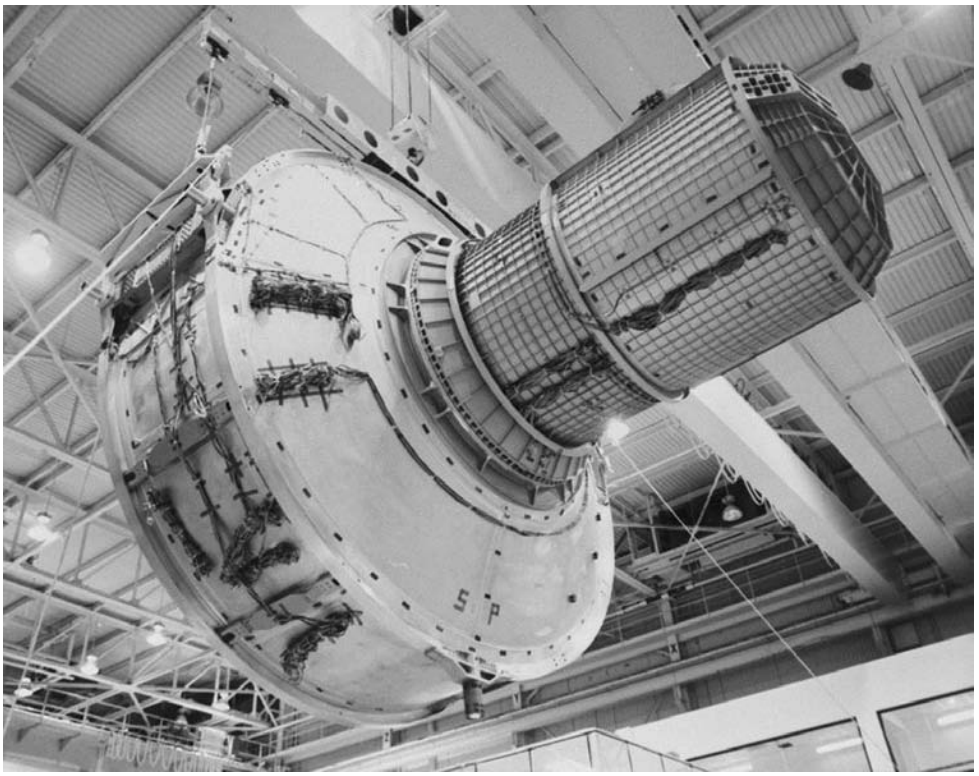

Fig. 33. The airlock for the *International Space Station* is lifted by crane in the fall of 1997, during manufacturing in the Space Station Manufacturing Building at the Marshall Space Flight Center in Huntsville, AL. The airlock includes two sections: the larger "equipment lock" on the left that will store spacesuits and associated gear and the narrower "crewlock" on the right from which astronauts will exit into space. (*NASA*.)

astronaut enters or leaves the ISS. It has two compartments: the crew lock, from which astronauts will enter and leave the station; and the equipment lock, where the spacewalkers will change into and out of their suits and stow all necessary gear.

Built at a cost of $164 million (including associated tanks) the airlock was designed and built by Boeing at NASA's Marshall Space Flight Center (MSFC) in Huntsville, AL. The Airlock is constructed of aluminum and weighs 6,064 kilograms (13,368 pounds). The overall length is 5.5 meters (18 feet) and 4 meters (13 feet) in diameter with a volume of 34 cubic meters (1,200 cubic feet). Boeing-MSFC manufactured the equipment lock pressure shell, mated the equipment lock with the crew lock, installed all subsystems, and successfully performed airlock qualification testing.

Japanese Experiment Module **(Kibo):** Japan is obliged to develop an experiment module called *Kibo*. *Kibo* is the first manned facility of Japan in which a maximum of four astronauts can perform experimental activities for a long duration of time. Kibo consists of four components. Two experimental facilities, the *Pressurized Module* and *Exposed Facility*, logistics modules attached to each of them and, a Manipulator to be used for experiments or for ORU changeout tasks.

Pressurized Module (PM) is a facility where astronauts conduct experiments or control the total JEM facility. Inside PM, the air composition and pressure are kept the same as on Earth, and temperature and humidity are controlled so as to be comfortable for astronauts' activity all the time. Therefore, astronauts can work in the PM in a shirt-sleeve environment as we do on the ground. See Fig. 34.

Devices on board PM can be categorized into two types, system devices, which are vital to maintain the JEM facility itself, and experiment devices.

System devices are required to maintain JEM's function or affect astronauts' activities. Power supply, communications, air conditioning, device cooling water control or devices with space experiment support functions are included. Also, the manipulator console used to exchange devices on the Exposed Facility, intersatellite communication equipment, or airlock through which devices can be exchanged between the EF and PM are very important, as such, if any of them were to be lost, the operation of JEM will face a serious situation.

Experiment devices are dedicated to conducting experiments invited from the public. They can perform their functions only in cooperation with the System Devices stated above. The PM contains a total of ten experiment racks equipped with mainly biological and material experiment functions. Researchers will attempt new material development or will try to solve scientific problems.

Experiment Logistics Module Pressurized Section (ELM-PS): When the *Experiment Logistics Module Pressurized Section* (ELM-PS) is launched for the first time, it will be used as a container to carry experiment racks and system racks. Once on orbit, it will be mainly used as a storage facility. System devices, tools to be used for maintenance of experiment devices, materials for experiments or spare items for trouble are stored inside the ELM-PS. The ELM-PS volume is less than that of the PM. See Fig. 35.

Although ELM-PS has not received much attention among the JEM components, it is going to be the first manned spacecraft of Japan. JEM will be launched by three separate Space Shuttle missions, and the ELM-PS will be the first of JEM's components to be launched to orbit.

When JEM assembly is completed on orbit, ELM-PS will be attached to the top of the PM. However, since it will be launched prior to the PM, it will first be attached to a US module with a common berthing mechanism. When PM arrives on orbit, the ELM-PS will be moved to its normal position. The ELM-PS will thus be the one most awaiting the arrival of PM.

Exposed Facility (EF): The *Exposed Facility* is a multipurpose experiment space where various activities such as scientific experiments, Earth observation, communication experiments, scientific and engineering experiments or material experiments can be conducted by utilizing environment which is exposed to space characterized with microgravity, high level vacuum and vast area.

On ISS, JEM and the Truss are the only facilities that allow experiments those being exposed to space environment, which many researchers are interested in.

EF will be utilized not only for activities peculiar to Japan, but will be utilized also as a facility for international cooperation.

As stated above, JEM EF is expected to contribute to the evolution of science and technology toward next generation, and also to maintain and to promote world wide cooperation.

Fig. 34. The (*Kibo) Pressurized Module* (PM) during assembly. (*NASA*.)

Fig. 35. The (*Kibo*) Experiment Logistics Module Pressurized Section (ELM-PS) during assembly. (*NASA*.)

The EF with its size of 6-meter × 5-meter × 4-meter (20-feet × 16.7-feet × 13.3-feet) weighs approximately 4,000 kilograms (8,890 pounds) at time of launch. Experiment payloads of EF can be exchanged, which allows various experiments to be conducted. The EF will be operated for ten years on orbit supporting exposed experiments. It will supply electric power, circulates coolant for cooling the experiment devices or collects experiment data.

The standard payload envelope is assumed to be of 1.85-meter × 1-meter × 0.8-meter (6.2-feet × 3.3-feet × 2.7-feet) and weighs 500 kilograms (1,110 pounds).

Remote Manipulator System: The Remote Manipulator System (JEM-RMS) serves as an arm to support experiments conducted on the Exposed Facility. The main arm handles large items, for delicate tasks, the small fine arm can attached at the end of the main arm. The main arm is equipped with a TV camera, which allows astronauts to monitor the operation from inside the pressurized module.

Express Pallet: EXPRESS is the acronym for EXpedite The PRocessing of Experiments to Space Station. The EXPRESS program consists of two separate systems: the EXPRESS rack for pressurized payloads and the EXPRESS pallet for attached payloads. See Fig. 36.

The EXPRESS pallet for attached payloads is provided by Brazil as a participant through a bilateral arrangement with the United States and the Brazilian Space Agency, which is also known as AEB.

Attached Payloads are located outside of the pressurized volume of the Space Station on the truss or the Japanese *Experiment Module Exposed Facility* (JEM EF). The EXPRESS Pallet can be located at any site on the truss segment. The EXPRESS Pallet has six robotically replaceable adapters for payloads or payload complements.

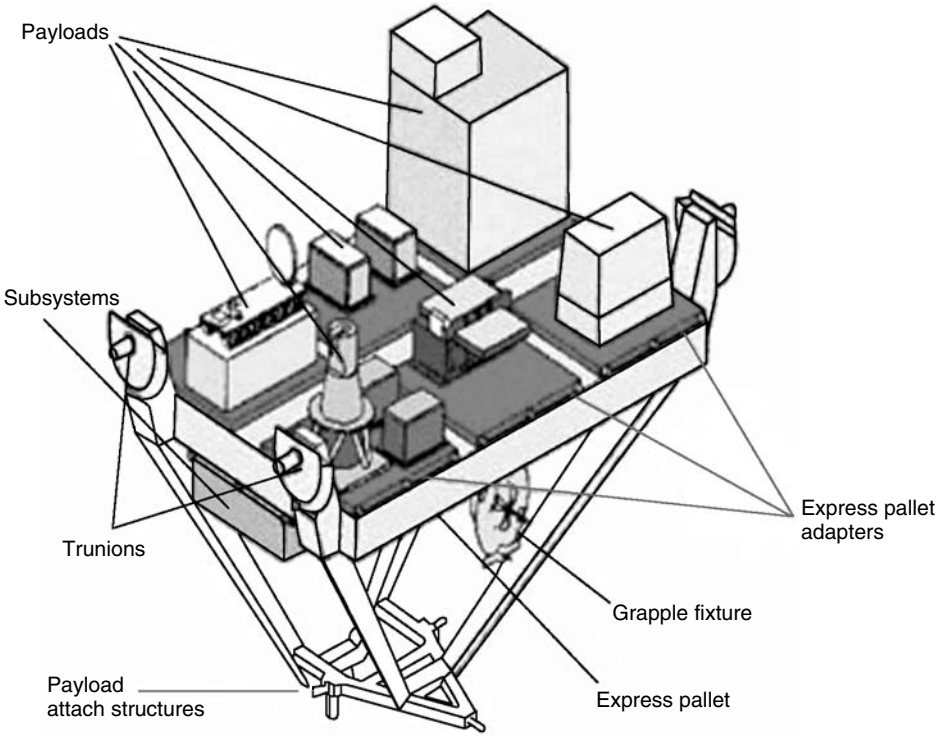

Fig. 36. Example of an EXPRESS pallet with payloads. (*NASA*.)

Attached payloads may use the Station power, command and data handling system and video. The crew will interface using robotics for installation and removal of the attached payloads, with no nominal EVA operations anticipated.

Columbus Laboratory: The *Columbus* Laboratory is a pressurized, habitable module, which will be attached to *Node 2* of the Station. The *Columbus* Laboratory's structure is derived from the Italian *Mini-Pressurised Logistics Module* (MPLM).

The internal facilities of the Columbus Laboratory consist of the Microgravity Facilities for *Columbus* (MFC) and the European Drawer Rack. The Microgravity Facilities for Columbus cover the development of five multi-user laboratories in the fields of Biology, Human Physiology, Materials and Fluid Science.

It is the goal of the MFC program to maintain the four disciplines constantly present and generating scientific data throughout the lifetime of the station. This will provide European and international scientists with a wide envelope of research opportunities offered from the unique vantage point of a world class facility in space.

The first phase of the MFC program covers the initial period between 1997 and 2003. It involves the design and development of the following facilities:

- Biolab.
- Fluid Science Laboratory (FSL).
- European Physiology Modules (EPM's).
- Material Science Laboratory (MSL).

During this phase, experiment specific hardware (e.g., experiment containers for fluid science and biology, cartridges for material science) will be developed to support the multi-user facilities. This phase will also see the development of second generation modules and facilities (different furnaces, a bioreactor, new physiology equipment, upgraded diagnostics) designed to enhance the capabilities of the current laboratories and provide research opportunities for the widest possible range of European researchers.

These multi-user facilities will be modular in design to allow for upgrading, easy refurbishment and repair. They will also feature advanced telescience capabilities designed to alleviate crew involvement and facilitate user access. Facility Operations will be handled through dedicated Facility Responsible Centres (FRC's); User Home Bases (UHB's), located at universities and research centers, will be the direct link between the user and the space laboratory.

The facilities are presently in the last stages of their Definition and Preliminary Design phase (Phase B), or early into their Design and Development phase (Phase C/D), with the exception of the EPMs, which is currently undergoing its Preliminary Analysis phase (phase A). Each facility is supported by a dedicated science team, which is following its development and advises the Agency on its best scientific use. Scientists are actively participating in the project reviews in order to assure that ESA receives proper feedback and attends to their needs as future users.

The *Columbus* Laboratory is scheduled for launch in April 2004.

X-38: Crew Return Vehicles: With technologies that blaze a trail for future human spacecraft, NASA's X-38 project is developing, at an unprecedented low cost, a prototype rescue vehicle that could provide astronauts on the *International Space Station* an immediate return home in an emergency.

The X-38 couples a proven shape, taken largely from Air Force's X-24A project from the 1970s, with dozens of new technologies — the world's largest parafoil parachute; the first all-electric spacecraft controls; flight software developed in a quarter of the time required for past spacecraft; laser-initiated explosive mechanisms for deploying parachutes; and global positioning system-based navigation.

An innovative combination of a shape first tested in the 1970s and today's latest aerospace technology, the X-38 already is flying in the actual conditions in which it must perform. Since 1997, increasingly complex, unpiloted atmospheric test flights of the X-38 have been under way at the Dryden Flight Research Center in California. An unpiloted X-38 space test vehicle, now under construction at the Johnson Space Center in Houston, Texas, will fly aboard the space shuttle in 2003 and descend to a landing independently. The X-38 is designed to fit the unique needs of a space station "lifeboat" — long-term, maintenance-free reliability that is always in "turnkey" condition, ready to provide the crew a quick, safe trip home under any circumstance. See Fig. 37.

In addition to contributions from companies and NASA centers coast-to-coast, international space agencies are participating with the United States in the X-38's development. Contributions to the X-38 are being made by Germany, Belgium, Italy, Netherlands, France, Spain, Sweden and Switzerland and 22 companies throughout Europe.

For more information on the X-38 see http://spaceflight.nasa.gov/spacenews/factsheets/pdfs/fs_x-38.pdf.

Fig. 37. The first atmospheric test vehicle for the X-38 prototype International Space Station crew return vehicle goes through a "captive carry" flight test in fall 1997 under the wing of a B-52 aircraft at NASA's Dryden Flight Research Center, California. (*NASA*.)

Research on the *International Space Station*

The *International Space Station* will establish an unprecedented state-of-the-art laboratory complex in orbit, more than four times the size and with almost 60 times the electrical power for experiments, critical for research capability, of Russia's *Mir*. Research in the station's six laboratories will lead to discoveries in medicine, materials and fundamental science that will benefit people all over the world. Through its research and technology, the station also will serve as an indispensable step in preparation for future human space exploration. Examples of the types of U.S. research that will be performed aboard the station include:

- **Protein crystal studies:** More pure protein crystals may be grown in space than on Earth. Analysis of these crystals helps scientists better understand the nature of proteins, enzymes and viruses, perhaps leading to the development of new drugs and a better understanding of the fundamental building blocks of life. Similar experiments have been conducted on the Space Shuttle, although they are limited by the short duration of Shuttle flights. This type of research could lead to the study of possible treatments for cancer, diabetes, emphysema and immune system disorders, among other research.
- **Tissue culture:** Living cells can be grown in a laboratory environment in space where they are not distorted by gravity. NASA already has developed a Bioreactor device that is used on Earth to simulate, for such cultures, the effect of reduced gravity. Still, these devices are limited by gravity. Growing cultures for long periods aboard the station will further advance this research. Such cultures can be used to test new treatments for cancer without risking harm to patients, among other uses.
- **Life in low gravity:** The effects of long-term exposure to reduced gravity on humans weakening muscles; changes in how the heart, arteries and veins work; and the loss of bone density, among others, will be studied aboard the station. Studies of these effects may lead to a better understanding of the body's systems and similar ailments on Earth. A thorough understanding of such effects and possible methods of counteracting them is needed to prepare for future long-term human exploration of the solar system. In addition, studies of the gravitational effects on plants, animals and the function of living cells will be conducted aboard the station. A centrifuge, located in the *Centrifuge Accommodation Module*, will use centrifugal force to generate simulated gravity ranging from almost zero to twice that of Earth. This facility will imitate Earth's gravity for comparison purposes; eliminate variables in experiments; and simulate the gravity on the Moon or Mars for experiments that can provide information useful for future space travels.
- **Flames, fluids and metal in space:** Fluids, flames, molten metal and other materials will be the subject of basic research on the station. Even flames burn differently without gravity. Reduced gravity reduces convection currents, the currents that cause warm air or fluid to rise and cool air or fluid to sink on Earth. This absence of convection alters the flame shape in orbit and allows studies of the combustion process that are impossible on Earth, a research field called *Combustion Science*. The absence of convection allows molten metals or other materials to be mixed more thoroughly in orbit than on Earth. Scientists plan to study this field, called *Materials Science*, to create better metal alloys and more perfect materials for applications such as computer chips. The study of all of these areas may lead to developments that can enhance many industries on Earth.
- **The nature of space:** Some experiments aboard the station will take place on the exterior of the station modules. Such exterior experiments can study the space environment and how long-term exposure to space, the vacuum and the debris, affects materials. This research can provide future spacecraft designers and scientists a better understanding of the nature of space and enhance spacecraft design. Some experiments will study the basic forces of nature, a field called Fundamental Physics, where experiments take advantage of weightlessness to study forces that are weak and difficult to study when subject to gravity on Earth. Experiments in this field may help explain how the universe developed. Investigations that use lasers to cool atoms to near absolute zero may help us understand gravity itself. In addition to investigating basic questions about nature, this research could lead to down-to-Earth developments that may include clocks a thousand times more accurate than today's atomic clocks; better weather forecasting; and stronger materials.
- **Watching the Earth:** Observations of the Earth from orbit help the study of large-scale, long-term changes in the environment. Studies in this field can increase understanding of the forests, oceans and mountains. The effects of volcanoes, ancient meteorite impacts, hurricanes and typhoons can be studied. In addition, changes to the Earth that are caused by the human race can be observed. The effects of air pollution, such as smog over cities; of deforestation, the cutting and burning of forests; and of water pollution, such as oil spills, are visible from space and can be captured in images that provide a global perspective unavailable from the ground.
- **Commercialization:** As part of the Commercialization of space research on the station, industries will participate in research by conducting experiments and studies aimed at developing new products and services. The results may benefit those on Earth not only by providing innovative

new products as a result, but also by creating new jobs to make the products.

Editor's Note: The staff of this encyclopedia is most appreciative of the cooperation extended by National Aeronautics and Space Administration (NASA) for furnishing information for numerous portions of this article.

SPACE TECHNOLOGY 5 (ST5) MISSION. The Space Technology 5 mission launched March 22, 2006, from Vandenberg Air Force Base, CA. and ended in 90 days as planned on June 20, 2006. ST5 focused on the design, development, integration and operation of three full service 25-kilogram-class (55 pound) spacecraft that implemented multiple new technologies, functioned as a single constellation, and achieved accurate research-quality scientific measurements.

At Goddard Space Flight Center (GSFC), the ST5 Project advanced the technology of miniaturizing smart and powerful electronic gadgets by building and testing three small satellites, also known as micro-sats. Development of these satellites tested and validated new technologies and manufacturing techniques. In addition, the mission contributed to scientists' understanding of the harsh environment of Earth's magnetosphere.

The ST5 Project is part of the New Millennium Program (NMP). NMP was created to identify, develop, build, and test innovative technologies and concepts for infusion into future missions. To select which capabilities will be needed, NMP is guided by NASA's Earth and Space Science "roadmaps." These roadmaps lay out the path of future scientific enquiry. They serve not only as a vital guide for NMP's selection of technologies, but are used to conceive and design the Program's test missions as well. See also **New Millennium Program (NMP)**.

At GSFC, miniaturized redundant components and technologies were integrated into each of the micro-sats. Each micro-sat weighed approximately 25 kilograms (55 pounds) when fully fueled and resembled a very large birthday cake at 53 centimeters (20.7 inches) across and 48 centimeters (18.7 inches) high. See Fig. 1. The ST5 Project also built the spacecraft bus that enabled the mission's multiple micro-sats to be launched from a Pegasus XL rocket and spun into a near-Earth polar orbit of approximately 4,500 kilometers (2,796 miles) altitude.

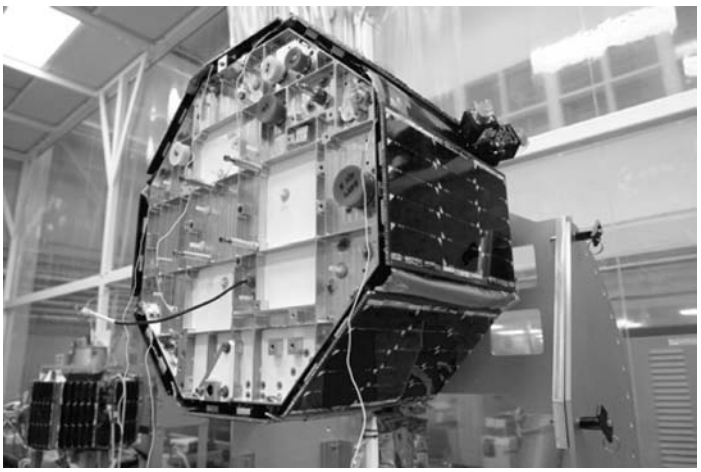

Fig. 1. A view of a microsatellite in the clean room at the Goddard Space Flight Center. (*Image courtesy of NASA*.)

Although smaller than any of their previous counterparts, each of these satellites is considered "full service," meaning it carries guidance, navigation and control, attitude control, propulsion, and high bandwidth and complex communication functions. In addition, each ST5 micro-sat validated NMP selected technologies, such as the Cold Gas Micro-Thruster (CGMT), X-Band Transponder Communication System, Variable Emittance Coatings for Thermal Control, and CMOS Ultra-Low Power Radiation Tolerant (CULPRiT) Logic.

Another value-added feature as a result of their miniaturize size and reduced weight is the ability to launch multiple micro-sats from one low-cost Pegasus XL rocket. The ST5 Project designed, fabricated, and tested a new innovative Pegasus launch rack that supports three micro-sats in a "stacked" configuration. This multi-rack design allowed each micro-sat to be individually deployed in a spinning motion. See Figs. 2 and 3.

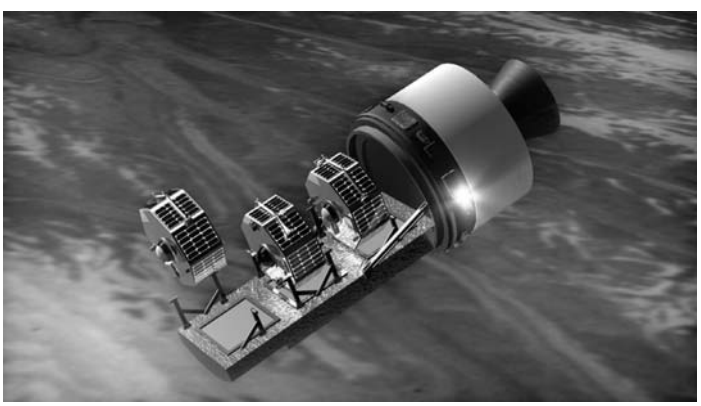

Fig. 2. An artist's rendering of the microsatellites being released — 'like frisbees' in NASA's words — from the Pegasus rocket. The rocket is initially launched from an L-1011 jet within the Earth's atmosphere. (*Image courtesy of NASA*).

After deployment, the micro-sats were positioned in a "string of pearls" constellation that demonstrated the ability to position the micro-sats to perform simultaneous multi-point measurements of Earth's magnetic field using highly sensitive magnetometers. Using data collected from the ST5 constellation, scientists can begin to understand and map the intensity and direction of the magnetic field, its relation to space weather events, and the affects on our planet.

Fig. 3. Interior view of the Pegasus XL launch rack. (*Image courtesy of NASA.*)

With the help of pathfinder missions such as ST5, NASA hopes to improve scientists' ability to accurately forecast space weather and thereby minimize its harmful effects on space and ground based systems.

Small, inexpensive, yet highly capable micro-sats such as these are instrumental in the validation of new miniaturized components that will help pave the way for flying tens to hundreds of micro-sats in future missions.

Mission Concept

The goal of the Space Technology 5 (ST5) mission was to reduce the weight, size, and cost of space missions while increasing their technical capabilities and concepts. The mission was managed out of Goddard Space Flight Center.

ST5's micro-sats flew within the magnetosphere that surrounds our planet like a shield. While testing its "small size" concept and multiple technologies, ST5 mapped the intensity and direction of the magnetic fields within the inner magnetosphere closest to Earth. Collected data has been returned to scientists on the ground for analysis. ST5 will certify the suitability of these small, densely packed satellites as platforms for making scientific measurements.

Flying clusters of multiple satellites reduces the risk of an entire mission failing if one system or instrument fails. Additionally, the ability to perform multiple measurements within the magnetosphere provides scientists a better understanding of changes occurring in this harsh environment. Future micro-sat or nanosat missions, with tens to a hundred spacecraft, must be capable of responding to changes in the charged particles and magnetic fields that sweep over them every few seconds to few minutes.

Results from this mission will aid scientists in NASA's Sun-Earth-Connection, http://sec.gsfc.nasa.gov/, field of research to plan future micro-sat or nanosat missions, such as the Magnetospheric Constellation mission. This "constellation" of hundreds of nanosats will explore the transport of the Sun's plasma and the processes that convert energy occurring within the "tail" of Earth's magnetosphere. Such exploration may enable scientists to construct a reliable method of predicting magnetospheric meteorology, "space weather."

Technology

Although small, the ST5 satellites were "full service," meaning they carried guidance, navigation and control, attitude control, propulsion, high bandwidth, and complex communication functions. Each performed some of the same functions as their larger counterparts. ST5's objective was to demonstrate and space-test the ability of "smart" satellites to identify scientific events and implement cooperative data-taking strategies.

The ST5 project also developed and built the spacecraft bus that enables the mission's multiple micro-sats to be launched from a single rocket and spun — like Frisbees — into an elliptical Sun synchronous orbit ranging from 300 kilometers (186 miles) to approximately 4,500 kilometers (2,796 miles) above Earth. See Fig. 2. The spinning motion was required to stabilize the spacecraft and allow for optimal use of sunlight by the solar array panels on the sides of the spacecraft.

Once deployed, magnetometers onboard each of these miniaturized satellites measured energetic particles in the magnetosphere. Returned data will help reveal ambient radiation levels and the spacecrafts' subsystem response to this hazard.

Each micro-sat was commanded individually from ground stations on Earth, except for a one-week period of "lights out." During this time, the micro-sats flew "autonomously" with pre-programmed commands in a test to find out whether ground commanding (for 24 hours) is really necessary.

ST5's "maiden voyage" paved the way for flying tens to hundreds of such miniature craft in future missions. These missions can be flown only if they are capable of responding to the changes in the charged particles and magnetic fields in the harsh environment of Earth's magnetosphere.

Enabling Technologies

Space Technology 5 tested multiple technologies to support the success of future micro-sat missions. Each technology represents a breakthrough in performance, capability, or application in a new and unique manner. See Fig. 4.

Goddard Mission Services Evolution Center (GMSEC). The Goddard Space Flight Center (GSFC) Mission Services Evolution Center (GMSEC) mission is an integrated effort across multiple GSFC organizations to provide GSFC mission services through the year 2010. GMSEC provides mission enabling, cost and risk reducing data system solutions applicable to current and future missions managed by GSFC. GMSEC will enable the continued recognition of GSFC as a leader in space mission expertise and services.

Communications Components for Small Spacecraft. Each Space Technology 5 smallsat x-band transponder is approximately the size of an inkjet printer cartridge ($2'' \times 2'' \times 3''$) and weigh less than 300 grams (just over 10 ounces). This is nine times smaller and twelve times lighter than previous communications systems. And, each transponder requires only one-fourth the voltage and half as much power as its predecessors. (Fig. 5).

These transponders will communicate directly with ground stations on Earth with 750 kilobit-per-second capability, a key enabler of future miniature satellite missions. This revolutionary space communication system was developed by leveraging commercial technology from cell phones, very small aperture terminals, and direct broadcast satellite television. This transponder is a step towards the next generation of miniature satellite applications and is critical to the success of future smallsat or nanosat missions.

The X-Band Transponder Communications System was activated at spacecraft turn-on and operated well within their specification.

Evolved Antenna. Among the new technologies to be tested aboard the ST5 spacecraft is an antenna that was designed by a computer running a simulation of Darwinian evolution. This evolved antenna was discovered by an evolutionary algorithm running for days on a supercomputer. Its unusual shape is expected because most human antenna designers would never think of such a design. See Fig. 6. However, this design works very well in meeting the mission requirements. In addition, this particular design was rapidly evolved after the orbit changed from the original orbit. Each ST5 spacecraft had one evolved antenna installed and all operated well within specification.

Lithium-Ion Power System for Small Satellites. Batteries powering satellites or spacecraft must be rugged enough to withstand the severe

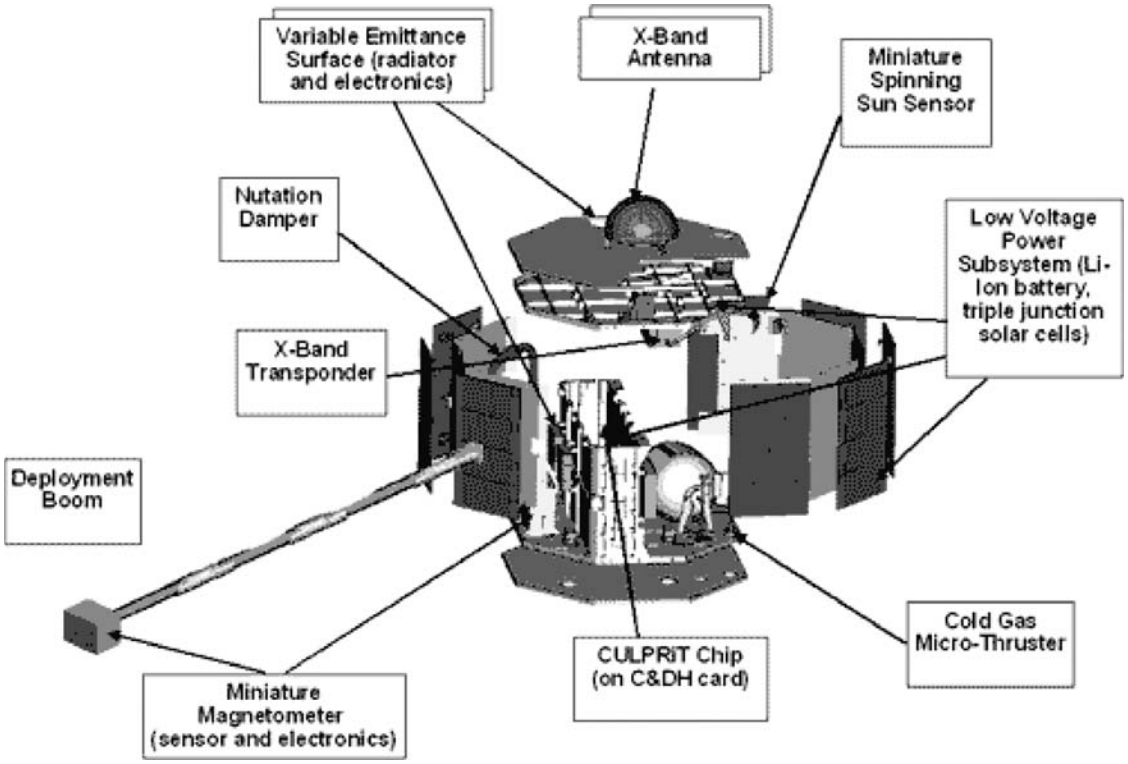

Fig. 4. ST5 micro-sat components. (*Image courtesy of NASA*.)

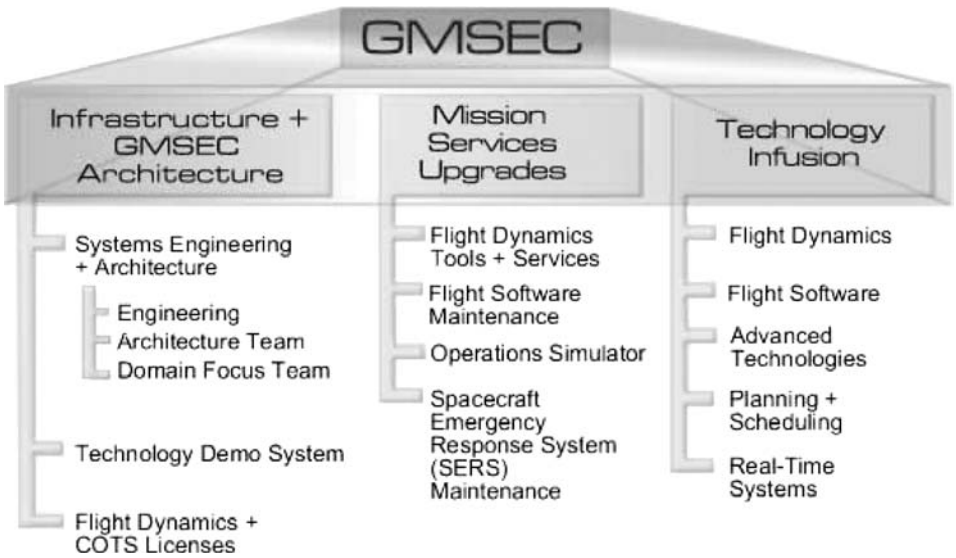

Fig. 5. Automation components within the ground system.

vibrations of launch. Once the craft is deployed, these batteries must operate in extreme conditions of heat and cold and solar radiation. And, they need to work in a vacuum without leaking or exploding. There are many types of batteries: carbon–zinc, lead–acid, nickel–cadmium, nickel–hydrogen, silver zinc, alkaline, and lithium-ion to name a few.

Most batteries currently used in space flight are nickel-cadmium. Also called NI-Cad, these batteries are charged by solar cells that convert the Sun's energy to electricity. But Ni-Cad batteries eventually wear out and are not rechargeable. Space Technology 5's small-sats will use Lithion-ion, or Li-ion, batteries, which use chemicals to store energy. And each cell of a Li-ion battery is equipped with a control circuit to limit the voltage peaks during charge and to prevent the voltage from dropping too low on discharge. This control circuit also limits the maximum charge and discharge current.

Ultra Low-Power Demonstration. The CULPRiT is a new type of microelectronic device that allows circuits to operate at 0.5 Volts. The technology will greatly reduce power consumption while achieving a radiation tolerance of ∼100 kRad total dose and latch-up immunity. The CULPRiT was activated on all three spacecraft and operated without a flaw.

Variable Emittance Coatings for Thermal Control. The Variable Emittance Coatings, provided by Sensortex, Inc. and the Applied Physics Laboratory (APL), are used for thermal control and consist of an electrically

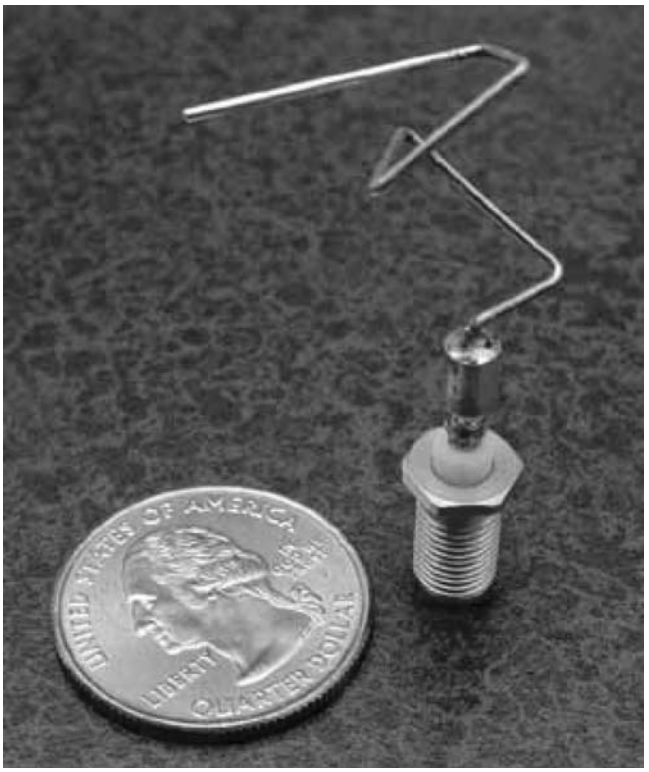

Fig. 6. Evolved Antenna. (*Image courtesy of NASA*).

tunable coating that can change properties, from absorbing heat when cool to reflecting or emitting heat when in the Sun. The Microelectromechanical System (MEMS) chip is part of this technology. This system operated within specification.

Propulsion Systems Components. A miniature microthruster that provides fine attitude adjustments on the spacecraft. The Cold Gas Microthruster (CGMT) is a tiny electromechanical system designed by Marotta Scientific Controls, Inc. to provide fine attitude adjustments on each of the micro-sats. It uses 1/8th the power and weighs only half as much as attitude control systems being used in other missions. The Cold Gas Microthruster successfully maneuvered all three spacecraft, including both attitude and orbit maneuvers.

Other technologies on ST5 include: Miniature magnetometer (All three magnetometers operated well); Miniature spinning sun sensor (Operated well); Spacecraft deployment mechanism (Deployments were flawless); Magnetometer deployment boom (Deployments were nominal); Nutation damper (Performed within their specification).

Challenges

Space Technology 5 (ST5) was a formidable technological challenge. The major consideration was size, a fundamental problem in space flight. Using the Space Shuttle as an example, the cost to deploy a payload into low-Earth orbit is about $13,200 per kilogram ($6,000 per pound). As a result, engineers try to design spacecraft and satellites to be as small as possible. Even so, most satellites with science payloads weigh in excess of 1,000 kilograms (2,200 pounds). Before ST5, the smallest "full-service" microsat weighed 100 kilograms (220 pounds). Nanosats are even smaller — in the sub-20 kilograms (38 pounds) range.

These small craft are nothing new. Russia's Sputnik, the first satellite launched into space, weighed only about 90 kilograms (180 pounds). However, Sputnik was and other small satellites are, even decades later, very limited in their capabilities. Typically they lack any propulsion, possess only limited ability for attitude control, and carry one single-function payload.

Besides size, an additional problem is that almost all space missions are flown with a single craft. This is because controlling spacecraft or satellites in flight is very complicated. Imagine the complexity of flying several satellites as one system. The ground-to-multiple-satellite communications path is more complex than when dealing with a single satellite.

Small, inexpensive, yet highly capable satellites are needed to discover, characterize (describe and measure), and monitor the effects of solar variability throughout near-Earth space. They are needed to help scientists gain a better understanding of the physical processes that cause magnetospheric storms and substorms. In order to increase our knowledge of these processes, we need to obtain simultaneous particles and fields measurements in a range of ~5,000 to 15,000 kilometers (just over 3,100 to 9,320 miles) over the mid-plane of the magnetotail between geosynchronous orbit and the orbit of the moon. These simultaneous-measurement requirements can be met only through the deployment of 60 to 100 small, 10-kilogram-(just over 22 pounds) each spacecraft carrying magnetic-fields, plasmas, and energetic-particles instruments.

We also need to characterize space weather, such as the intensity of the Earth's radiation belts. Space weather would be most efficiently tracked over the solar cycle by periodically deploying one or two small satellites carrying particles and fields instruments.

ST5 reduced satellite size while increasing their capabilities. Additionally, the technologies validated by ST5 contribute to the development and eventual deployment of small satellites by NASA and other governmental and commercial organizations.

NANCY J. LEON, Jet Propulsion Laboratory, Pasadena, CA

SPACE TECHNOLOGY 6 (ST6) MISSION. Since the dawn of the space age, unmanned spacecraft have flown *blind*, with little or no ability to make decisions without humans continuously directing them. Many of these missions are guided and controlled by ground crews — from a long distance away — using delayed commands. The spacecraft are not able to react quickly to these long distance, delayed commands. All this will change in the near future.

Some of these changes will be made by the New Millennium Program's (NMP) Space Technology 6 (ST6) Project. ST6 has developed two advanced, experimental technologies for use on spacecraft of the future. See also **New Millennium Program (NMP)**. These technologies, the Autonomous Sciencecraft Experiment and the Inertial Stellar Compass, will improve a spacecraft's ability to: make intelligent decisions on what information to gather and what to send back to the ground; determine its own attitude and adjust its pointing (where it is aimed)

All without help from humans!

The common goal of the two technologies is to free the spacecraft from its continuous link with the ground and shift the decision making to the spacecraft itself. With their many "firsts," each technology is flight tested in the harsh environment beyond Earth to validate performance prior to use on expensive, actual space exploration missions.

The Autonomous Sciencecraft Experiment, referred to here as Sciencecraft, allows a spacecraft to perform several tasks that have never been done before. Sciencecraft processes data onboard, sends data back to Earth that the craft decides are scientifically important, and chooses to make science observations that appear interesting — autonomously (all by itself). This technology involves feature and change detection, continuous planning technology, and robust execution. It is equipped with software that checks spacecraft performance and has resources to prevent errors.

Sciencecraft was beamed onboard the New Millennium Program's in-flight Earth Observer 1 early in 2004. Since that time, the Sciencecraft team has steadily increased the level of autonomy during the validation period, conducting numerous experiments with over 100 autonomously planned image data takes. Jet Propulsion Laboratory (JPL) is the technology provider. In addition to JPL, the Sciencecraft team includes Goddard Space Flight Center, the University of Arizona, Arizona State University, and Interface Control Systems.

The Inertial Stellar Compass, referred to here as Compass, enables a spacecraft to continuously determine its attitude or the direction in which it is pointing. It also enables a spacecraft to recover its orientation (direction and pointing) after a temporary malfunction or power loss. This is done by the "marriage" of a miniaturized star camera and gyro system. Although this is not a new concept, the small size and low power consumption are revolutionary and an important feature for the new, smaller spacecraft and satellites of the future.

Compass technology uses an active pixel sensor in a star-tracking camera and a three-axis system of microelectromechanical gyros. Draper Laboratory is the technology provider. Compass was successfully launched on the TacSat-2 satellite on December 16, 2006 from Wallops Flight Facility, Wallops, VA.

TacSat-2 is a joint project of the Air Force Research Laboratory (AFRL), the DoD Space Test Program, (Space and Missile Systems Center's Space Development and Test Wing), the Naval Research Laboratory, the Army Space Program Office, Air Force Space Command and the Space Warfare Center.

The technologies of ST6 will revolutionize future NASA spacecraft and allow mission resources to focus on science goals. They will reduce current human intervention in spaceflight missions of the 21^{st} century. Flying "blind" will be a thing of the past.

Autonomous Sciencecraft Experiment

NASA is successfully using onboard autonomous decision-making software, known as Autonomous Sciencecraft Experiment (ASE), to change a science satellite's priorities without the involvement — or even knowledge — of ground controllers so it can observe unexpected phenomena in its path such as an active volcano. Normally, an ongoing event such as an eruption might be missed because of the time required for the spacecraft to send its data to ground controllers, who have to process and study the data and then send commands back to the spacecraft to make further observations. On future interplanetary space missions, ASE software will enable onboard capture of short-lived science phenomena at the finest time-scales without overwhelming onboard memory or downlink capacities. Examples include: eruption of volcanoes on Io, formation of jets on comets, and phase transitions in ring systems. The approach can cut lengthy time lags inherent to taking an observation, transmitting it to the ground for study, and later decisions by scientists to direct the satellite to take further measurements.

In early 2004, Sciencecraft was beamed onboard the New Millennium Program's in-orbit Earth Observer 1 to begin validating its "feature and change detection," "planning," and "robust execution" capabilities. Since that time, the experiment team has been conducting numerous tests of the software's autonomy capabilities. See also **Earth Observing System (EOS)**. As of mid-2004, they have successfully triggered over 100 autonomously-planned image data takes and performed the first closed-loop execution where Sciencecraft autonomously analyzes science data onboard and triggers subsequent observations. See the technical paper "Using Autonomy Flight Software to Improve Science Return on Earth Observing One" for details; http://nmp.jpl.nasa.gov/st6/TECHNOLOGY/AIAA-12923-137.pdf.

Sciencecraft's image formation module transforms raw radar instrument data into synthetic aperture radar (SAR) images. See also **Synthetic Aperture Radar (SAR)**. The science algorithms (a procedure for solving a problem) module analyzes image data, generate science products from that data, and detect changes that have occurred since previous observations. Changes that are detected trigger new data collection. The onboard continuous planner replans activities. It also decides when to send the data back to Earth, based on science observations made during previous orbits. These capabilities:

- dramatically increase science observations with each downlink (signal that returns data) by determining the highest priority science data
- enable study of science events (volcanic eruptions and dust storms, etc.) that don't last very long
- reduce instrument inactivity due to anomalies (unexpected events) because the software includes a lot of checks of spacecraft performance and resources to prevent errors
- reduce instrument setup time by using autonomy software that uses execution information to streamline operations

Sciencecraft technology allows missions to focus more of their resources on science events. It enables radically different missions, equipped with significant decision-making capability, to take advantage of science opportunities and return only the most interesting science data. Successful demonstration of Sciencecraft's capabilities opens up tremendous new opportunities in planetary science, space physics, and Earth science. Such opportunities aren't available without this technology.

The proven Sciencecraft software was uploaded to the Mars Exploration Rovers, Spirit and Opportunity, to assist in collecting images of Martian dust devils passing in the vicinity of the rovers.

Using Sciencecraft technology, the highly autonomous spacecraft of future NASA missions will achieve significantly greater science returns. And, they will achieve these returns with reduced risk and cost.

Jet Propulsion Laboratory is the technology provider. In addition to JPL, the team includes the University of Arizona and Arizona State University.

Inertial Stellar Compass

The Inertial Stellar Compass, referred to here as Compass, is a real-time, miniature, inertial stellar attitude determination system. In simple terms, this is a system that periodically uses a star camera to tell the spacecraft where it is pointing and gyroscopes to continuously monitor the spacecraft's motion. The gyroscopes also inform the control system how to keep the spacecraft stable and pointed in the right direction, in case the camera is "blinded" by the Sun. Periodic updates from the star camera allow the continuous gyro information to be corrected for drift and bias. Such systems have been in use for awhile as individual devices, but never as a small, integral, low power package.

What is unique about Compass is that information from two miniaturized devices is integrated. Combining these two devices in a very low-mass and low-power unit — with enough performance — is revolutionary. These are important features for the new, smaller spacecraft and satellites of the future. When a gyro assembly and star camera are used together, the spacecraft has a more robust system to determine attitude accurately without the shortcomings of either device.

Compass technology uses an active pixel sensor in a wide-field-of-view miniature star camera — often referred to as a star tracker — and microelectromechanical system (MEMS) gyros. Together, they provide extremely accurate information for navigation and control.

Compass is built as two connected assemblies: the camera-gyro assembly (CGA) and the data processor assembly (DPA). The CGA is separated from but interconnected to the DPA. Compass will provide precision attitude determination for long-duration space science missions. A spacecraft using Compass technology will be able to continuously sense its position. It will also be able to recover its orientation after a temporary malfunction or power loss. Additionally, Compass technology reduces risk for large and medium size spacecraft and allows additional mass and power to be used for scientific payloads (instruments). Draper Laboratory is the technology provider of this experiment. Compass was successfully launched on the TacSat-2 microsatellite on December 16, 2006 from Wallops Flight Facility, Wallops, VA.

Benefits

The New Millennium Program's Space Technology 6 (ST6) project includes two innovative, experimental technologies to be validated in a space-borne laboratory — to reduce risk and cost to first-time users on an actual space exploration mission. Once these new technologies are successfully validated, they may offer significant science applications on future NASA space science missions.

The Autonomous Sciencecraft Experiment (Sciencecraft) technology will equip radically different future missions with significant onboard decision-making. Such capability will allow these missions to take advantage of novel science opportunities. For example, Sciencecraft may be used to capture science phenomena as they occur on Jupiter's moons, by tracking Europa's surface ice or monitoring Io's volcanoes. Sciencecraft could capture the flexing and cracking of Europa's ice crust or data on Io's volcanic eruptions or the formation of jets on comets.

This technology's science algorithms could be used to identify regions where change — new flooding, ice melt, or lava flows — have occurred. The algorithms determine where the science instrument should be aimed on the next orbit in order to identify and capture the full extent of a change. They also analyze planetary images to extract static (unchanging) features and detect changes in previous observations.

In addition to space applications, Sciencecraft's planning software would be useful in large factories or companies as a tool to better plan manufacturing activities. It also can be used for many everyday life products. One such commercial use is the investigation of patterns of credit card spending. This would enable quick discovery of fraudulent use.

The Inertial Stellar Compass (Compass) provides the capability of low-power, low-mass, and high-precision attitude determination for long duration space science missions. This includes the ability to recover spacecraft control (tumbling) or attitude after power loss. The ultra-low power and low mass of Compass are particularly beneficial for future nano-satellite missions, where low power and mass are critical to successful operations. When equipped with Compass technology, a small satellite will be able to carry an attitude determination system with high accuracy. The additional mass and power can then be used for scientific payloads (instruments). There are also many future uses for micro-gyroscopes in planetary surface rovers and terrestrial vehicles.

Additionally, these technologies may contribute to the development of commercial products. Since NASA was formed in 1958 the commercially significant technologies developed in the course of mission research have been shared with industry to solve engineering and manufacturing problems.

SPACE TECHNOLOGY 7 (ST7) MISSION. Ocean waves are created by large disturbances, such as storms or other atmospheric conditions. Similarly, disturbances in space cause gravitational waves. See also **Gravity Wave**. Scientists want to know more about these gravitational waves and their sources because they can us help us understand more about the cosmos. For, unlike electromagnetic light waves that eventually break up and scatter, scientists think that gravitational waves travel across the Universe undiminished. See also **Electromagnetic Light Waves**. Therefore, the signals they carry will give us important information about ancient cosmic events. To aid scientists in their quest to detect and measure gravitational waves, the Space Technology 7 project will flight test a Disturbance Reduction System (DRS) that will be flown on the LISA Pathfinder mission in late 2009 or 2010. LISA Pathfinder is a mission of the European Space Agency (ESA) http://sci.esa.int/science-e/www/area/index.cfm?fareaid=40. Space Technology 7 is a project of NASA's New Millennium Program. See also **New Millennium Program (NMP)**.

ST7's Disturbance Reduction System incorporates enhanced thruster technology, which works with enhanced sensor technology provided by ESA. Together, these technologies will demonstrate precision spacecraft control, validating position-measurement of objects in weightlessness with 100 times greater accuracy than ever before. In fact, during the ST7 test flight, the DRS is expected to achieve close to the ultimate in weightlessness.

ST7's validated DRS will contribute to the success of future missions — formation-flying interferometer missions that require precise spacecraft-position control and missions to measure gravitational forces. One such mission is the joint ESA and NASA Laser Interferometer Space Antenna (LISA), http://lisa.nasa.gov/.

LISA will detect and measure passing gravitational waves and map the curvature of space-time. This curvature, an idea first proposed by Albert Einstein in 1915, is caused by the gravity of planetary bodies such as the Sun and Earth or by gravitational waves generated by the motions of supermassive objects such as extra-galactic (outside of our galaxy) black holes. As part of LISA, ST7's DRS technology will "ride" the gravitational waves, and enable scientists to conduct tests of Einstein's Theory of General Relativity. See also **Laser Interferometer Space Antenna (LISA)**; and **Space Science Missions: Universe**.

Jet Propulsion Laboratory's Astronomy and Physics Directorate manages ST7's technology development, in partnership with Goddard Space Flight Center, and the Busek Company, Incorporated, http://www.busek.com/. The DRS will help create the ultimate still and quiet environment for science measurements. ST7's refined technology may lead to a whole new understanding of planetary and cosmic gravitational forces.

Technology

Space Technology 7's (ST7) Disturbance Reduction System (DRS) consists of clusters of micronewton thrusters and control software residing on a dedicated computer.

The micronewton thrusters, along with the spacecraft electrical interface and other electronics, sit outside of and around the thermal-shielded instrument box. The thrusters are mounted in clusters at two points on the host spacecraft perimeter. They will continuously and smoothly counteract both external and internal pressures on the test masses within the LTP and control the spacecraft position.

Both the European Space Agency's LTP Inertial Sensor and NASA's New Millennium Program ST7 thruster technologies are essential for DRS performance. The LTP test masses are used as reference for spacecraft-position control and as high-precision accelerometers to validate the performance characteristics of the microthrusters. The micronewton thrusters provide spacecraft-position control, keeping noise forces on the freely floating test masses small enough to meet acceleration-noise performance goals. These technologies:

- use freely falling masses to measure femtonewton forces in space (a newton is a unit of force that is equal to the weight of about 100 grams (four ounces). A femto equals 10^{-15}, a very minute part of a newton)
- demonstrate disturbance-free orbits
- demonstrate ultra-low accelerations in space

Once validated, these enhanced position measurement and control technologies will be applied to follow-on missions well into the 21st century. The capability of following a trajectory determined by purely gravitational forces will enable tests of general relativity, determination of planetary gravity fields, and detection of gravitational waves. The capability of controlling spacecraft position to a fraction of a wavelength of light will enable new types of separated-spacecraft interferometer missions.

Spacecraft Technology. Space Technology 7's (ST7) Disturbance Reduction System (DRS) will fly onboard the European Space Agency's (ESA) LISA Pathfinder, formerly called SMART-2, in late 2009 or 2010. The spacecraft will be launched in an Earth-escape trajectory and then delivered to its predetermined orbit by the propulsion module, which is supplied with power and driving signals by the spacecraft through an umbilical connection.

Following final orbit acquisition, the propulsion module will separate from the spacecraft. Once in its operational orbit, LISA Pathfinder will fly far above Earth's gravitational field in a low-radiation environment for one year. During this time the DRS will be operational for up to 90 days, during which time it will demonstrate disturbance reduction using ESA's LISA Technology Package Inertial Sensor.

Spacecraft pointing (direction and position) will be aided by startrackers, which identify star patterns in the sky. These modern-day instruments enable spacecraft and earth-orbiting satellites to navigate space much the same way ancient mariners navigated Earth's oceans, by using groups of stars as a reference point. The spacecraft will be powered by a solar array fixed to the body of the spacecraft. The solar array will be pointed to the sun using the data from the star tracker, or, in 'safe mode,' sun sensors mounted outside the craft. A sunshield will protect the DRS and LTP instruments. Commands and telemetry will be relayed through LISA Pathfinder's mission operations center.

LISA Pathfinder is a prelude to the Laser Interferometer Space Antenna (LISA) joint ESA and NASA mission (launch date indefinite). LISA will search for and make minute measurements of gravitational waves. Onboard LISA Pathfinder, DRS will demonstrate that a solid body can float freely in space completely undisturbed.

LISA Technology Package (LTP) Inertial Sensor. The LISA Technology Package (LTP) Inertial Sensor (IS) (Fig. 1), which is an ESA technology provided as part of its LISA Pathfinder mission, is interlocked with Space Technology 7's Disturbance Reduction System (DRS)

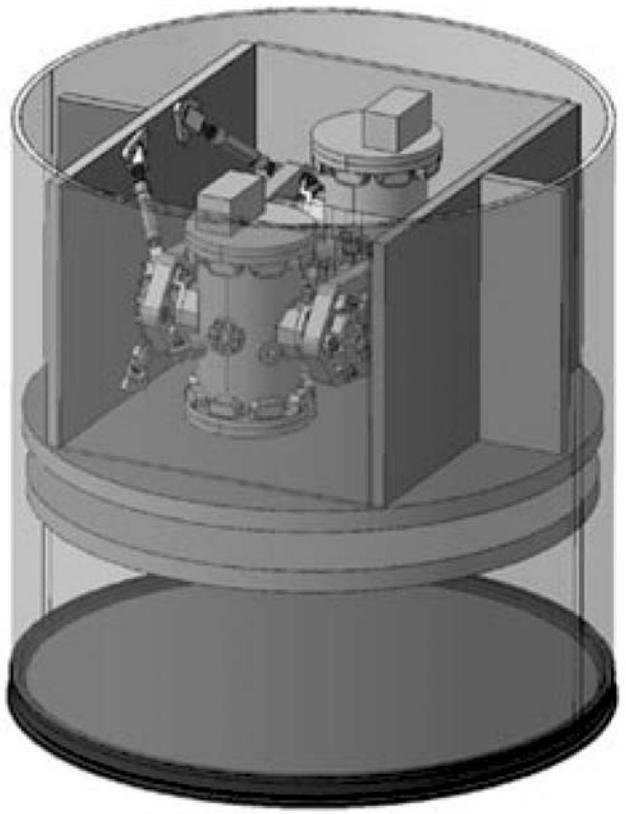

Fig. 1. European Space Agency's LISA Technology Package Inertial Sensor inside the Lisa Pathfinder spacecraft.

micronewton thrusters and software algorithm control system. See also http://sci.esa.int/science-e/www/object/index.cfm?fobjectid=35589.

Micronewton Thrusters. The Space Technology 7 Disturbance Reduction System (DRS) requires thrusters that are capable of varying thrust. They must smoothly and continuously counter all external disturbances, primarily solar pressure, with control authority over all six degrees of freedom (to move in all directions) of the spacecraft motion. DRS uses micronewton thrusters — a newly improved technology that has high-stability dual electrode thrusters, a high-stability propellant feed system, nanotube field emission, and high voltage converters. See Fig. 2.

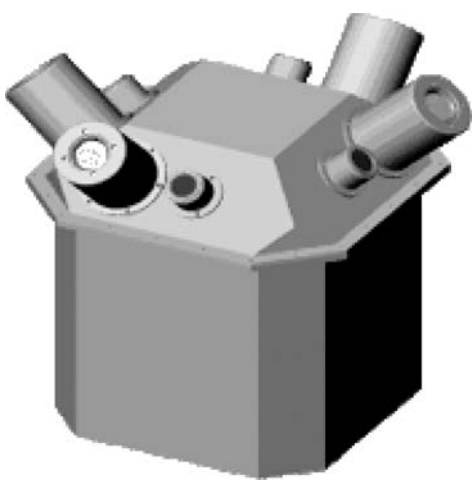

Fig. 2. Micronewton thrusters.

A newton is a unit of force, equal to the weight of about 100 grams (about four ounces). The thrusters produce a force of about 30 micronewton. Using these thrusters while DRS is in operation will enable scientists to measure a force change on the test masses of about one femtonewton, where femto equals 10^{-15}, during a ten minute measuring session.

The DRS micronewton thrusters consist of miniature ion engines. They are propelled by colloidal fluid that is fed through a needle by a pressurizing system. At the tip of the needle, a high electrical field is applied. This causes droplets to form and to be ejected from the tip of the needle. The droplets are spontaneously ionized and accelerated by high voltage, to generate variable thrust in the desired range.

Precise changes in thrust can be achieved by changes to the accelerating voltage. A cathode is included to emit electrons, which keeps the spacecraft neutral. This prevents the spacecraft from becoming negatively charged by the continual ejection of positively-charged droplets.

Eight colloidal thrusters are mounted in clusters at two points on the host spacecraft's perimeter. The thrusters generate enough thrust to control the spacecraft in the required six degrees of freedom. They will counteract both external and internal pressures on the test masses. For example, the strongest external force on the ST7 spacecraft will be from sunlight, which will be equal to one-hundredth the weight of a postage stamp. The thrusters have just enough thrust to push back against the Sun's pressure. This will balance the force of the Sun almost perfectly, leaving a residual that is 10,000 times smaller still.

One undesired internal pressure will be gravity from the spacecraft itself. Sensitive instruments on Earth are ordinarily constructed to directly register gravity, an inherently weak force, generated by any object other than the Earth itself. Weighing about one ton, the spacecraft is capable of exerting force on the test masses far in excess of the minimum level that instruments are required to measure. This minimum level is enough to give it the weight of a flea!

This new type of miniature ion-engine microthruster, along with the DRS instrument technologies, will provide alternative approaches to position control of future separated-spacecraft missions.

Benefits. Space Technology 7's Disturbance Reduction System (DRS) is system-level technology that will enable spacecraft control with nanometer precision. Successfully validated DRS technology will be used in future separated-spacecraft interferometer missions — missions involving multiple spacecraft, flying in formation, with instruments that use waves of light to determine distances or wavelengths. On such missions, DRS position-measurement technology can be used to:

- test theories of gravity, including general relativity
- map the gravity fields of the Earth or other planets to study properties of planetary crust and ocean currents
- detect cosmic gravitational waves, which are ripples in space-time generated by massive objects

Following the New Millennium Program's validation, DRS technology will be used on the Laser Interferometer Space Antenna (LISA) space science mission. LISA is the first dedicated in-space gravitational-wave observatory, with the primary objective to detect and make measurements of Einstein's predicted gravitational waves. There is also a preliminary plan to use the DRS in the future EX-5 mission, which will map the Earth's variable gravity field. Spacecraft-position control with nanometer precision is also of interest to other missions that won't study gravity as their prime objective.

The capability of controlling spacecraft positions to the nanometer level simplifies the optics for visible and infrared interferometry missions. And, separated-spacecraft interferometers require the control of mirror position at nanometer precision. With such precision, fine control of mirrors measuring visible and infrared wavelengths can be done in stages. The DRS position-control technology may enhance mission performance and reduce mission cost. This technology will be validated for use in:

- gamma-ray or x-ray separated spacecraft interferometers future missions, such as the microArcsecond X-ray Imaging Mission (MAXIM)
- optical and infrared separated seacraft interferometry missions, such as the Terrestrial Planet Finder (TPF) mission

Since NASA was formed in 1958, the commercially significant technologies developed in the course of mission research have been shared

with industry to solve engineering and manufacturing problems. The DRS technology may contribute to the development of commercial products.

NANCY J. LEON, Jet Propulsion Laboratory, Pasadena, CA

SPACE TECHNOLOGY 8 (ST8) MISSION. As part of NASA's New Millennium Program (NMP), Space Technology 8 (ST8) is a mission to validate four new subsystem-level technologies never before tried in space. Each of these technologies was selected for its promise in advancing NASA's most important future science missions, as so deemed by the science community of the U.S. and the world. See also **New Millennium Program (NMP)**.

Like its predecessor Deep Space 1, which validated 12 new technologies for use in space, ST8 will fly all its test technologies on one dedicated spacecraft, and the overall mission is designed to give each of the technologies a realistic workout as part of the whole spacecraft system. See also **Deep Space 1**.

The ST8 spacecraft will be launched from Vandenberg AFB (launch vehicle TBD) into an elliptical, near-polar Earth orbit with a perigee altitude = 300 km (186 miles), an apogee altitude of 1300 km ± 200 km (808 miles ± 124 miles), and an inclination of 98.6°. The target launch date is 28 February 2009. The mission duration is scheduled for 7 months (1 month checkout period and 6 months of experiments). A sun-synchronous terminator orbit was selected to minimize solar eclipses, providing thermal stability for the experiments. As a result, there are no eclipses during the nominal seven-month mission. The low perigee provides drag to passively de-orbit within the 25 years post-mission required by NASA regulations, and the radiation levels near apogee will provide the single-event upsets (SEUs) required by the Dependable Multiprocessor experiment.

With an orbital period of approximately 100 minutes, there are typically several opportunities per day for spacecraft contact through tracking passes on the three primary United State Naval stations that will be used by ST8 — Alaska, Hawaii, and Australia. Additional stations are available if more coverage is needed for critical events. The current baseline is three tracking passes per day on average, with most of the passes around ten minutes in duration. The mission will be operated out of Orbital Sciences Corporation facilities in Dulles, Virginia.

The ST8 Mission, will host a varied payload of four advanced technologies. Each technology validation experiment will include diagnostic instruments. They will perform detailed measurements to characterize and determine how well the technologies performance in space corresponds to predictions derived from ground-based testing and modeling. The resulting data will be provided to science mission planners to enable a broad range of space-based science projects at significantly reduced risk and cost. The selected suite of advanced technology experiments includes:

- *Dependable Multiprocessor*. A commercial-off-the-shelf (COTS)-based computing architecture that enhances the immunity of a high-performance onboard processing system to the error-causing radiation environment of space.
- *UltraFlex 175*. A deployable solar array system that is a highly efficient power producer for the entire spacecraft.
- *Sailmast Ultra Lightweight Boom*: A technology for strong, ultra-lightweight structures that can be used to support huge, deployable solar sails and other large structures.
- *Thermal Loop*. A miniature thermal management system for small spacecraft that tightly controls the operating temperatures of the instruments while using little power.

Dependable Multiprocessor: High-performance Computing in Space. The Dependable Multiprocessor is a technology being developed by Honeywell Inc. It allows us to do complex processing of science data onboard the spacecraft. Using standard commercial components arranged in a unique architecture, along with special software to detect and correct radiation induced errors, this technology will allow us to build computers that are up to 1000 times more capable than current day spaceborne computer systems. These new, highly capable computers will make possible a new generation of intelligent spacecraft and robotics for future NASA science and exploration missions.

Space is a mean, unfriendly place, and not just for astronauts. Any materials, scientific instruments, or electronic components we place above Earth's protective atmosphere are subjected to wildly variable accelerations, mechanical shock and vibration, harsh vacuum conditions, extreme temperatures, and often, intense particle and electromagnetic radiation.

Perhaps the most unusual (and hostile) aspect of this environment is the radiation. Earth's surface and different regions of the space surrounding Earth experience different levels and types of radiation.

Radiation, in the form of the charged particles, as well as ionizing electromagnetic waves, can degrade or destroy spacecraft electronic components, wreak havoc with digital data, and upset the operation of instruments, computers, and software. Even in the relatively safer region of Low Earth Orbit (LEO), radiation is still a serious problem for both humans and computer electronics.

Ordinary computers, that work fine on Earth, are useless in space. The high-energy electromagnetic waves and charged particles, collectively known as "ionizing radiation" pass through them, damaging whatever gets in their way.

There are two main types of effects caused by ionizing radiation: permanent damage and temporary errors.

Typical design solutions for protecting spacecraft computers from ionizing radiation have involved surrounding the computer with radiation shielding and using custom components specially designed and built to be radiation resistant. The difficulty with this approach is that radiation shielding is heavy and bulky, while custom "radiation hardened" electronics are power hungry, slow and large compared to their standard "Commercial Off The Shelf" (COTS) counterparts. They are also extremely expensive and generally a generation or more behind the state of the art of their commercial equivalents. Since a spacecraft's most precious commodities are mass (weight), volume, and power budgets, it is difficult to build a modern, powerful, space-going computer system within acceptable mass, volume and power constraints.

The problem gets even worse as space science and exploration missions move toward more self-contained and autonomous spacecraft that are also smaller, lighter, and more power constrained. Space missions are becoming more and more data intensive and ranging farther and farther from home. Imaging instruments are becoming so sophisticated that they can generate data at rates of over a terabyte per day! With the current, relatively low-bandwidth, satellite-to-ground-station data links, we cannot get this much data down to Earth for processing by ground based supercomputers. In cases where the results of the data processing are to be used to make mission decisions, such as 'what to do next,' we don't have the time to download, process, decide, and then upload the resulting commands. We must process the data onboard the spacecraft, make required decisions onboard, and send down a much reduced, processed-data set. What we need now are ***small, lightweight, low-power supercomputers*** in space.

If we could get such a computing architecture into space, we could design the spacecraft to process its own science data onboard and make complex decisions immediately about the scene it is observing, without sending the data down to Earth for analysis. Unfortunately, adapting even simple general purpose computing technologies for use in the harsh, error-inducing environment of space has encountered significant difficulties and delays. Transcending these computational limitations is of extremely high priority in the development of the next generation of space missions. Therefore, any adjunct technology that would improve the fault tolerance of state-of-the-art COTS computing technology would help greatly.

Fault tolerance, as the term implies, is the ability to continue to provide correct computation in the presence of faults or errors. In other words, instead of taking the usual approach of fault avoidance — shielding the system and/or designing custom electronics that will not be affected by the radiation — we would like to use standard, low-cost, high-performance, low-power components to build machines that recognize that an error has occurred and autonomously take action to correct the error. Similarly, if radiation damage breaks part of the computer, we would like the machine to identify the damage and fix itself.

We can categorize faults into two types: permanent faults — that is, faults that break computer components — and soft errors, which cause an error but do not cause permanent damage. Techniques have been developed to deal with both types of faults. Unfortunately, these techniques, especially

those for fixing soft errors, rob the computer of much of its efficiency. They usually consist of a combination of replication and voting, that is, performing the computation multiple times and then voting on the result.

If we have, for instance, three computers, each performing the same computation and feeding their result to a similarly triplicated voter, the computer system could tell whether one of the computers had experienced an error and could identify the incorrect answer, as it would be out-voted by the other two. Alternatively, we could use just two computers and voters to detect an error, but then we would have to repeat the computations as we could not tell which answer was correct.

Other techniques use redundancy in the form of codes or computational algorithms that have the capacity to detect that an error has occurred by checking the results for certain characteristics. A simple example of a coding technique is parity. Here an extra bit is inserted into each digital word and is used to make the number of ones in the word either even (even parity) or odd (odd parity) depending on the design of the machine (an even parity or odd parity machine). To check for an error, a parity checker simply adds the number of ones in each word every time it is accessed and determines whether it is an even or odd number. If the parity is incorrect, an error has occurred and that data word is incorrect.

Other techniques (http://nmp.jpl.nasa.gov/st8/popups/fault_corr_techniques.html) exist for error detection and correction in data and in computational algorithms. While these techniques require less overhead than straight replication, they still incur overhead and are limited in their application, that is, they can not cover all machine operations.

Is there a way we can gain back that lost efficiency, or even improve over standard COTS computing capabilities with some other technique?

It turns out that much of the science data processing we wish to do makes extensive use of mathematical routines such as linear algebra. These routines could be performed very efficiently if we had special purpose hardware to carry out theses calculations. Unfortunately, we don't know, beforehand, what algorithms will be required, and custom chips designed to perform these algorithms would be prohibitively expensive.

There is, however, another solution. If we had a component that was made up of reconfigurable hardware elements, i.e., sets of digital hardware elements whose wiring could be "programmed" as needed, we could use these reconfigurable logic parts to implement the required algorithms on an as-need basis. To do this efficiently, we would need to design our computer system so that these parts could be re-programmed on the fly, in space, as needed — perhaps from a library of pre-designed configurations — one for each algorithm we might want to use over the course of the mission.

The readily available Field Programmable Logic Array (FPGA) is such a part. The use of FPGAs as "accelerators" or "reconfigurable co-processors" can give us as much as 100x to 1000x improvement over standard processors for some types of science data analysis programs. Unfortunately, this part, because it is chock full of memory elements (to hold its configuration program) is also subject to soft errors and so, it too, must be made fault tolerant, or the computing system of which it is a part, must be made aware of its susceptibility and taught to deal with it. See Fig. 1.

Dependable Multiprocessor Solution. The Dependable Multiprocessor technology to be tested as part of Space Technology 8 is composed of a state-of-the-art COTS-based supercomputer architecture incorporating FPGA-based algorithmic co-processors. It will autonomously and adaptively configure the level of fault tolerance applied to the COTS-based computer system in response to the changing mission environment and the criticality of the mission application. At times when the radiation environment is minimal, the applications being run are non-critical, and timeliness of data is not an issue, fault tolerance techniques that do not require significant additional power and that may take longer to detect and fix errors will be used. As the radiation environment worsens and/or the criticality or timeliness of the application becomes significant, other techniques will be used that, while consuming additional power and resources, provide enhanced fault tolerance capabilities. In this way, the system configuration is kept optimal, resource utilization is minimized, and stress on other spacecraft systems such as the power generation, power conditioning/distribution, and thermal management, is likewise minimized. This results in highly intelligent, lower cost, smaller, and more capable spacecraft.

A Dependable Multiprocessor consists of three key technology enablers:

1. Radiation environment sensing to measure, in real time, the amount of radiation to which the computing system is being exposed (radiation flux exposure).

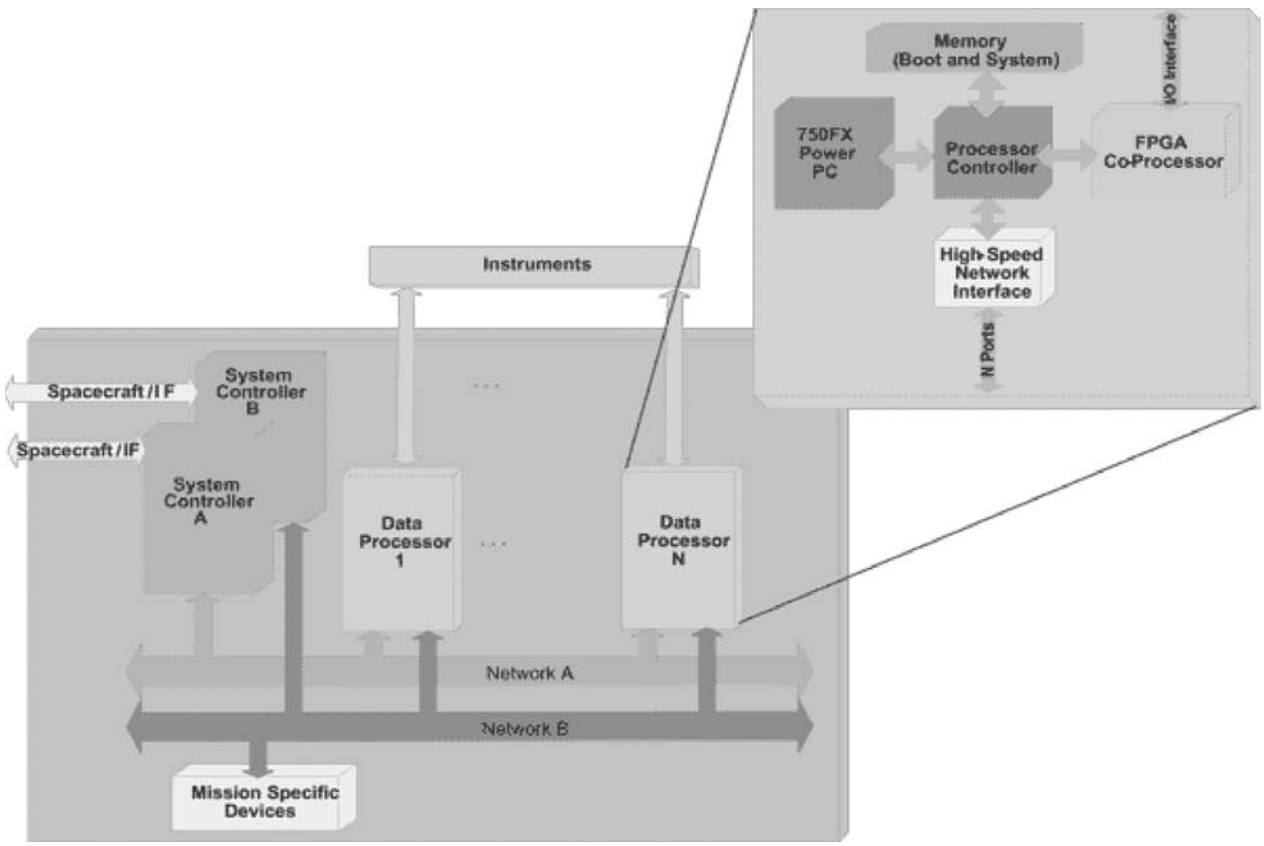

Fig. 1. Hardware architecture of the Dependable Multiprocessor.

2. A computer architecture that uses COTS processing components and supports adaptable configuration, providing multiple levels of fault tolerance.
3. A system controller mechanism to manage the environmental sensing and the determination and development of appropriate fault tolerant configurations so as to optimize performance and efficiency while maintaining reliable operation.

Dependable Multiprocessor technology facilitates the reliable use of COTS components where soft errors are likely, while avoiding the unwarranted drawbacks of traditional redundancy techniques.

The Dependable Multiprocessor experiment will validate a computer system architectural approach that allows flexibility by applying redundancy only to the level required by the environment and the criticality of the task or computation. The experiment further develops several key technology enablers for space missions, such as fault mitigation software, adaptive processing computer architecture, FPGA-based co-processing, and miniaturized SEU-inducing-radiation sensors.

The major elements of a Dependable Multiprocessor-based system are a Dependable Multiprocessor controller, an environmental sensor, and a reconfigurable parallel processing cluster computer. The steps in the Dependable Multiprocessor process are:

1. Sense the computer's environment,
2. Assess the environmental threat to the computer's reliability and availability,
3. Assess the criticality of the application,
4. Determine whether a hardware co-processor is required,
5. Configure the co-processor (load the configuration which implements the required algorithm), and
6. Adapt the processing system's configuration (that is, fault tolerance) to mitigate the threat.

For this experiment, the environmental sensors measure high-energy particle flux. Readings of this parameter make it possible to assess the computer system's expected rate and types of soft errors (single event upsets, SEUs).

UltraFlex 175. Past interplanetary spacecraft have required from 300 to 25,000 Watts of electrical power to supply all the computers, radio transmitters and receivers, motors, valves, data storage devices, instruments, hosts of sensors, and other devices. But now, with solar ion propulsion a proven technology (validated on the New Millennium Program's Deep Space 1 mission), many future missions will need considerably more electrical power to take advantage of the low but steady acceleration provided by ion propulsion.

Ion propulsion involves ionizing a gas to propel a craft. Instead of a spacecraft being propelled with standard chemicals, the gas xenon (which is inert like neon or helium, but heavier) is given an electrical charge, or ionized. It is then electrically accelerated to a speed of about 30 km/second. When xenon ions are emitted at such high speed as exhaust from a spacecraft, they push the spacecraft in the opposite direction.

Ion propulsion requires a considerable power supply to keep a continuous electrical charge on the gas and to charge the grid through which the ions are expelled.

Choices of technology to meet these power requirements are today constrained largely to two: photovoltaics and radioisotope thermoelectric generators. Mostly for launch safety reasons, photovoltaics (solar arrays) are used for all but the most distant planetary missions where the sunlight is too faint to generate enough power.

As the term suggests, photovoltaic materials have the ability to convert light directly to electricity. Individual photovoltaic, or solar, cells are affixed to some sort of panels or arrays that can be pointed toward the Sun.

Because the power output is directly proportional to surface area exposed to the Sun, solar arrays need to be larger if they are to produce additional power. The design challenges for large solar arrays are to make them lightweight, deployable, stowable in a small space for launch, and strong. They must also be able to point at an optimum angle to the Sun, though they may be off-pointed slightly for periods when it may be desirable to generate less power.

The power subsystem on most spacecraft makes up a good part of the entire spacecraft mass. The existing state-of-the-art solar array is based on rigid composite honeycomb structures with complex synchronization mechanisms. They tend to be heavy, take up a lot of space in their stowed configuration, and provide low deployed frequencies. Recent advances in photovoltaic technology and lightweight structures can be applied to spacecraft solar arrays to greatly improve them, both decreasing their mass and increasing their power generation capability.

Lightweight solar arrays have already been developed that can produce three times the power per unit of mass as the solar arrays currently being used on spacecraft. However, these lightweight arrays are too flimsy and their deployment mechanisms too unusual to make ground testing adequate for predicting their performance in a near-zero gravity environment. What is needed is an experiment in space to make sure the deployment technology works in the environment for which it was designed and to find out how the space environment affects the structural dynamics and power generating performance of these ultra-lightweight arrays.

Space Technology 8 will flight test a new type of solar array, called the UltraFlex 175. See Fig. 2. This system merges the best features of these technology improvements.

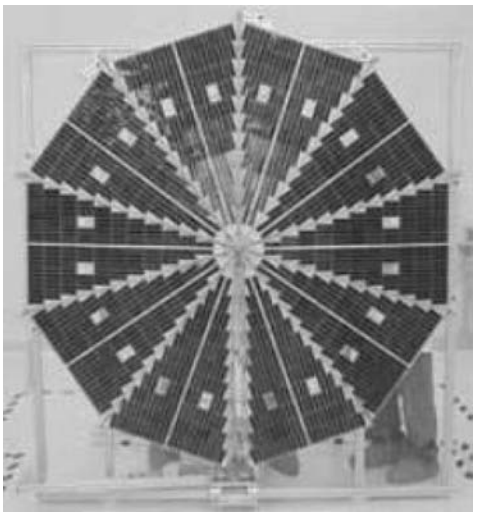

Fig. 2. UltraFlex 175 fully deployed in the laboratory. Notice size comparison with legs of man standing behind it.

- The design of the array efficiently uses its structure to obtain the largest electrically active area.
- The innovative use of materials and power enhancement strategies maximize electrical output per unit mass.
- The technology emphasizes compact stowage in order to minimize stowed volume for pre-launch packaging.

However, a compactly folded lightweight structure introduces additional issues. What happens when it is deployed? What effect will the deployment have on structural dynamics of the array itself and the spacecraft? How well can the deployment forces be controlled? Hence, this experiment will also validate how well and rapidly any induced vibration of the parts of the solar array can be damped. The successful deployment of this new, ultra-lightweight solar array will mitigate concerns over the handling of lightweight power generating structures and will be a major contribution to future applications of this technology.

SAILMAST Ultra Lightweight Boom. For a number of years, deployable masts have been used in space missions to support solar arrays, magnetometers, cameras, and antennas. The Shuttle Radar Topography Mission in 2000, for example, used a 60-meter- (200-foot-) long mast to deploy one of two radar antennas. This was the longest mast ever deployed in space.

The next step in development of deployable structures in space is to make them suitable to support large membrane structures such as solar sails. Solar sails, which use solar radiation photon pressure in much the same way that a sailboat uses wind, promise to provide the means for high-speed interplanetary or interstellar propulsion. A rocket burns for only a few minutes before releasing its payload and letting it cruise at a constant

speed the rest of the way to its destination. A solar sail, in contrast, keeps on accelerating and can ultimately reach speeds much greater than those of a rocket-launched craft.

To be useful for solar sails, deployable structures will need to be of gossamer lightness. Solar sails must be huge, typically about the size of a football field, to generate even as much force as the weight of a first-class letter. Even though this is a very tiny force, it is perpetual, and over days, weeks, and months, this snail-paced acceleration produces velocities large enough to overtake and pass the Voyager and Pioneer spacecraft launched in the 1970s that are now speeding away through the outer reaches of our solar system.

Besides their use in huge solar sails, ultra lightweight deployable structure technology will also be useful for telescope sunshades, solar array assemblies, large aperture optics, instrument booms, and antennas.

Ultra lightweight structures will enable or benefit several future NASA science missions that employ solar sails, solar arrays, large apertures, and telescope sunshades. Examples of applicable missions include the following:

- Sun Earth Connection (SEC): Solar Polar Imager (SPI), Magnetospheric Multi-Scale (MMS), Solar Sentinel (GeoStorm);
- Structure and Evolution of the Universe (SEU): Advanced Radio Interferometry between Space and Earth (ARISE); and
- Astronomical Search for Origins (ASO): Terrestrial Planet Finder (TPF), Filled Aperture InfraRed Telescope (FAIR), Life Finder (LF).

The basic deployable mast technology has been used successfully on numerous space missions previously.

The fiberglass-based coilable boom is a well-understood, flight-proven structure, with proven self-deployability, reliability, and mass efficiency. The longerons and battens for the coilable masts previously flown were made of fiberglass, which gave them a deployed mass of around 93 grams/meter.

Now the use of advanced, highly flexible graphite fibers instead of fiberglass will give still better performance and even lower mass. The fiber strain limitations of these composites does require that the individual structural elements be made more slender than were the fiberglass elements, however. Luckily, highly slender elements are also appropriate for gossamer applications such as solar sails. This very slenderness, though, makes the elements more sensitive to any imperfections in the manufacture and assembly of the structure, which can significantly reduce the overall structure's stiffness and, therefore, strength.

The new masts use the same proven structure as the previous masts — that is, continuous, coilable, longerons running the complete length of the mast. The longerons can be coiled and stowed in less than 1% of their deployed length. The mast is self-deployed by the strain energy of the coiled and stowed longerons. A lanyard controls the rate of deployment. The mass of this type of structure is less than 35 grams / meter when deployed.

The diagonals are of a length that buckles the battens, thus maintaining tension in the diagonals and providing stiffness. For more information on the design and technical specifications of the SAILMAST, please see the technical paper "The ST8 SAILMAST Validation Experiment," http://nmp.jpl.nasa.gov/st8/tech_papers/AIAA%202005-18840-McEachen-SAILMAST.pdf, prepared by Michael A. McEachen et al. for the American Institute of Aeronautics and Astronautics.

This ultra lightweight graphite coilable mast to be demonstrated in flight is of slenderness far beyond that of any other structure previously flown, and thereby presents an advance beyond the current technology of deployable structures. This structure is being developed for near-term use as a solar sail mast, but it is generally applicable to many future required lighter booms that stow compactly. This new technology will be broadly enabling to future gossamer spacecraft missions, just as the coilable fiberglass boom structure has been employed in a wide array of past and ongoing missions.

The SAILMAST flight experiment will test a 40 meter (131 foot) boom deployed straight down from the ST8 spacecraft. The mast will be deployed in the zenith direction to eliminate any gravity gradient forces on the spacecraft. The free-state shape (degree to which the boom is less than perfectly straight) will be measured by three digital video cameras mounted at the base of the mast, viewing LED optical targets distributed along the length of the mast. Experiment operations will be controlled and carried out by an integrated electronics package that provides power distribution, command, and telemetry of the experiment.

Designers do not yet understand just how sensitive a structure made with the new composite material will be to possible slight imperfections. The questions are

1. What is the local waviness of the longerons?
2. How much does the entire boom structure bend or twist?
3. What is the effect of these imperfections on the overall structure?

The first question can be answered by ground testing in 1-g conditions. The second question can be answered only by observing the deployed structure in zero-g conditions. The third question also needs verification of assumptions using observation data from a zero-g deployment.

Why is it important to know how well a structure tolerates manufacturing imperfections? Lacking empirical evidence under real flight conditions, the structure would have to be designed for the worst-case set of imperfections in order to guarantee its operational success. A structure so designed would no doubt compromise its lightness, stowability, and possibly deployment performance.

The in-space experiment will begin by deploying the SAILMAST from the stowage canister, to zenith, by paying out a lanyard with a motor. It is a phenomenon of uncoiling a "spring-loaded" boom that there is an instantaneous "kick-over" as the final few centimeters of its length snap to straightness. Therefore, when the boom is 80% deployed the spacecraft's attitude and articulation control system (ACS) will be put on standby. This way, when the coiled boom is fully released, the degree of this kick-over and its effect on the spacecraft can be measured and recorded without the spacecraft's ACS attempting to correct for it. See Fig. 3.

Upon full deployment, the three video cameras positioned equidistantly around the base of the mast will record the positions of the target LEDs positioned on each of the three longerons at four distances along the mast. This measurement technique is called photogrammetry (when still images are analyzed) or videogrammetry (when video sequences are analyzed). Small oscillations will be induced by piezoelectric actuators at the root of each longeron. Piezoelectric actuators are made of a modified ceramic material that expands slightly when a voltage is applied across its surface. A two-axis accelerometer at the end of the mast, as well as videogrammetry, will record the response.

Then the lanyard motor will be reversed, pulling on the lanyard, putting a known load on the axis of the mast. (For the purpose of supporting solar sails, it is in the axial direction that the predominant load forces will act.) The mast will experience some displacement, which again will be measured by taking images with the three cameras. This process will be repeated at increasing known loads until the mast begins to buckle. The loading process will then be reversed in increments and the displacements measured.

Thermal Loop. Managing the temperature of the various components of a spacecraft is the task of the thermal control system. While we generally think of space as being very cold, spacecraft are exposed to extremes of temperature, from extremely hot on the sunward side to extremely cold on the shadow side or in the outer solar system. In addition, heat is generated by electronic components inside the spacecraft.

The thermal control system is usually 4 to 6% of the mass of the spacecraft. The usual approach is to connect the components that generate heat to a radiator that conducts the waste heat to space, while warming colder components with electric heaters. More mass is often added to various components solely to enhance their properties of heat conduction. These approaches are not suitable for smaller, more efficient spacecraft. They do not make efficient use of power resources, and they put constraints on the locations of individual components within the spacecraft.

The need for mass savings becomes ever more critical as spacecraft shrink to accommodate smaller and more efficient payloads. There is a critical need for advanced thermal control technology that would allow the low mass, low power, and compactness necessary for future spacecraft. This new technology will not only save mass but it will also allow greater design flexibility in deciding where components are placed. It will also minimize — if not eliminate — the need for supplemental electrical heaters.

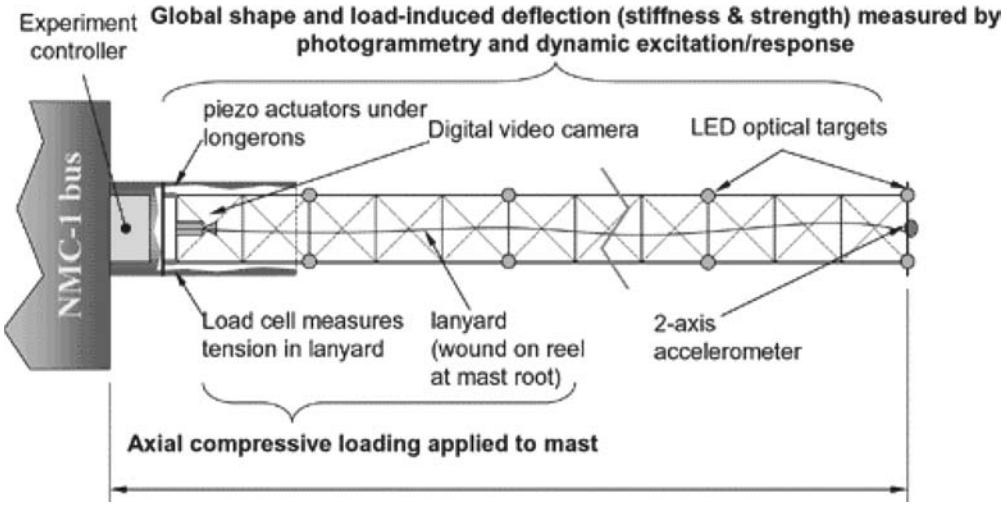

Fig. 3. On ST8, the performance of the mast will be measured using video cameras, strategically placed LEDs, and an accelerometer.

The thermal control system to be validated on ST8 is called a "Thermal Loop." This advanced temperature control system can transport large heat loads over long distances with small temperature differences and without external pumping powers. Key to this system are a loop heat pipe with multiple evaporators (with outer diameters of 13 mm) and multiple condensers, thermal electrical coolers, and deployable radiators coated with variable emittance coatings. The loop heat pipe collects heat generated within a spacecraft and transmits the heat to radiators for dissipation to space. The deployable radiators can be placed at various locations on the spacecraft surface, and the variable emittance coatings can adjust the amount of heat disposed of by each radiator to achieve optimal system performance. The thermal electrical coolers control the system temperature within a tight range. See Fig. 4. The system can cool the "on" instruments and warm the "off" instruments simultaneously without using auxiliary electrical heaters while maintaining all instruments at the same temperature.

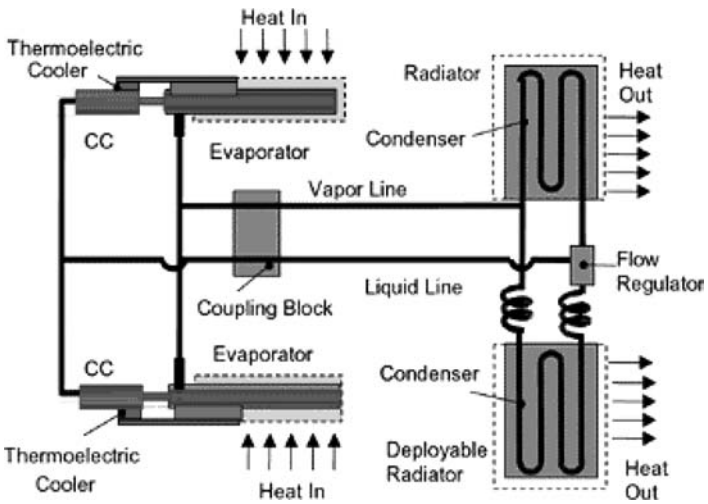

Fig. 4. Diagram shows flow of heat through the Thermal Loop system.

1. The Thermal Loop retains all the operating characteristics and advantages of the state-of-the-art loop heat pipe (LHP) and offers many additional advantages:
2. The mass, volume and control heater power are reduced.
3. Multiple evaporators in a single LHP provide a single interface temperature to all instruments and allow the "off" instruments to receive heat from the "on" instruments, eliminating the need for supplemental heaters.
4. Multiple condensers allow the radiators to be placed at different locations and can be exposed to different heat sinks.
5. The flow regulator prevents heat from being transmitted back to the instruments.
6. Thermal Electrical Coolers (TECs) enhance LHP start-up success and provide tight operating temperature control.
7. Variable Emittance Coatings (VECs) can change the emittance of the radiators and eliminate or reduce the supplemental heater power required to prevent liquid freezing.
8. The coupling block allows the returning liquid to absorb heat from the vapor, reducing the control heater power required to maintain a constant operating temperature.
9. Deployable radiators can radiate heat from both sides, reducing the radiator area.

The Thermal Loop therefore enhances the functionality, versatility and reliability of the state-of-the art LHPs, while offering the low mass, low power and compactness necessary for future spacecraft.

Engineers cannot effectively validate on the ground in 1-g how well a thermal control system within a small spacecraft will work in a microgravity environment. In-space testing will validate both the thermal control operational procedures and the modeling tools used to predict the performance of these systems over a range of design and environmental conditions relevant to future missions.

No loop heat pipes with 13-mm (0.5 inch) outer diameter evaporators have been flight validated, nor have any loop heat pipes with multiple evaporators. Ground tests show strong interaction among multiple evaporators. It is well known that capillary two-phase devices are strongly influenced by gravity. Flight validation is therefore essential. The variable emittance coating has never been tested in the space environment for long-term operation, either. The large time constant involved in heat transfer requires a long-duration space flight experiment to verify the zero-g performance the miniature loop heat pipe.

The ST8 mission will validate a miniature loop heat pipe with two evaporators and two condensers through a flight experiment. Both radiators will have variable emittance coatings, and one of the radiators will be deployable. The intent of the validation experiment is to

- Validate the performance of a thermal control subsystem designed specifically for small (<150 kg) spacecraft having a total power generation of lte 250 W and corresponding power dissipation of lte 200 W;
- Validate predicted savings in spacecraft mass, power, and volume of a thermal control system designed for small spacecraft when compared with conventional thermal control techniques; and
- Validate analytical models used to predict thermal performance of optimized component locations enabled by new thermal control system.

In addition, scaling rules will be established to validate the scalability and applicability of the flight results when extending to other loop heat pipes with different geometries and configurations, and/or under different environments.

During flight validation, the entire miniature loop heat pipe flight unit will be made into a self-contained package that can be "bolted" onto the surface of the host spacecraft. The Thermal Loop will be operated as a stand-alone experiment functionally isolated and independent from the other ST8 experiments.

The Thermal Loop can provide tight temperature control, reduce the need for supplemental heaters, modulate heat rejection, allow optimal placement of components, and afford flexibility for spacecraft design, integration and testing. This technology will enable future space missions to be designed more efficiently and result in low mass, low power consumption, and compactness.

Successful validation of this advanced thermal control technology will be a major contribution toward the advancement of small spacecraft.

Implementation of such a thermal management system will benefit several future NASA missions, including: Mars Missions: Mars Science Laboratory, Mars Scouts and Sun Earth Connection Theme: Magnetospheric Constellation, Solar Sentinels.

SPACE-TIME. A space of four dimensions which specify the space and time coordinates of an event. In the absence of a gravitational field, space-time reduces to Minkowski space.

See also **Space (Minkowski)**; **Gravitation**; and **Relativity and Relativity Theory**.

SPACE VELOCITY (Stellar). The space velocity of a star is its actual velocity in space relative to the sun. The term *fixed star* is one which has been handed down to us from the era when philosophers believed that the stars were fixed on a sphere, rotating about the earth, which they referred to as the celestial sphere. At present, we believe that practically all of the stars are actually in motion in space with velocities comparable in magnitude to the velocities with which the planets are moving about the sun in their orbits. In measuring any velocity it is necessary to have a definite reference point and the space velocity of a star is its velocity referred to the sun.

In Fig. 1 we have the space velocity of a star represented by the vector (directed straight line proportional to the velocity in direction and magnitude) AB. The angle β, which this vector makes with the direction of the star from the sun at any particular instant, gives the direction of the space velocity at that instant.

As observed from the solar system this space velocity may be resolved into two components: AC the radial velocity, and m the proper motion.

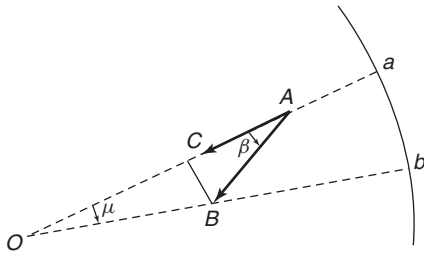

Fig. 1. Vector representation of space velocity.

The radial velocity is determined directly in terms of linear velocity (i.e., in miles or kilometers per second), but the proper motion may only be determined in angular units, usually expressed in seconds of arc per year. In order that the space velocity may be known, the proper motion must be converted into a linear velocity, commonly known as the transverse velocity of the star. This may be accomplished only if the distance of the star is known. Expressing the distance in terms of the stellar parallax, π, and calling the transverse velocity T (the line CB in the figure), the following relations may be derived:

$$T = 4.74\ \mu/\pi \text{ kilometers/second}$$

or

$$T = 2.94\ \mu/\pi \text{ miles/second}$$

With both the transverse velocity, T, and the radial velocity, R, known in the same units, the problem of determining the space velocity S in the same units is merely that of solving the plane right-triangle ACB. This solution yields

$$S^2 = T^2 + R^2 \quad \cos\beta = R/S \quad \sin\beta = T/S$$

SPACE WEATHER. The Sun's activity causes large changes in the Sun's plasma and energetic particle populations, and these changes are responsible for the "space weather" that affects Earth. Space weather can impact the upper atmosphere and may influence long-term climate trends. The affects are related to CMEs, SEPs, and coronal holes, the source of high-speed streams. The largest storms occur when a fast CME hits Earth shortly after its shock arrives. See also **Coronal Holes**; **Coronal Mass Ejections**, **Solar Energetic Particles**; and **Sun (The)**.

In January 1997, for the first time, a coronal mass ejection was observed in real-time http://helios.gsfc.nasa.gov/CME.mpg all the way from the Sun to its dramatic consequences at Earth four days later. The SOHO; http://sohowww.nascom.nasa.gov/, Wind; http://www-spof.gsfc.nasa.gov/istp/wind/wind.html, Polar; http://www-spof.gsfc.nasa.gov/istp/polar/polar.html, and GEOTAIL spacecraft http://www-istp.gsfc.nasa.gov/istp/geotail/geotail.html were all involved. See also **Earth-Sun System Missions**.

Geomagnetic storms (magnetic storms on Earth due to solar activity) produce the awe-inspiring *Aurora borealis* and *Aurora australis* — the Northern and Southern lights. However, they can also cause a variety of highly undesirable consequences. Electrical current surges in power lines, interference in the broadcast of radio, television, and telephone signals, and problems with defense communications are all associated with magnetic storms. Odd behavior in air and marine navigation instruments has been observed, and a compass anywhere on Earth is certainly affected. These storms are known to alter the atmospheric ozone layer. Even increased pipeline corrosion has been attributed to them. See also **Geomagnetic Storm**.

Variations over the 11-year solar cycle in the intensity of the Sun's electromagnetic output at some wavelengths significantly affect the chemistry, structure, and dynamics of the Earth's upper atmosphere. Longer-term solar variations may be linked to major shifts in the global climate. See also **Solar Cycle (The)**.

Major solar activity is a very serious concern in space flight. Communications may be disrupted. Large solar disturbances heat the upper atmosphere, causing it to expand and create increased drag on spacecraft

in low orbits, shortening their orbital lifetime. Spacecraft could potentially tumble and burn up in the atmosphere.

Intense SEP (Solar Energetic Particles) events contain very high levels of radiation, more than a million times the normal daily dose of a human on Earth. Radiation sickness can result when humans are outside the protective magnetosphere of the Earth, as in missions to the moon and to Mars. Monitoring of astronaut's exposure to radiation began during Project Mercury and has continued through the current Shuttle Program. The space radiation environment is very different from that found on Earth. See also **Space Radiation**.

High-energy solar protons can produce increased radiation in the atmosphere at altitudes where supersonic aircraft fly. This is especially true for flights over the north and south magnetic poles, areas unprotected by the Earth's magnetic field, where the radiation has direct access to the atmosphere. To reduce the risk to aircraft crews and passengers, and reduce risk to the aircraft, routine forecasts and alerts are sent through the Federal Aviation Administration so that a flight in potential danger can consider what course of action to take to minimize radiation exposure. The National Oceanic and Atmospheric Administration (NOAA), Space Environment Center (SEC) forecasts high-speed solar wind and solar particle events. http://www.sec.noaa.gov/today.html. The SEC has a Space Weather Advisories page. http://www.sec.noaa.gov/advisories/.

See also **Solar Wind**.

SPALLANZANI, LAZZARO (1729–1799). Lazzaro Spallanzani was a Italian priest and naturalist who disproved the theory of spontaneous generation. Born in Scandiano, Spallanzani was educated in classics by the Jesuits before studying jurisprudence and especially physics with Antonio Vallisneri and Laura Bassi in Bologna. He received his degree in philosophy, was ordained a priest around 1755 and then dedicated himself freely to the study of nature.

His mastering of the many techniques available at the time, in microscopy, experimental biology and physiology, allowed him to study a wide range of different topics in the life sciences. He refuted the spontaneous generation of infusoria claimed by John Needham (1765), by an experimental setting that was taken up and improved by Louis Pasteur. Influenced by Abraham Trembley and Charles Bonnet, he studied the conditions of regeneration of the head of snails (1768, 1782); his enquiries on the hydrodynamic conditions of the movement of the blood contributed to the basis of the modern cardiology (1773). In 1776 he extended his discoveries relating to the division of unicellular organisms. Partly guided by Bonnet, Spallanzani investigated the structure and functions of spermatozoa and began performing artificial insemination and hybridization experiments. By improving an experimental procedure of A.-F. Réaumur, he also contributed to elucidating the role of the gastric juice in digestion (1777). Famous throughout Europe from 1765, his works were rapidly translated into the main European languages. He traveled several times in Italy and Turkey, for pioneering works on vulcanology, meteorology and marine zoology. Under his direction, and with the many objects he brought from his travels, the Museum of Pavia became one of the best in Italy. Spallanzani was a professor in Modena (1763–1769) and in Pavia (1769–1799), honored by many distinctions. SPAR. In marine parlance, a spar is a round timber used to extend a sail. Used with this meaning, it could be a mast, a boom, or a yard.

A structural member used similarly to extend a surface to obtain an air reaction is found in the wing of an airplane. There, the spar is a principal structural member running the length of the wing. Usually there are two, parallel to one another, but wings have been built having only one spar. In such a design the spar is required to take torsion and bending as well as compression if the wing is externally braced. The spars support the ribs upon which the wing covering is stretched. The reaction of the air upon the latter is transmitted to the spars, which in turn are attached to the fuselage. The air reaction may be carried by the spars entirely by bending as in the case of a truly cantilever wing, or it may be carried by spars which are braced outboard of the fuselage by wires or struts.

SPARK CHAMBER. A device used for the study of high-energy nuclear reactions and related particle physics. The device consists of a chamber filled with an inert gas, often helium or helium and neon, in which there is a stack of parallel conducting plates. These plates are connected alternately to the positive and negative terminals of a high-voltage source (10,000 volts upward). A chamber may have from 25 to 100 plates, each about 1 millimeter thick and 1 millimeter square, spaced about 0.6 centimeter apart. The chamber is operated in conjunction with a counter used as a detector for ionizing particles entering the chamber. The counter is used to connect the high-voltage circuit momentarily to the plates, and to trigger the shutter of a camera when a particle enters the chamber. As a particle traverses the chamber, it produces many ion-pairs along its path, so that the gas becomes conducting, and sparks occur between the plates in the region through which the ionizing particles pass. The light from them is focused by the lens system so that stereoscopic photographs may be obtained of the events. See also **Bubble Chamber**; **Cloud Chamber**; and **Particles (Sub-atomic)**.

SPARROW *(Aves, Passeriformes)*. A common form of small seedeating bird (*Aves*) of the family *Fringillidae*. The many species are for the greater part rather quietly colored in browns and grays with streaked and spotted plumage, but some bear conspicuous black or white marks and the browns of some species are very bright. Some of the sparrows have beautiful songs, although none rival such outstanding singers as the brown thrasher and the mockingbird.

The field sparrow, *Spizella pusilla*, chipping sparrow, *S. passerina*, white-throated, *Zonotrichia albicollis*, and white-crowned, *Z. leucophrys*, sparrows, song sparrow, *Melospiza melodia*, and in the west the lark sparrow, *Chondestes grammacus*, are among the well known North American species.

SPARTAN SPACECRAFT. See **Space Science Missions: Sun**.

SPAWNING. Reproduction and the bringing forth of young in fishes. In the cases of many species of fishes, the reproductive process is quite simple in that the male sheds his sperm and the female sheds her eggs in adjacent water wherein the mingling of these two materials causes fertilization. But, in numerous species, the process is varied and often reasonably complex. Most fishes have particular preferences for what might be termed idealized spawning conditions for their particular species. These conditions include water temperature, water salinity (fresh versus marine waters), and geographic location. The relative stillness of the water also plays a role. Because temperature, in particular, varies with season, the spawning habits usually have a very marked seasonal influence. This factor alone can cause long migrations of fishes to their desired water conditions, but salinity essentially does not change with seasons and, therefore, migrations from marine waters to fresh waters (or vice versa) is a major factor. These water conditions not only affect spawning, but more importantly they affect the survival of the fertilized eggs and the early development of the young. The eggs, which usually float on the surface of the water with many species, are subject to all manner of danger. In compensation for the great degree of chance involved in survival of the early life-giving processes, most species produce eggs in astronomical numbers. The eggs sometimes number into the several millions. For this reason, in many species, the ovaries are extensive, for example comprising about one-fifth of the body weight of a

female salmon. At a single spawning, the cod routinely deposits from 4 to 6 million eggs. Most fish eggs have a yolk, upon which the embryo feeds during incubation and often for a period after hatching. Then the very tiny mouth of the tiny fish commences to consume plankton. In the very early stages of life, the tiny fish frequently is referred to as a *larva* or *fry*. It is interesting to note that the larva forms of many species appear quite different in form from the adult fish, although a larval cod, for example, leaves no question but that it is a very small cod.

Another protective means occurs in the species of some fishes by way of the phenomenon of changes in sex and hermaphroditism. Some species are always self-fertilizing.

The oviparous (egg-laying) species often exhibit unusual ways of depositing and protecting their eggs: burrowing in a sandy bottom; attaching eggs by way of sticky substances to vegetation; or depositing eggs by drilling into the bodies or shells of other creatures, where the eggs are left for safekeeping and development. An unusual adaptation is found in the male Australian kurtus where eggs are incubated in a pouch on the male's forehead. Some species deposit their eggs in moist places on land, where they may remain for a few minutes or few days. The grunion is very precise about time of year, phase of moon, and tide, depositing its eggs in wet sand, whereupon they are immediately fertilized by the male. Then, within a few minutes, they are hatched and carried back to sea by the waves. See also **Silversides (Osteichthyes)**.

The spawning habits of several species are described briefly in this volume. Refer to list of entries under **Fishes**.

There are numerous species where the young are born alive. These are termed ovoviviparous, the incubation and hatching of the eggs occurring within the body of the female. The young in these instances usually require careful attention and monitoring of one or both parents. In the discus, for example, the young "nurse" upon fluids and mucus present on the sides of both male and female parent. The parents take turns in this procedure.

SPECIAL WEATHER STATEMENTS. See **Meteorology**.

SPECIFIC ACTIVITY. Three common uses of this term are: 1. The activity of a radio element per unit weight of element present in the sample. 2. The activity per unit mass of a pure radionuclide. 3. The activity per unit weight of any sample of radioactive material. Specific activity is commonly given in a wide variety of units (e.g., millicuries per gram, disintegrations per second per milligram, counts per minute per milligram, etc.). See also **Radioactivity**.

SPECIFIC GRAVITY. For a given liquid, the specific gravity may be defined as the ratio of the density of the liquid to the density of water. Because the density of water varies, particularly with changes in temperature, the temperature of the water to which a specific gravity measurement is referred should be stated. In exacting, scientific observations, the reference may be to pure (double-distilled) water at 4 °C (39.2 °F). In engineering practice, the reference frequently is to pure water at 15.6 °C (60 °F). A value of unity is established for water. Thus, liquids with a specific gravity less than 1 are lighter than water; those with a specific gravity greater than 1 are heavier than water. From a practical standpoint, it usually is more meaningful to express the specific gravity of gases with reference to pure air rather than to pure water. Thus, for a given gas, the specific gravity may be defined as the ratio of the density of the gas to the density of air. Since the density of air varies markedly with both temperature and pressure, exacting observations should reflect both conditions. Common reference conditions are 0 °C and 1 atmosphere pressure (760 torr; 760 millimeters Hg; 29.92 inches Hg).

Specific Gravity Scales. Arising essentially from a lack of communication between various scientific and industrial communities, a number of different specific gravity scales were formulated in earlier times. Because so much data and experience have been accumulated in terms of these scales, several methods of expressing specific gravity persist in common use. The most important of these scales are defined here.

API Scale — This scale was selected in 1921 by the American Petroleum Institute, the U.S. Bureau of Mines, and the National Bureau of Standards (Washington, DC) as the standard for petroleum products in the United States.

$$\text{Degrees hydrometer scale (at } 15\,^{\circ}\text{C}; 60\,^{\circ}\text{F}) = \frac{141.5}{\text{sp gr}} - 131.5$$

Balling Scale — This scale is used mainly in the brewing industry to estimate percent wort but also is used to indicate percent by weight of either dissolved solids or sugar liquors. Hydrometers are graduated in percent weight at 60 °F or 17.5 °C.

Barkometer Scale — This scale is used essentially in the tanning and tanning-extract industry. Water equals zero. Each scale degree equals a change of 0.001 in specific gravity. The following formula applies:

$$\text{Sp gr} = 1.000 \pm 0.001 \times (\text{degrees Barkometer})$$

Baumé Scale — This scale is used widely in connection with the measurement of acids and light and heavy liquids, such as syrups. The scale originally was proposed by Antoine Baumé, a French chemist, in 1768. The scale has been widely accepted because of the simplicity of the numbers which represent liquid specific gravity. Two scales are in use:

$$\text{For light liquids, } ^{\circ}\text{Bé} = \frac{140}{\text{sp gr}} - 130$$

$$\text{For heavy liquids, } ^{\circ}\text{Bé} = 145 - \frac{145}{\text{sp gr}}$$

The standard temperature for these formulas is 15.6 °C (60 °F).

To calibrate his instrument for heavy liquids, Baumé prepared a solution of 15 parts by weight of sodium chloride in water. On his hydrometer, Baumé marked zero at the point to which the float submerged in pure water; and he marked the scale 15 at the point to which the float submerged in the salt solution. He then divided the distance between the two marks into 15 equal spaces (or degrees as he termed them). In connection with liquids lighter than water, Baumé prepared a 10% sodium chloride solution. In this case, he marked the scale zero at the point to which the float submerged in the salt solution; and he marked the scale 10 at the point to which the float submerged in pure water. Thus, he created a scale which provided increasing numbers with decreases in density.

Users of the Baumé method found that the scale generally read 66 when the float was submerged in oil of vitriol. Thus, early manufacturers of hydrometers calibrated the instruments by this method. There were variations in the Baumé scale, however, because of lack of standardization in hydrometer calibration. Consequently, in 1904, the National Bureau of Standards made a careful survey and finally adopted the scales previously given for light and for heavy liquids.

Brix Scale — This scale is used almost exclusively by the sugar industry. Degrees on the scale represent percent pure sucrose by weight at 17.5 °C (63.5 °F).

Quevenne Scale — This scale is used for milk testing and essentially represents an abbreviation of specific gravity. For example, 20° Quevenne indicates a specific gravity of 1.020; 40° Quevenne, a specific gravity of 1.040, and so on. One lactometer unit approximates 0.29° Quevenne.

Richter, Sikes, and Tralles Scales — These are alcoholometer scales, which indicate directly in percent ethyl alcohol by weight in water.

Twaddle Scale — This scale is the result of attempting to simplify the measurement of industrial liquids heavier than water. The range of specific gravity from 1.000 to 2.000 is divided into 200 equal parts. Thus, 1° Twaddle equals 0.005 sp gr.

An abridged compilation of specific gravity conversions is given in Table 1. The specific gravities of numerous materials are given throughout this volume.

Determination of Specific Gravity. The principal means for measuring specific gravity (and density) of liquids and gases are listed in Table 2.

Hand Hydrometer. This instrument consists essentially of a long, slender glass float weighted at the lower end and provided with a scale so graduated that the depth to which the instrument sinks in the liquid indicates the specific gravity by direct reading of the scale. See Fig. 1. The numbering of the scale increases from the top downward. The instrument sometimes is proportioned so that the numbering begins with unity at the top, being applicable only to liquids heavier than water; in others, it increases from the top to unity at the lower end and is for use with liquids lighter than water; in still other designs, unity is marked at the middle of the scale

and thus the instrument may be used for both light and heavy liquids. To be sensitive, the stem carrying the scale must be slender. It may be observed that the scale intervals corresponding to equal increments of density cannot be equal where the stem is of uniform diameter. These intervals, in fact, are inversely proportional to the square of the density, being much smaller at the lower than at the upper end of the scale. To avoid this, some hydrometers are graduated with an arbitrary scale having uniform spacing, as in the case of the Baumé scale, the readings of which may be converted into density by reference to tables. Nicholson devised a hydrometer for measuring the densities of small solids, the specimen being placed on the hydrometer, first above and then below the surface of the water in which the instrument floats, and its volume deduced from the resulting alteration in buoyant force. See Fig. 2. Hand hydrometers are used extensively where automatic, continuous, and remote readings of specific gravity or density are not required. However, a simple hydrometer can be used in a standpipe, equipped with an overflow at reading level, thus allowing for visual observations of a continuously flowing liquid.

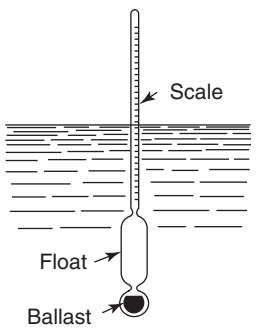

Fig. 1. Hydrometer for liquids.

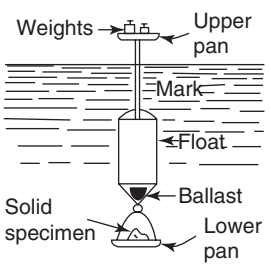

Fig. 2. Nicholson's hydrometer for small solids.

Automated Hydrometers. One form of hydrometer utilizes an opaque stem which, as the stem rises and falls, effects the amount of light which passes through a slit to a photocell. In this way, the photocell output is proportional to specific gravity and may be recorded by an electric instrument. In another industrial version, designed for remote transmission, the hydrometer is contained within a metal cylinder. A rod connects the bottom portion of the float to an armature, which moves vertically between inductance coils. Changes in inductance are transmitted by cable to a central instrument panel receiving instrument.

Chain-balanced Float. In this device, a submerged plummet, which is self-centering and operates essentially without friction, moves up or down with changes in specific gravity. A section of chain is fastened to the bottom of the plummet to provide a counter-buoyancy force. The effective chain weight varies as the plummet moves up and down. For each value of density or specific gravity, the plummet assumes a specific point of equilibrium. By means of a differential transformer, readings may be transmitted to a receiving instrument. A resistance thermometer bridge may be used where compensation for density changes with temperature is required. See Fig. 3.

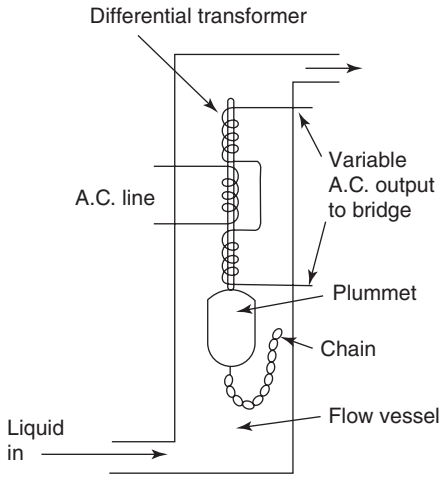

Fig. 3. Chain-balanced float or plummet-type specific gravity or density meter.

Balanced-flow Vessel. In this method of specific gravity measurement, a vessel with a fixed-volume is weighed automatically by means of a scale, spring, or use of a pneumatic force-balance system. The liquid being measured flows continuously into and out of the vessel by way of flexible connections. Accuracy of the system is very good.

Displacement-type Meter. In this instrument, the liquid being measured flows continuously through a chamber. A displacer element, usually a hollow metal sphere or cylinder containing air, is submerged fully in the liquid. The buoyant force on the displacer is measured, often by a pneumatic force-balance system, and any variations in this force reflect changes in the specific gravity or density of the liquid. The system can be compensated for changes in liquid temperature by thermostatically heating the chamber.

Differential-pressure Method. As shown in Fig. 4, two bubbler tubes, the exit of one being lower than the other, are installed in a vessel containing the liquid being measured. Air is bubbled into the liquid through these tubes. The difference in pressure required by each tube represents the weight of a constant-height column of the liquid equal to the difference in level of the ends of the two tubes. Thus, the instrument can be calibrated directly in terms of specific gravity or density. The accuracy ranges from 0.3 to 1% and provides a good approach for liquids that do not tend to crystallize in the measuring pipes. The system is used extensively in the pulp and paper industry for the measurement of white liquor, light black liquor, and bleach. There are several variations of the air-bubbler method, including the use of a reference column and a system with range suppression.

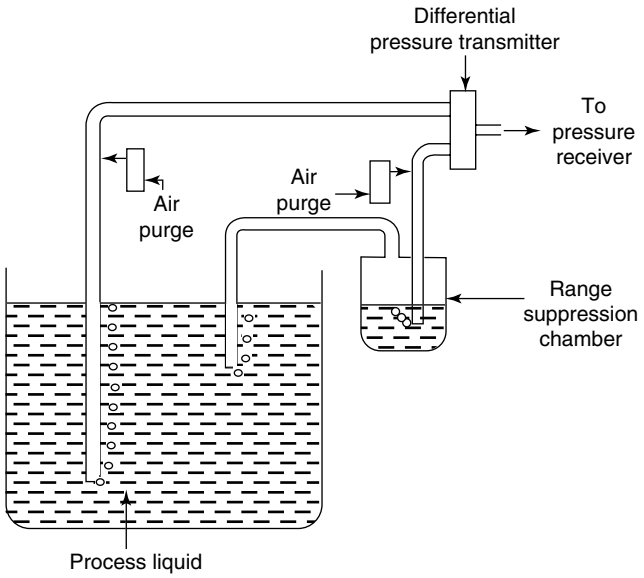

Fig. 4. Differential-pressure method for specific gravity measurement.

Boiling-point Rise System. For certain liquids, the temperature of a boiling solution of the unknown may be compared with that of boiling water at the same pressure. For a given solution, the boiling-point elevation may be calibrated in terms of specific gravity at standard temperature. Usually two resistance thermometers are used. The system finds use in the control of evaporators to determine the endpoint of evaporation. Good accuracy is achieved in the determination of one dissolved component, or of mixtures of fixed composition.

Nuclear-type Density Meters. As illustrated in Fig. 5, a radioisotope source is placed on one side of a pipeline while a detector is placed on the opposite side. Transmitted radiation is in proportion to the density of the material within the pipeline. Standard radiation detectors and associated electrical instrumentation can be used. An A.C. type amplifier is used for accurate determinations when the measurement spans are narrow. For wider spans, D.C. amplifiers may be used. A compensating cell may be used for zero suppression. This essentially eliminates zero drift rate that results from radioisotope source decay. The method is particularly attractive for the density and specific gravity determination of slurries. See also **Radioactivity**.

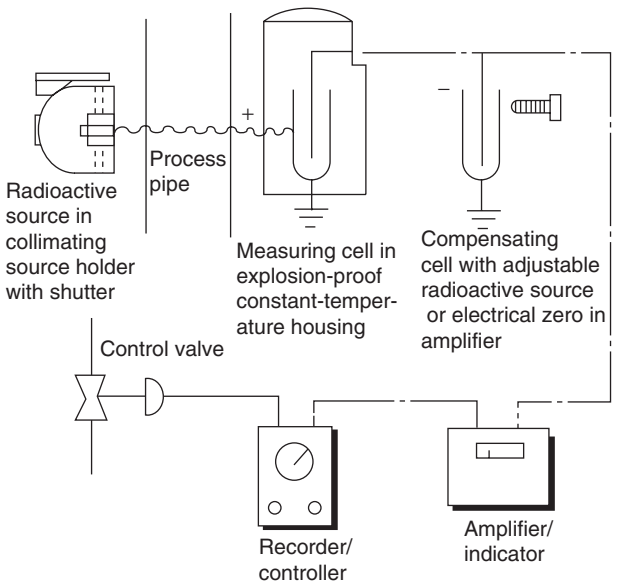

Fig. 5. Nuclear radiation-type density meter.

Gas Density Measurements. In the gas specific gravity balance, a tall column of gas is weighed by the floating bottom of the vessel. This weight measurement is converted to the motion of an indicating pointer or recording pen over a graduated scale, calibrated in units of density or specific gravity. In a viscous-drag type of instrument, one set of impellers is driven in a chamber containing a standard reference gas, and the power required to achieve rotation is measured. A matching set of nonrotating impellers is located in a chamber containing the gas under test. The sets of impellers are connected by a linkage and measure the relative drag shown by the tendency of the impellers to rotate in the test gas. The balance point is a function of relative gas density. In the buoyancy gas balance, a displacer is mounted on a balance beam in the vessel containing the test gas. A reading of the air pressure required to maintain the displacer at a perfectly horizontal position (observed through a window in the chamber) is read from a manometer. Then, the air is displaced in the chamber by the gas under test. The foregoing procedure is repeated. The ratio of pressure with air to pressure with the gas provides a measure of the density of the gas relative to air. This is primarily a laboratory type measurement.

SPECIFIC HEAT. Sometimes called specific heat capacity. The quantity of heat required to raise the temperature of unit mass of a substance

by one degree of temperature. The units commonly used for its expression are the unit mass of one gram, the unit quantity of heat in terms of the calorie. See also **Heat**.

Specific Heat at Constant Pressure. The amount of heat required to raise unit mass of a substance through one degree of temperature without change of pressure. Usually denoted by C_p, when the mole is the unit of mass, and c_p when the gram is the unit of mass.

Specific Heat at Constant Volume. The amount of heat required to raise unit mass of a substance through one degree of temperature without change of volume. Usually denoted by C_v, when the mole is the unit of mass, and c_v when the gram is the unit of mass.

SPECIFIC HEAT (Electronic). In the original formulation of the Drude free electron theory of metals, it was assumed that the electrons formed a classical gas whose specific heat is just $3Nk$ (N being the number of particles, k, Boltzmann's constant). No such specific heat was observed, but it was pointed out by Sommerfedd that the electrons should be treated as a Fermi-Dirac gas, for which the heat capacity at constant volume per mole of electrons is given by

$$C_v = \tfrac{1}{2}\pi^2 NkT/T_F$$

where T_F is the Fermi temperature. This formula suggests that only the fraction $(\pi^2/6)(T/T_F)$ of the electrons can actually contribute to the specific heat. Since this fraction is of the order of 10^{-3} at room temperatures, the electronic specific heat is negligible compared with the lattice specific heat except at temperatures of a few degrees absolute. In the band theory of solids, C_v is roughly proportional to the effective mass of the electrons.

SPECIFIC HEAT (Humphries Equation). An expression for the ratio of specific heats of moist air, useful in the calculation of the velocity of sound in the atmosphere:

$$C_p/C_v = \gamma = 1.40 - 0.1e/p$$

where γ is the ratio of specific heats, p is the total atmospheric pressure, e is the water vapor pressure.

SPECIFIC HUMIDITY. In a system of moist air, the (dimensionless) ratio of the mass of water vapor to the total mass of the system. The specific humidity may be approximated by the mixing ratio for many purposes: $q = w/(1 + w)$ where q is the specific humidity and w is the mixing ratio.

SPECIFIC SURFACE. The surface, or area, of a substance or entity per unit volume; obtained by dividing the area by the volume, and expressed in reciprocal units of length.

SPECIFIC VOLUME. The volume of a substance or entity per unit mass, obtained by dividing the volume by the mass; and expressed in units of length to the third power and reciprocal units of mass. Reciprocal of the density.

See also **Density**.

SPECTRAL ANALYSIS. A method of analyzing stationary time-series into a series of harmonic terms. In effect, the series is correlated with trigonometrical functions of type $\cos(\omega t + \beta)$ for a range of values of ω. A high correlation indicates the possibility of a harmonic of corresponding period in the original series; and in any case the pattern of variation of the correlation over a range of ω is typical of the constitution of the series. The process is analogous to the splitting of a ray of polychromatic light into a spectrum exhibiting its monochromatic constituents.

The correlation, or some simple function of it called the intensity, is usually graphed as ordinate either against the period $2\pi/\omega$, giving the *periodogram*, or against the frequency ω, giving the *power spectrum*.

The word periodogram is also used for other methods that attempt to detect periodicity in the series.

Similar methods can be applied to examine the relationship between two or more series. For two series this leads to two components, real and imaginary, of the spectral density. The real component is called the co-spectrum and the imaginary component the quadrature spectrum. The two are amalgamated to form a measure known as the coherence.

The spectrum can be regarded as a Fourier transform of the autocorrelation fraction. See also **Spurious Correlation**. A more sophisticated generalization concerns the Fourier transform of third-order moments and is known as the bi-spectrum, not a term to be recommended.

SIR MAURICE KENDALL, International Statistical Institute, London

SPECTRAL CENTROID. An average wavelength, computed especially for light filters and other light-transmitting devices, by taking a weighted average, for each wavelength, of the spectral energy distribution, of the incident light, the transmittance of the device, and the luminosity data of the eye.

SPECTRAL CHARACTERISTIC. A relation, usually shown by a graph, between wavelength and some other variable. 1. In the case of a luminescent screen, the spectral characteristic is the relation between wavelength and emitted radiant power per unit wavelength interval. 2. In a photoelectric device, it is the relation between wavelength and sensitivity per unit wavelength interval.

SPECTRAL CLASS. A casual examination of the stars with the eye or small telescope reveals that stars have different colors. If stars radiate approximately as black bodies, then it will be expected that they can be graded according to their temperature, i.e., their color. The first attempt to grade stars into groups or classes was at Harvard in the famous Henry Draper catalogue. This system has been refined into the present powerful system called the Yerkes or MKK classification and is contained in the Yerkes Atlas of Stellar Spectra.

In the modern classification, the Harvard classes are still retained; thus, there is the sequence of stars W, O, B, A, F, G, K, M, R, N, and S. The Yerkes classification is essentially one of ratios of various ionized and excited levels of atoms. For example, a BO-type star is determined primarily by the fact that the ratio of the 4552 Si III line to that of the 4089 Si IV line is less than one; whereas, in a B1-type star, this ratio is greater than one. For the later types of stars (in particular, the M, R, N, and S stars), the intensity of the TiO bands is read for classification. The classes from B through M are subdivided into ten units; thus, there is B0, B1, B2, etc., to B9 and G0, G1, G2, etc., to G9.

At the time when this spectral classification was developed, it was apparent that the stars were of different luminosity; i.e., that there were giant and supergiant stars. A criteria was developed for increasing luminosity based essentially on ratios of certain lines. The ratios will be slightly different due to the sharpening of lines in a giant atmosphere. This is due to the reduced pressure in these atmospheres.

The luminosity types are Ia, the most luminous supergiants; lb, the less luminous supergiants; II, the luminous giants; III, the giants; IV, the subgiants; V, the main sequence stars or dwarfs; and VI, the subdwarfs. It is apparent, then, that there is a two-dimensional classification involving luminosity and spectral type. This is called the luminosity spectral diagram or the Hertzsprung-Russell diagram, and is exhibited in the article on the **Giant and Dwarf Stars**.

In order to use the MKK classifications, one merely obtains spectrograms at the dispersion available to his spectrograph and compares them with a series of MKK standards. To do this, he selects an unknown star, takes its spectrum at the same dispersion, and compares it with his catalogue of MKK standards. In this way, he can easily classify within one subdivision of a spectral type many, many stars in any given period of time.

A second and perhaps much more powerful method of classification has been developed by Barbier, Chalonge, and Divan. The spectrum of a star is taken at very low dispersion, traced out by means of a microphotometer, and the Balmer decrement is measured. The three coordinates are obtained — Φ, D, and λ. Thus there is a three-dimensional classification, which differentiates very neatly between Population I and Population II. However, the resulting three-dimensional surface applies

only to spectral types O through approximately F6 and in the various luminosity classes, and so has the drawback that the fainter or redder end of the spectral sequence is not considered.

SPECTRAL COLORS. 1. Colors present in the spectrum of white light. 2. Colors that are represented by points on the chromaticity diagram that lie on straight lines between the achromatic point and the spectrum locus.

SPECTRAL ENERGY DISTRIBUTION. When radiation exhibiting a continuous spectrum, as that from a hot stove or the light from an incandescent lamp, is quantitatively analyzed, it is found that quite different amounts of power are represented by the radiation within equal ranges of wavelength or of frequency having different limits. The proportion in any such range depends upon the character of the source. Thus, in the radiation from a candle, the ratio of the energy output between 6,500 and 6,600 angstroms (red) to that between 4,500 and 4,600 angstroms (blue-violet) is greater than the corresponding ratio for the radiation from an arc lamp. If we divide the spectrum into small intervals of wavelength, say 10 angstroms, and plot the power output for each range as ordinate, with the mean wavelength of the interval as abscissa, the result is a curve showing the distribution of power through the spectrum. When the radiation is due to high temperature, as in the above examples, there is always a wavelength interval having maximum power, that is, the curve has a "peak," from which the ordinates fall off in both directions. Wien pointed out that the higher the temperature of the source, the farther toward the short-wavelength end of the spectrum does this peak lie. See Fig. 1.

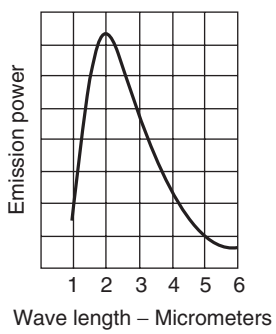

Fig. 1. Spectral energy distribution for black body at 1170° (1443° absolute) with peak at 2000 angstroms (0.2 micrometer).

An instrument utilizing a prism for dispersing the radiation, together with a thermocouple or similar device for measuring its flux density in different ranges, may be used to analyze infrared thermal radiation, and is called a spectroradiometer. The spectrophotometer performs a similar service for visible light, except that the results in this case are usually tabulated in terms of the visibility rather than the actual power of the emission. See also **Wien Laws**.

SPECTRAL FUNCTION. A necessary and sufficient condition for $\rho(\tau)$, where $\tau = 0, 1, 2, \ldots$, to be an autocorrelation function of a discrete stationary stochastic process is that it is expressible in the form

$$\rho(\tau) = \frac{1}{\pi}\int_0^{\pi} \cos\,\tau\omega\, dF\,(\omega)$$

where $F(\omega)$ is a nondecreasing function with $F(0) = 0$, $F(\pi) = \pi$. For a continuous process the corresponding condition is that:

$$\rho(\tau) = \frac{1}{\pi}\int_0^{\infty} \cos\,\tau\omega\, dF\,(\omega)$$

With $F(0) = 0$, $F(\infty) = 1$. Conversely, we have

$$F(\omega) = \omega + 2\sum_{j=i}^{\infty} \frac{\rho_j}{j} \sin j\omega, 0 \le \omega \le \pi$$

For the discontinuous process, and

$$F(\omega) = \frac{2}{\pi}\int_0^{\infty} \rho(x)\frac{\sin x\omega}{x} dx, 0 \le \omega \le \infty$$

for the continuous case. The function $F(\omega)$ is variously called the spectral function, *integrated function*, power spectrum or integrated power spectrum; the first appearing to be the simplest usage. Similarly, $dF(\omega)/d\omega$ is called the *spectral density*.

Both spectral function and spectral density can be defined directly without invoking the concept of autocorrelation.

SPECTRAL SENSITIVITY. Three uses of this term are: 1. The sensitivity of a detector measured for narrow spectral bands throughout the spectrum. 2. The emitted radiant-power wavelength distribution of a luminescent screen under a given condition of excitation. 3. The sensitivity of a photoelectric device in relation to the wavelength of the incident radiant energy.

Spectral sensitivity is usually displayed on a spectral characteristic.

SPECTROCHEMICAL ANALYSIS (Visible). Chemical systems that exhibit a selective light absorptive capacity are colored. Hence, the terms *colorimetric analysis* and *colorimetry* often are used to designate the measurement of such systems when the objective is to determine the concentration of the constituent responsible for the color. The use of the term *colorimetry* in this respect is not to be confused with the use of the same term in physics where the term refers strictly to the measurement of color. See also **Colorimetry**.

Visible spectrometry may be used to determine a constituent constituting the major part of a sample, but it also may be applied to the determination of trace quantities. Some methods are applicable to amounts of a few parts per million, with some tests sensitive to 0.01 ppm or less.

Like other areas of spectroscopy, visible spectrometry has a wide range of applications. Included are most of the elements, many anions, functional groups, and innumerable compounds.

The main practical problems in the methodology of visible spectrometry are: (1) to prepare a suitable colored solution; and (2) to measure the light absorptive capacity of this solution, or to compare it with that of a colored solution of known concentration.

Visual spectrochemical analysis has largely been displaced by other, more automated instrumental methods.

SPECTRO INSTRUMENTS. *Spectro* is used as a prefix for a wide assortment of analytical instruments. *Spectro* is derived from *spectrum*, which originally referred to the component colors that make up visible light, the so-called rainbow colors of violet, indigo, blue, green, yellow, orange, and red. A very simple device made up of a glass prism to break up sunlight into color bands is referred to as a *spectroscope*. Much more sophisticated instruments are available for manual manipulation and observation, which still rely on this basic, simple principle; these are termed visual spectroscopes, and the field is called visual spectroscopy.

Over the years, the term *spectrum* has increased in application and meaning and now embraces the total electromagnetic radiation span — no longer being confined to the visible portion. Concurrently, the term *spectroscope* has broadened in meaning so that mention of spectroscope no longer signifies an instrument which operates in the visible region. This situation gave rise to the need for modifying words for use with the term *spectroscope* to signify the portion of the electromagnetic spectrum with which the instrument is concerned. Thus, there are infrared spectroscopes, x-ray spectroscopes, ultraviolet spectroscopes, microwave spectroscopes, and so on. Further, the term *spectrum* has widened to include practically any orderly array of phenomena. For example, a mass spectrometer sorts atoms or radicals by their atomic weight — over a spectrum of values. Other spectrometers analyze the decay "spectra" of radioactive isotopes.

In terms of what is measured or observed, there are (1) portions of the electromagnetic spectrum: gamma-ray, cosmic ray, x-ray, ultraviolet, infrared, far-infrared, microwave, and radiowave instruments; (2) regions pertaining to the energies of particles: beta ray (electrons), protons, neutrons, and mass associated instruments; and (3) instruments dealing with other "spectra" such as radioactive decay and Mossbauer effects.

The suffix *scope* was ample when spectro instruments were essentially manual and confined to visual observations with the unaided eye. As the functions of these instruments increased, new suffixes were required to completely describe the instruments. Thus, if the instrument provides a record of the measurement, either by means of photographic film or by pen recording on a chart, the suffix *graph* is used. Where a meter is utilized to display the information detected by a device such as a bolometer, thermocouple, or thermistor, and so on, the suffix *meter* may be used. In cases where an instrument is designed to measure the intensity of various portions of spectra (again not confined to visible light), the suffix *photometer* may be used. Thus, there are spectrographs (spectrography), spectrometers (spectrometry), and spectrophotometers (spectrophotometry).

But, with increasing complications of instrument design and flexibility of use, the foregoing terms still are not sufficient to fully describe many instruments. Although some instruments display a continuous spectrum of what is being measured, other instruments filter out, for example, certain incident radiation. In other words, certain radiation may be absorbed, giving rise to the terms *absorption spectrometer* or *absorption spectrograph*. In some cases, the energy level of the specimen under analysis must be raised, as by means of flame heating or a spark discharge. Instruments in this category are of the emission type — and hence such terms as *flame photometer* and *optical emission spectrometer*. The names of spectro instruments can be complicated further where some special function may be incorporated in the title. A few examples are:

Spectroheliograph: a spectrograph designed for use with a telescope and for making photographs of the sun, in which the radiation of a particular element in the radiation of the sun may be recorded.

Ultraviolet-visible Spectropolarimeter: an instrument for measuring the rotation of the plane of polarization in accordance with wavelength and light intensity.

Spectrophotofluorometer: an instrument which provides means for both controlling the exciting wavelength and for identifying and measuring light output of a fluorescing sample. If the term *fluorometer* alone were used, it could indicate an instrument with a filtered light input that will measure the fluorescent light from a sample, usually by wavelength.

SPECTROMETER (SBUV/TOMS). See **Nimbus Satellite Program**.

SPECTROSCOPE. Several types of instruments for producing and viewing spectra are included under this term. Variations in form are due, not only to differences in principle, but also to the type of radiation or phenomena to be examined. Terminology employed in this field of instrumentation is described under **Spectro Instruments**.

The earlier spectroscopes, developed by Fraunhofer, Ångström, and others in the early part of the last century, adapted Newton's discovery of the dispersion of light by a prism. The essential features shown in Fig. 1 are a slit, S, a collimator, C, for rendering the light from the slit parallel before entering the prism, one or more dispersing prisms, P, and a telescope, T (or a camera), for forming images of the slit in the various wavelengths and thus providing a method for viewing or photographing the spectrum. The light passes through these in the order named, being deviated by the prism through various angles according to the wavelength. When a spectroscope is provided with a graduated circle for measuring deviations, it is called a "spectrometer." The"direct-vision" or nondeviation spectroscope, employing an Amici prism, is a compact instrument for qualitative purposes. The photographic spectroscope, known as a "spectrograph," is now almost universally used in spectral research.

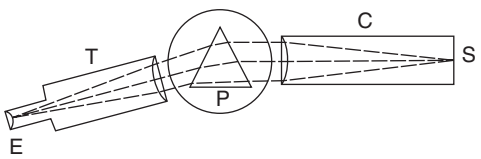

Fig. 1. Simple prism spectroscope: Collimator, C; slit, S; prism, P; telescope, T; and eyepiece for viewing spectrum, E.

Many modern spectroscopes employ the diffraction grating instead of the prism. In the concave grating spectroscope, developed by Rowland, the collimating lens and telescope or camera objective are unnecessary because of the focusing effect of the grating itself. See Fig. 2.

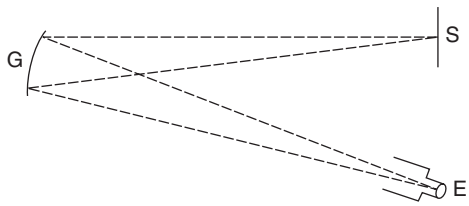

Fig. 2. Concave grating spectroscope: Slit, S; grating, G, eyepiece or plate-holder, E.

The growth of the importance of infrared spectrography and spectrophotometry in determining the structure of compounds and the composition of substances has led to the development of many infrared spectroscopes and other instruments. Most infrared spectroscopes and spectrophotometers employ front-surface mirrors instead of lenses. This eliminates the necessity for energy to pass through glass, quartz, or similar material. Furthermore, it would be difficult or impossible to make lenses that would bring rays of the widely varying wavelengths in the infrared region to focus at one point. Occasionally a rock salt lens will be found in an infrared spectrophotometer, but such lenses are usually not essential optical components. Parabolic mirrors bring energy of all wavelengths to focus at one point. Reflection from most metallic surfaces is generally very efficient in the infrared region. Both gratings and prisms can be used for dispersing the energy, but prisms seem to be more common, perhaps because energy in the infrared region is at a premium and none can be wasted in higher order spectra. The materials most suitable in the infrared region are quartz, calcium fluoride, sodium chloride, and sodium bromide, all in the form of single crystals.

The energy source for an infrared spectroscope or spectrophotometer is a Nernst glower or a Globar. The receiving element for the infrared radiation must be a bolometer, Golay cell or thermistor since photocells are not sensitive in this region of the spectrum. Indeed, the thermoelectric element chosen must be extremely sensitive, since the average energy in the dispersed beam is very small.

Most available infrared instruments use the Littrow mount for the prism, the beam being reflected from a plane mirror behind the prism and thus returning it through the prism a second time. This doubles the dispersion produced. Actually, a double-pass system is also used so that the beam goes through the prism four times. Other design modifications include those with single beam and double monochromator, double beam and double monochromator, and related combinations. See also **Infrared Radiation**.

Check alphabetical index for a wide range of spectroscopic instruments that are based upon numerous materials-energy relations. Also see **Analysis (Chemical)**.

SPECTROSCOPIC BINARIES. Discovery of the brighter component of Mizar in 1889 introduced a class of binary stars, which are not double stars in the ordinary sense of the term. The components are too close together for them to be observed separately even with optical telescopes of high resolving power. In such binaries the period is usually short and the orbital velocities high. Unless the orbit plane happens to be perpendicular to the line of sight, the orbital velocities will have components in the line of sight and the observed radial velocity of the system will vary periodically. Since radial velocity is measured with the spectroscope, employing the Doppler-Fizeau principle, the binaries so observed are known as spectroscopic binaries. In some spectroscopic binaries the spectra of both stars are visible and the lines are alternately double and single. Such stars are known as double-line binaries. In others the spectrum of only one component is seen and the lines in this spectrum move periodically from violet toward the red and back again. See Fig. 1.

The determination of the orbit of a spectroscopic binary is made from a long series of observations of the radial velocity of one or more components

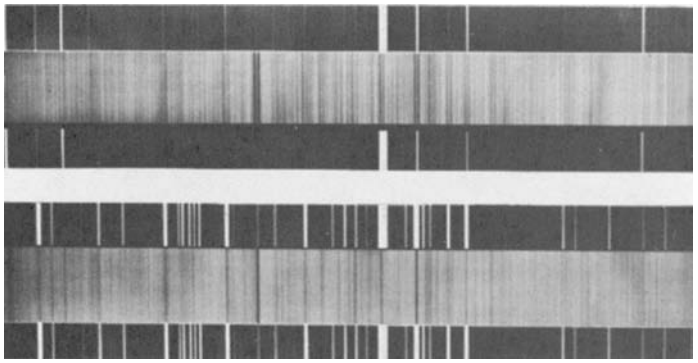

Fig. 1. Spectrogram of *Mizar*. The lines of the two components are separated in the upper photo and superposed in the lower. This was a classical observation made several decades ago at Yerkes observatory.

of the system. The observations are first plotted against time and from the resulting curve the period may be obtained. With this period determined observations are then reduced to a single epoch and the best possible curve drawn through the points, obtaining what is known as the velocity curve of the system. If the orbit is circular, the velocity curve will be a sine curve. If the orbit is elliptical, the shape of the curve will depend upon the eccentricity of the ellipse and the orientation of the major axis with reference to the line of sight. From the shape of the velocity curve the orbit of the system in space may be determined. In the solution of the spectroscopic orbit it is impossible to determine individually the semimajor axis, a, and the inclination of the orbit plane, i. However, the product of the semimajor axis by the sine of the inclination (i.e., $a \sin i$) may be determined directly in linear units (i.e., in either miles or kilometers). If either a or i can be obtained from other types of observations, as in the case of eclipsing binaries, a complete solution for the orbit can be made.

See also **Binary Stars**; **Eclipsing Binary**; and **Visual Binaries**.

SPECTROSCOPIC PARALLAX. The term *spectroscopic parallax* of a star is applied to a determination of the distance of a star in which the stellar parallax is determined from observations of spectral peculiarities of the star, together with determinations of the apparent brightness of the object.

The apparent brightness of a star depends upon two fundamental factors: the intrinsic brightness of the star and its distance from the observer. Expressed on the stellar magnitude scale, we find the apparent magnitude, m, the absolute magnitude, M, and the stellar parallax, p, to be connected by the analytical expressions: $M = m + 5 + 5 \log_{10} \pi$. The apparent magnitude of a star may be determined by a variety of methods of stellar photometry, and if a method is available for the determination of the absolute magnitude the value of the stellar parallax may be determined.

The relative intensities of certain spectral lines are different in giant and dwarf stars of the same spectral type. The relative intensities of selected pairs of lines may be compared in stars of the same spectral type and known absolute magnitudes and a "calibration curve" obtained. The relative intensities of the same pairs may then be found in stars of unknown absolute magnitudes and the calibration curves used to determine the absolute magnitude. Thus, the parallax may be determined from a study of spectra. The accuracy of the determinations of spectroscopic parallax compares very favorably with parallaxes obtained from the relative trigonometric methods.

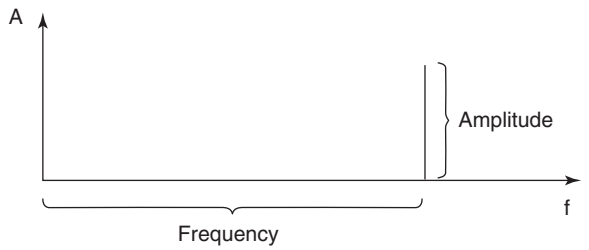
SPECTROSCOPY (INSTRUMENTAL ANALYSIS). A branch of analytical chemistry devoted to identification of elements and elucidation of atomic and molecular structure by measurement of the radiant energy absorbed or emitted by a substance in any of the wavelength of the electromagnetic spectrum in response to excitation by an external energy source. The types of absorption and emission spectroscopy are usually identified by the wavelength involved, γ-ray, X-ray, UV, visible infrared, microwave, and radiofrequency. The technique or spectroscopic analysis was originated by Fraunhofer who in 1814 discovered certain dark (D) lines in the solar spectrum, which were later identified as characterizing the element sodium. In 8161 Kirchoff and Bunsen produced emission spectra and showed their relationship to Fraunhofer lines X-ray spectroscopy was utilized by Moseley (1912) to determine the precise location of elements in the periodic system. Since then, a number of sophisticated and highly specialized techniques have been developed including the Raman spectroscopy, nuclear magnetic resonance, nuclear quadrupole resonance, dynamic reflectance spectroscopy, laser, microwave, and γ-ray spectroscopy, and electron paramagnetic resonance.

See also **Spectrochemical Analysis (Visible)**; **Spectro Instruments**; **Spectroscope**; and **Raman Spectrometry**.

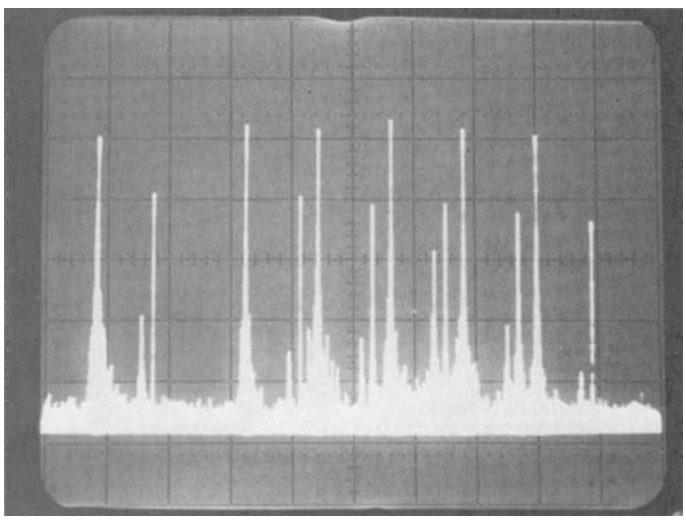
SPECTRUM. The radiant energy emitted by a substance as a characteristic band of wavelengths by which it can be identified.

See also **Spectroscope**; and **Radiation**.

SPECTRUM ANALYSIS. An electronic measurement technique for quantifying the level of electrical signals over a specific frequency range. The spectrum analyzer, an electronic instrument for making spectrum analysis measurements, conveys its signal information usually by displaying a rectangular plot of signal amplitudes (level) versus signal frequency (spectrum) on a cathode ray tube (CRT). Figure 1 shows a diagrammatical plot of a frequency spectrum and the comparable CRT photo of a spectrum analyzer output.



(**a**)



(**b**)

Fig. 1. (**a**) Information content of spectrum analyzer display; (**b**) Six-channel spectrum analyzer CRT display of six television broadcasts.

Signal analysis. An electrical *signal* transfers energy from one point to another. A signal may be strictly for power transfer, such as in high voltage power distribution, or it may be for information transfer, such as a telephone voice channel. It is necessary to quantify electronic signals for the effective design and maintenance of all types of equipment and machinery.

An electrical signal is composed of one or more frequency components channeled into a single transmission path, such as a cable, waveguide, or antenna. (A dc signal is no exception, it has one signal component at zero

frequency.) An instrument that is capable of identifying and quantifying each frequency component is a signal analyzer. A spectrum analyzer is a type of *signal analyzer*.

The number of different types of signal analyzers are differentiated mainly by the electronic measurement techniques used. Each has a significant contribution to make to spectrum analysis measurements. These techniques are: (1) Fourier transformation of an input time domain signal by mathematical computation (Fourier analyzer); (2) filtering an input signal through a number of piecewise tuned bandpass filters (real-time spectrum analyzer); (3) scanning an input signal with a tunable filter (spectrum viewer); and (4) heterodyne receiver (spectrum analyzer, tuned voltmeter, and wave analyzer).

Fourier analyzer. Any nonsinusoidal periodic signal has sinusoidal components predicted by the mathematical Fourier series equations. The Fourier analyzer processes a given input voltage signal with a digital computer, transforming the signal into the frequency domain with both phase and amplitude information. See Fig. 2.

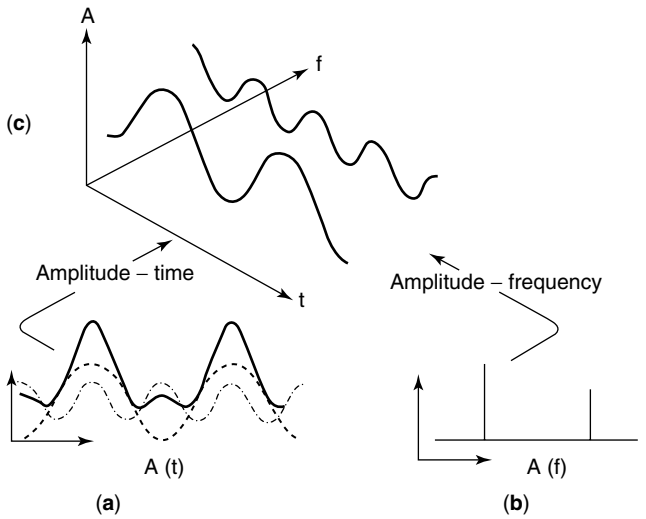


Fig. 2. (**a**) A time-varying input signal; (**b**) the Fourier analyzer transforms the signal into the frequency domain (with phase information also available, but not shown; (**c**) composite 3-dimensional plot showing relationship of time and frequency graphs.

The Fourier analyzer is also capable of translating nonperiodic voltage signals by calculating the Fourier transform in a form convenient for the digital computer sampling processes:

$$S_x''(t) = \Delta t \sum_{n=-\infty}^{n=+\infty} x(n\Delta t)e^{-2\pi f n \Delta t}$$

where $x(n\Delta t)$ are the analyzer-measured values of the input voltage signal.

Any time-varying voltage can be transformed. When a signal is not periodic, the total elapsed input time, T, is taken as the period. The analyzer develops a frequency spectrum (with phase information) of the signal as if it were being repeated at a $1/T$ rate. See Fig. 3. The CRT display is capable of showing either the real or imaginary frequency components on a rectangular grid or the magnitude/phase diagram on a polar plot.

The fundamental parameters that govern the Fourier analyzer's performance capability can be summarized by these equations:

$$T = n \times \Delta t \text{ (for the time domain)}$$

where T = total time of the sample, in seconds
n = number of samples taken, usually a power of 2, reflecting the amount of computer storage available
Δt = time between samples, in seconds
$F_{\max} = n/2 \times \Delta f$ (for the frequency domain)

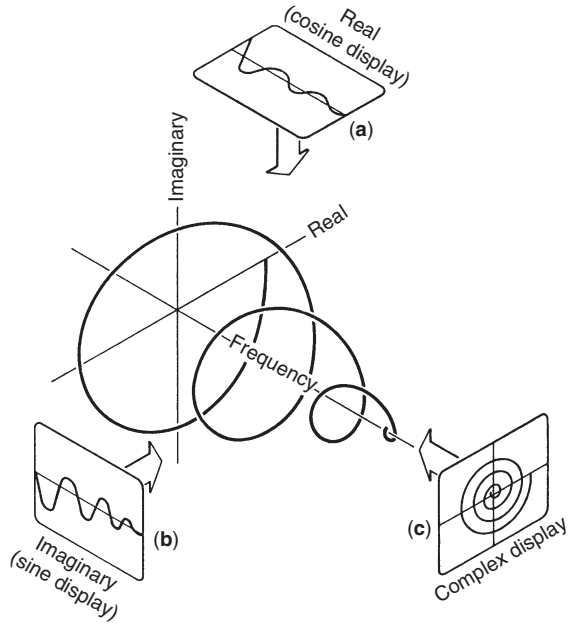

Fig. 3. Fourier analyzer processing a nonperiodic input voltage signal with the digital Fourier transform. (**a**) The real frequency component envelope (individual frequency spikes are not shown); (**b**) imaginary frequency component envelope; and (**c**) complex amplitude and phase display.

where $F_{\max}$ = maximum frequency of display, bandwidth, in Hz
$n/2$ = the number of frequency points, $\frac{1}{2}$ of n points are dedicated to either the real or imaginary frequency planes
Δf = the number of Hz between displayed frequency points, frequency resolution

Solving these to eliminate n:

$$\Delta t = \tfrac{1}{2}F_{\max} = \text{sample spacing in time}$$

$$\Delta f = 1/T = \text{frequency resolution}$$

$F_{\max}$ is typically 100 kHz or below. For a given n, either $F_{\max}$ or Δf can be optimized only at the expense of the other. However, the selection of sample times and bandwidths can be tailored to the individual application requirement.

Because of the Fourier analyzer's measurement and computational strength, it can be used to simulate the transfer function for processes that have measurable input/output voltage signals. The analyzer can then be used to simulate the processed frequency spectrum response to stimuli too difficult, dangerous, or costly to input to the real process.

Real-time spectrum analyzer. This instrument, shown in Fig. 4, displays the frequency spectral components on a CRT as they occur. The display response is directly proportional to the input signal at each instant of time. (The Fourier analyzer presents a computed display that simulates this real-time response, and thus it is sometimes referred to as a real-time analyzer.)

A real-time spectrum analyzer is able to respond to input stimulus essentially instantaneously because it passes the input directly to the display through a set of filters and detectors which quantify the spectral energy. See Fig. 5.

The real-time spectrum analyzer shows accurate stimulus-response characteristics up to 10 kHz. With as many as 500 high-resolution bandpass filters, the analyzer can display signals close together in frequency even when they differ in amplitude. Filter rolloff is typically a 15:1 voltage decrease per octave.

Spectrum viewer. The *spectrum viewer* uses the same input filter-detector as the real-time spectrum analyzer except the viewer uses only a single filter which is swept-tuned through the frequency band of interest. See Fig. 6.

The advantage is cost effective octave or greater band spectral coverage from 2 GHz to over 18 GHz made possible by a tunable yttrium iron garnet

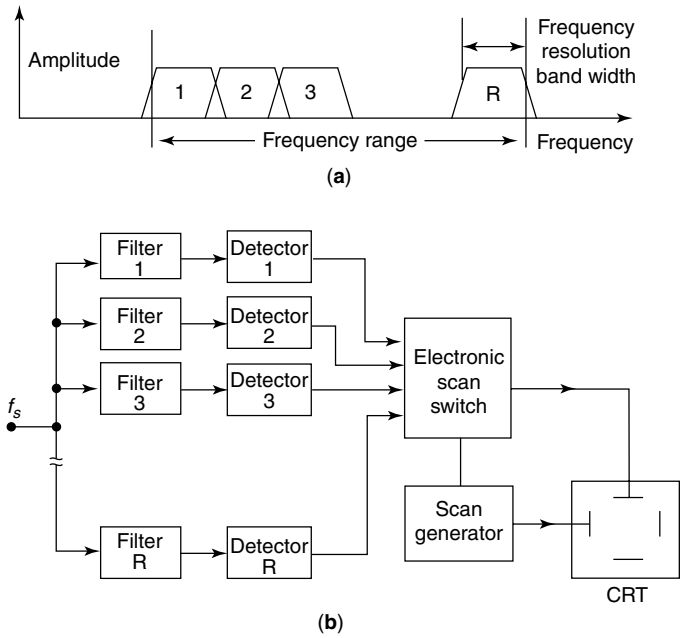

Fig. 4. (**a**) The real-time spectrum analyzer consists of a number of passband filters aligned such that their passbands continuously cover the spectrum of interest; (**b**) the electronic scan switch samples the filters fast enough to display instantaneous response of the input signals.

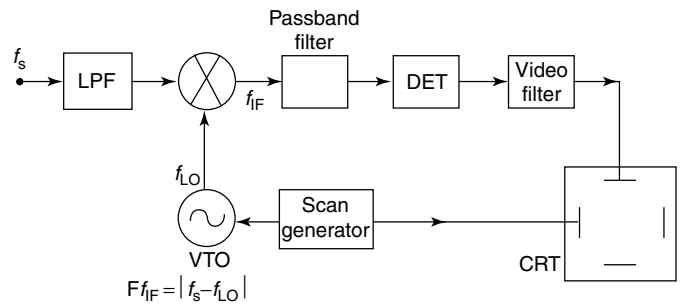

Fig. 5. Application of superheterodyne principle in real-time spectrum analyzer.

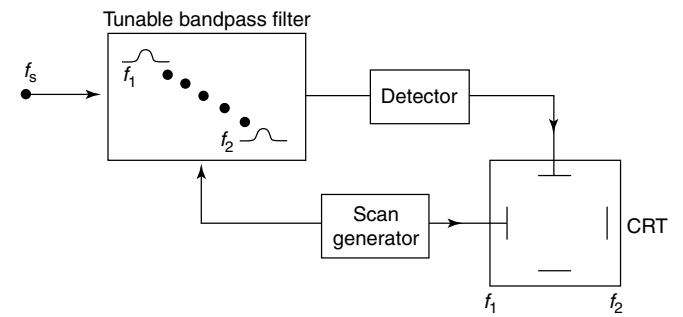

Fig. 6. Spectrum viewer operation. Synchronizing the tunable filter center frequency with the cathode ray tube horizontal deflection results in a spectral display for each sweep.

(YIG) filter. As with all swept-tuned analyzers, the spectrum viewer is not a real-time analyzer. Since it views only one small segment of frequency spectrum in any one instant, the filter must charge and discharge as it is tuned past various spectral signals. (The parallel filters of the real-time analyzer always remain responsive to input spectra, even though they are sampled for display by sweeping process.)

The spectrum viewer is the least expensive technique for displaying frequencies above 1 GHz; however, it generally does not have absolute amplitude calibration, high frequency resolution, or high sensitivity.

Superheterodyne receiver spectrum analyzer. The final category of signal analyzers utilizes the same technique used in almost every commercial radio receiver, the *superheterodyne* principle. The technique uses a bandpass filter as in the other analyzers, but in the heterodyne process the filter is not centered at the input frequency. Rather the filter is at a fixed frequency called the intermediate frequency (IF). Since most of the instrument's signal processes are done at the single IF, more sophisticated filtering and scaling is possible. This results in accuracy and high performance.

The local oscillator (LO) frequency is varied from a control on the instrument's front panel until the following condition is met:

$$f_{LO} - f_S = f_{IF}$$

where f_{LO} = local oscillator frequency
f_S = input signal frequency
f_{IF} = intermediate frequency

The resulting IF signal is processed with the familiar bandpass filter and displayed. This technique is operable from dc to over 40 GHz.

Tuning the superheterodyne signal analyzer is done either manually, reading only one point in the spectrum at a time, or automatically, sweeping and reading over a frequency range called a *frequency span*. Traditionally only the swept-tuned analyzer is called a *spectrum analyzer*. See Fig. 7. The manually tuned analyzer, or *wave analyzer*, is capable of spectrum analyzer measurements. Many of the operational characteristics are common to both the wave and spectrum analyzers.

The output for the wave analyzer is a meter or digital display, calibrated in units convenient for the industry to be served. Most spectrum analyzer detection methods are proportional to power; thus, units of power and voltage referred to a transmission characteristic impedance (Z_o) are the most commonly used.

Here are their definitions:

V = voltas (rms) into Z_0
mV = millivolts into Z_0
μV = microvolts into Z_0
dBm = decibel above a milliwatt
$$= 10 \log \frac{P}{10^{-3}}$$
dBmV = decibel above a milliwatt referred to Z_0
$$= 20 \log \frac{v}{10^{-3}}$$

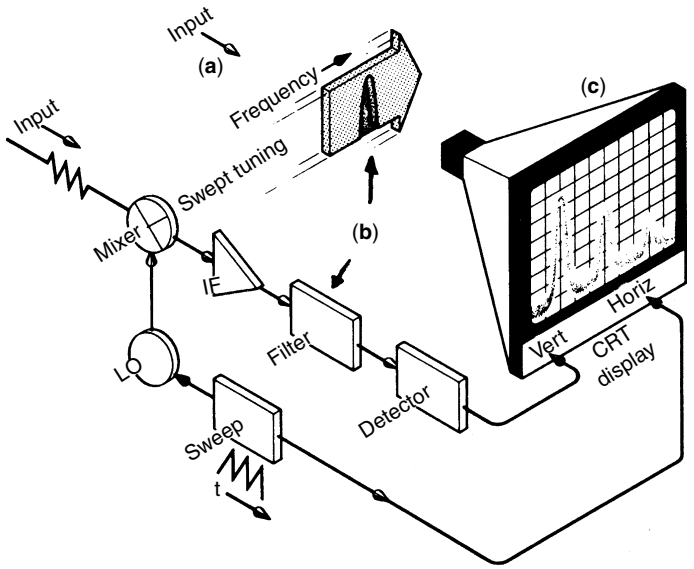

Fig. 7. Swept-tuned spectrum analyzer. Input spectrum (**a**) is mixed with sweeping local oscillator to produce three successive responses at f_{IF}. These are ushered through the IF filter (**b**) to the display (**c**) Note the displayed signal takes on the filter shape.

dBmV = decibel above a milliwat referred to Z_0

$$= 20\frac{v}{10^{-6}}$$

where P = power in watts
v = voltage in rms volts
Z_0 = transmission line characteristic impedance, such as 50 Ω, 75 Ω, 600 Ω

Absolute amplitude calibration means each point on the meter or CRT display represents a specific voltage or power level. *Dynamic range* is the amplitude ratio of the largest to the smallest signal that can be displayed simultaneously with no analyzer distortion products present. (Distortion products are harmonic and intermodulation signals generated inside the spectrum analyzer, which are displayed as legitimate signals.)

The lowest level signal that can be detected by the analyzer is specified by *sensitivity*. A spectrum or wave analyzer's sensitivity is limited by its inherent average noise. An unknown signal can be detected when the signal power is equal to the inherent average noise power. On the CRT this signal will appear 3 dB above the noise level. This relationship is given by

$$\frac{P+n}{N} = 2$$

where P = signal power, in watts
N = inherent analyzer noise power, in watts.

The ability to distinguish between two input signals that are close together in frequency is *resolution*. In spectrum analyzers this capability is primarily dependent upon IF resolution bandwidth, the 3 dB down points (half power) on the filter response curve. See Fig. 8. The narrower the resolution bandwidth, the better the resolution. However, since the IF filter must respond fully to the input signal ($f_{IF} = f_s - f_{LO}$) on each sweep, the sweep speed (Hz/second) must be slow enough to accommodate the filter. This relationship is shown by

$$T \propto \frac{S}{(BW)^2}$$

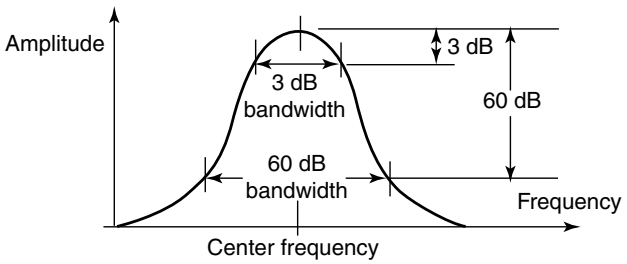

Fig. 8. Typical Gaussian filter. Signals of equal amplitude can just be resolved when they are separated by the 3 dB bandwidth. Unequal signals can be resolved if they are separated by greater than half the bandwidth at the amplitude difference between them. Shape factor is defined as the ratio of the 60 dB bandwidth to the 3 dB bandwidth.

or

$$BW \simeq \frac{S}{T} \times K$$

for Gaussian shaped filter,

where BW = 3 dB bandwidth, or resolution bandwidth of filter, in Hz
S = frequency span, in Hz
T = time to sweep S, in seconds
$K = 0.94(\text{Hz sec})^{1/2}$

Applications. Spectral response from electrical signals provides insight in a number of scientific fields. With the wide selection of transducers available, almost every industry and technology has areas where spectrum analysis can make a useful contribution. Some of these are summarized in Table 1.

JEFFREY L. THOMAS, Hewlett-Packard, Santa Rosa, CA

SPEECH CLIPPING. The clipping of peak speech signals (peak clipping) or the reduction of weaker speech signals to zero (center clipping) in intelligibility tests.

SPEED. The magnitude of the vector velocity. Speed is a scalar quantity and is expressed in units of length divided by time. See also **Velocity**.

SPEMANN, HANS (1869–1941). Hans Spemann was a German embryologist who, through his technical finesse and masterly design of experiment, exemplified the pinnacle of achievement of classical experimental embryology; his work culminated in the discovery of the amphibian embryonic organizer.

Hans Spemann was born in Stuttgart, Germany, in 1869. A traditional Gymnasium education led on to his starting a medical training at Heidelberg. But this he soon abandoned, having become caught up in the new prospects offered as biology entered its golden age of laboratory-based discovery. He continued studying biology at Munich (where he was especially intrigued by the discovery of Wolffian lens regeneration) and then (in 1894) undertook doctoral work at Würzburg, where he was a favorite pupil of the much revered Theodor Boveri, an important and far-sighted pioneer whose interests spanned descriptive embryology, cell biology and genetics. Here Spemann first worked with the newt embryo, the object of most of his subsequent research.

Spemann's work is characterized by, and outstanding in, two aspects. Firstly, regarding technique, he developed to a high degree new, precise methods and skills of microsurgery of embryos, including extirpation and transplantation. Secondly, he displayed supremely the art of the careful, logical design of experiments in order to reveal unambiguous answers to clearly formulated and fundamental questions. Thus he exploited the use of cross-species tissue exchange, a method that allowed him to follow (through the differing pigmentation of the cells) the subsequent fates of his grafts and so to unravel the source of signals controlling the development of the embryo.

At the time he began his work the trend was very much towards the use of experimental intervention (in place of mere description and

TABLE 1. APPLICATIONS OF SPECTRUM ANALYSIS

Type of Instrument	Frequency Range	Application	Examples
Fourier analyzer	dc-100 kHz	Sound and vibration	Acoustic imprints for voice, noise pollution, and sonar; structural analysis for rotating machinery; stimulus-response testing
		Time-to-frequency transformation	Mechanical structure models; real-time transfer function determination; improving signal-to-noise ratios (noise rejection)
Real-time analyzer	dc-10 kHz	Sound and vibration	Real-time acoustic and structural analysis
		Electronic circuit analysis (100 kHz)	Filter design
Swept-tuned analyzer (Spectrum analyzer)	10 Hz-40 GHz	Electronic circuit analysis	General circuit design measurements; modulation, noise, distortion, power, frequency, and stability

classification) as a method of uncovering insights about biology. Wilhelm Roux had advanced this approach in the field of embryology, naming it *Entwicklungsmechanik* (or developmental mechanics) but so far the applications had been few and relatively crude. After the customary apprenticeship in descriptive, comparative embryology, Spemann's first experiments were concerned with the problem of whether the parts of the future amphibian were mapped out right from the start of development and even perhaps within the egg. Roux had opened up investigations in the frog with experiments which showed that this seemed to be the case. But Hans Driesch had recently launched a classic debate with entirely opposite results in the sea-urchin. In an attempt to resolve the conflicting positions Spemann, famously using hair from his baby daughter, tied a constricting loop round a newt's egg and so divided it in two. The result was the formation of two complete newts from the one egg. This phenomenon of completion of the whole out of embryo parts (*embryonic regulation*) set the rest of his agenda; how could the entire final anatomical complexity come from starting conditions in the egg which were fully adjustable in this way and involved no commitment to form specific derivatives? It was Spemann above all who went on to refine the questions that arise from this basic phenomenon and who worked his way through a sustained series of discriminating experiments to tease apart solutions in terms of mechanisms. See also **Driesch, Hans Adolf Eduard (1867–1941)**; and **Roux, Wilhelm (1850–1924)**.

Spemann was soon looking at the possibility that the pattern of the embryo emerged sequentially, one part triggering the development of the next. By ablating the eye rudiment before it moved from the brain towards the skin surface where the lens normally forms, he found that the lens failed to form. This was the first demonstration of *embryonic induction*, indeed the first clear example of a specific causal dependence of one part on another. Further study of induction of the lens revealed puzzling complications (for example, variations among species, multicausal mechanisms, Spemann's "double assurance"), but many other cases were eventually to follow. Indeed, by the 1960s, inductors were identified for most vertebrate tissues and organs. The basic notion of what was later called an *epigenetic* causal cascade leading from a simple starting condition to a stepwise, increasingly complex anatomical organization began to be established.

From 1908 Spemann was Professor of Zoology at Rostock. His interests were now wide (homology, symmetry, twinning, teratology, embryonic fields, potency of daughter nuclei in the dividing egg cell, polarization in the inner ear) but they all led back to the fundamental question of the origins and control of developmental signals. In 1914 his prominence was recognized by his appointment as department head in a new, national research center, the Kaiser-Wilhelm Institute in Berlin. In 1919 he followed in the footsteps of his admired August Weismann (who had been a major early influence on his thinking) to Freiburg, where he stayed until his retirement in 1937.

Through a slow build-up of results and concepts Spemann now moved towards his crucial discovery of 1921. By deftly employing cross-species transplantation, Spemann was able to show that one specific region of the embryo dominated over everything else. When transplanted to a variety of noncorresponding locations in a host embryo this region (what we now know as the center of gastrulation movements), which he named "the organizer," deflected development around it and caused a second, normal array of embryo structures to be formed out of host tissue. In the organizer he had found the origin of the signals that initiate and coordinate the entire pattern of embryonic development. The results were published in full in 1924 with his student Hilde Proescholdt, who had died meanwhile. In 1933 he gave the Silliman lectures at Yale (Embryonic Development and Induction), which summed up all his work. In 1935 he was awarded the Nobel Prize in Medicine and Physiology.

Spemann's discovery was immensely influential. He himself probably always had an inclination to see the organizer as a vindication of an *organicist*, holistic or even quasi-vitalistic view of living organisms. However, from 1924 many researchers set out in pursuit of the nature of the organizer, particularly in chemical terms. The search for the organizer substance, initially taken up so enthusiastically by many international groups, ultimately led to considerable disappointment. Spemann's pupils were scattered by the war and took up different embryological issues. Eventually a "double gradient theory" emerged, but a "definitive" understanding remains somewhat elusive even today, despite vastly increased knowledge of available cellular and molecular machinery in the embryo.

Spemann had a "philosophy," a code of values and a style inherited from the previous century and this makes it difficult to integrate his work within today's biology. All his technical papers are in German. He is remembered for his "mystical" side, although this should in part be understood as a side effect of culture, language or translation. He belongs among the giants who laid out the foundations which define the modern domains of genetics, cell biology and embryology, and separated these domains from the evolutionary concerns which predominated when Spemann was young. He defined the issues that remain most crucial within developmental biology, issues that have often been obscured and sidetracked by premature and over-simplistic molecular interpretations. Spemann used to point out how important it is to ask questions about embryological development that made sense in terms of the embryo's own rules, to "speak the language of the embryo" as it were. His work did just that.

SPENCER, HERBERT (1820–1903). Herbert Spencer was an English sociologist and psychologist best known for his synthetic writings on natural science, evolutionary thinking, social progress and cultural development.

Spencer, the son of a private school teacher, was educated at home by his father and his uncle, the Rev. Thomas Spencer. He also frequented the Derby Philosophical Society, imbibing further ideas of freedom in religious thought, provincial radicalism, evolutionary thinking and a belief in scientific progress. He supplemented this feisty education with independent reading, public lectures and intercourse with active scientists. In this spirit he joined the railway boom as an engineer (1837) but by way of local politics found himself in London in 1848 as sub-editor of the *Economist*. This provided a base for his career as a writer, reviewer and cipher for, and synthesizer of, many aspects of the natural, life and human sciences in the second half of the nineteenth century within the framework of evolution.

Among Spencer's original work, *The Principles of Psychology* (1855) had a direct impact on its development as a discrete discipline. Spencer moved away from a previous emphasis on introspection and advocated instead a physiological approach. In this way he was a forerunner to W.M. Wundt, William James and I. Pavlov and their schools of experimental psychology. In his psychological wrting he supported the idea of a species or racial character but failed to formulate precisely what he meant. See also **Pavlov, Ivan Petrovitch (1849–1936)**.

Other works that can be placed within definite fields include *The Study of Sociology*, (1873); *The Principles of Sociology* (3 volumes, 1876–1897) and *The Principles of Biology* (2 volumes, 1864–1867). However, Spencer's interdisciplinary writings on evolution were particularly significant, in part for their subsequent use by social Darwinists.

Spencer was a proponent of *laissez-faire* and a committed evolutionary thinker, although he did not accept Darwin's theoretical mechanism of natural selection, but remained to the end of his life a Lamarckian. His notions of evolution were inextricably bound up with development as

progress, particularly the progress of the human race and the crucial unity of biological, social and cultural development: Lamarckian "use-inheritance" shielding this better than the contemporary alternatives. In his early writing Spencer discussed development and coined the phrase "**survival of the fittest**" in an essay (1852) in which he applied the ideas of Malthus to animal populations. This seemingly Darwinian approach was confounded by "Progress: Its Law and Cause," an essay from 1857 where he expounded his search for a theory that could replace religion in encompassing the universe, organic life, individual development and social/cultural evolution. See also **Lamarck, Jean — Baptiste Pierre Antoine de Monet de (1744–1829)**.

Spencer's ideas were often unsubtle, and were taken up and used with less subtlety still by political polemicists such as American anti-government agitators and right-wing thinkers in Europe. In imperialism, reaching a new height in the 1880s with the scramble for Africa, recourse to Spencerian "natural laws" supported the imposition of a racial hierarchy as an example of biological entities competing for survival.

SPERRYLITE. A mineral diarsenide of platinum, $PtAs_2$. Crystallizes in the isometric system with the pyrite group structure. It forms cubic, octahedral or pyritohedral crystals in addition to massive and reniform habits. Hardness, 6–7; specific gravity, 10.58; color, white; opaque. It was discovered by Francis Louis Sperry, an American chemist, in 1889 at Sudbury.

The most important occurrence of Sperrylite is in the nickel ore deposit of Sudbury Basin in Ontario, Canada. It also occurs in the layered igneous complex of the Bushveld region of South Africa and the Oktyabr'skoye copper-nickel deposit of the Eastern-Siberian Region, Russia.

SPERRY PROCESS. An electrolytic process for the manufacture of lead carbonate, basic (white lead) from desiliverized lead containing, some bismuth. The impure lead forms the anode. A diaphragm separates anode and cathode compartments, and carbon dioxide is passed into the solution. Impurities, including bismuth, remain on the anode as a slime blanket.

SPHALERITE BLENDE. Also known as zinc blende, this mineral is zinc sulfide, [CAS: 1314-98-3] (Zn, Fe)S, practically always containing some iron, crystallizing in the isometric system frequently as tetrahedrons, sometimes as cubes or dodecahedrons, but usually massive with easy cleavage, which is dodecahedral. It is a brittle mineral with a conchoidal fracture; hardness, 2.5–4; specific gravity, 3.9–4.1; luster, adamantine to resinous, commonly the latter. It is usually some shade of yellow brown or brownish-black, less often red, green, whitish, or colorless; streak, yellowish or brownish, sometimes white; transparent to translucent. Certain varieties are phosphorescent or fluorescent. Sphalerite is the commonest of the zinc-bearing minerals, and is found associated with galena, chalcopyrite, tetrahedrite, barite, and fluorite, as a result of contact metamorphism, and as replacements and vein deposits.

Crystals of suitable size and transparency have been fashioned into gemstones, usually featuring the brilliant cut to best display sphalerite's high dispersion of 0.156 (B-G interval) — over three times that of diamond. Freshly cut gems are lively with an adamantine luster and could conceivably be mistaken for a fancy-colored diamond in passing, but due to sphalerite's softness and fragility the gems are best left unset as collector's or museum pieces (although some have been set into pendants). Collectors may pay a premium for stones over one carat (200 mg), as clean crystals are usually quite small. Gem-quality material is usually a yellowish to honey brown, red to orange, or green; the two most important sources are the Chivera mine, Cananea, Sonora, Mexico; and the Picos de Europa, Cordillera Cantabrica, near Santander on Spain's northern coast.

There are many European localities, including Saxony; Bohemia; Switzerland; Cornwall, in England; Sweden; Japan; and elsewhere. In the United States, sphalerite is found in Arkansas, Iowa, Wisconsin, Illinois, Colorado, New Jersey, Pennsylvania, Ohio, and especially in the area that includes parts of Kansas, Missouri, and Oklahoma. The word sphalerite is derived from the Greek, meaning treacherous, and its older name, blende, meaning blind or deceiving, refers to the fact that it was often mistaken for lead ore.

SPHENE. This mineral occurs as a yellow, green, gray, or brown calcium titanosilicate, corresponding to formula $CaTiSiO_2$, crystallizing in the monoclinic system. Fracture conchoidal to uneven; brittle; habit usually wedge-shaped and flattened crystals, also massive and lamellar; luster, resinous to adamantine; transparent to opaque; hardness, 5–5.5; specific gravity, 3.45–3.55.

Sphene is an accessory mineral of widespread occurrence in igneous rocks, and calcium-rich schists and gneisses of metamorphic origin, and very common in nepheline-syenites. In the United States sphene is found in Arkansas, California, New Jersey, New York; in Ontario and Quebec in Canada; and from Greenland, Brazil, Norway, France, Austria, Finland, Russia, Madagascar and New Zealand, as well as many other world localities.

SPHENISCIFORMES *(Aves, Spheniscidae)*. A group of flightless seabirds with very distinguishing characteristics. Their relationship to other orders of birds is uncertain, and therefore some ornithologists separate the penguins as a superorder or even a subclass which is distinct from all other living birds. Their closest relatives appear to be the Tube-Nosed Swimmers (*Procellariiformes*).

The morphological characteristics that distinguish these birds from other birds are a result of their adaptation to life in the water. The length is from 40 to 115 centimeters (16 to 45 inches), and the weight ranges from 1 to 30 kilograms (2 to 66 pounds). The long, spindle-shaped body has legs which are inserted far back, so they are most effective as oars and steering organs. The tail, as a steering rudder, is streamlined and triangular; the wings are transformed into flippers, but contain all the bones of a wing suitable for flying. The bones, however, are shortened, flattened, and tightly connected by ligaments, thus forming a rigid surface. The breast muscles (wing muscles) are large, taking up the whole front from the neck on down to the lower abdomen. The trachea is, as in *Procellariiformes*, divided lengthwise. The body is uniformly covered with feathers except for the brood patch; they have thick subcutaneous fat-pads. There are 6 genera with 18 species, which are confined to the Southern Hemisphere. See also **Penguin**.

SPHERE. A solid bounded by a spherical surface. It may be generated by revolving a semicircle about its diameter as an axis. A *radius* of a sphere is a straight line from the center to the surface of the solid. A *diameter* is twice as long as a radius for it passes through the center of the sphere and ends on the surface. All radii of a sphere are equal and all diameters are equal. A great circle of a sphere is determined by a plane passing through the center; if the plane does not pass through the center, the section is a small circle. An *axis* of a sphere is any diameter and its ends are called poles, often a north or a south pole.

Two arcs of great circles intersecting on a sphere determine a spherical angle. A spherical polygon is a part of the surface of a sphere bounded by three or more arcs of great circles. When it has three sides it is a spherical triangle, which may be right, obtuse, acute, equilateral, isosceles, or scalene. See also **Angle (Mathematics)**.

The volume of a sphere, $V = 4\pi r^3/3$, where r is its radius and its area, $A = 4\pi r^2$, which also equals the lateral area of a cylinder circumscribed about it. If the sphere is hollow, that is a closed spherical surface, so that its radius to the inside wall is r_1 and to the outside wall r_2, then $V = 4p(r_2^3 - r_1^3)/3$.

For area and volume of torus, see also **Anchor Ring (or Torus)**.
For other properties of a sphere, see also **Spherical Surface**.

SPHERE OF INFLUENCE (Planet). The surface in space about a planet where the ratio of the force with which the sun perturbs the motion of a particle about the planet, to the force of attraction of the planet equals the ratio of the force with which the planet perturbs the motion of a particle about the sun, to the force of attraction of the sun on the particle. The volume inside this surface defines the region where the attracting body exerts the primary influence on a particle. See also **Planets and the Solar System**.

SPHERICAL ABERRATION. If the surfaces of a lens or the reflecting surface of a mirror are spherical, the rays refracted through or reflected from the outer portions will be brought to a focus in a different plane than those from the center, thus producing a blurring of the resultant image, known as spherical aberration. This effect is more pronounced in short-focus lenses or mirrors than in long-focus instruments, for the curvature of the surfaces of the short-focus instruments is greater.

The decrease of spherical aberration with increase in focal length was discovered very early in the history of optical instruments, and during the seventeenth century we find telescope builders increasing the focal lengths of their instruments to tremendous proportions. Telescopes with focal lengths between 100 and 200 feet were not uncommon during this period, and the problem of supporting the long thin tubes so that they could be used for astronomical purposes and remain straight was one calling for great ingenuity. Descartes in 1637 published the theory of spherical aberration and showed that theoretically it could be corrected by grinding the surfaces of lenses and mirrors in curves other than spheres. The difficulties of grinding the required lens curves were apparently greater than those of operating the long-focus telescopes. About the middle of the eighteenth century John Dolland published the fact that spherical aberration could be corrected by the same method employed for the treatment of chromatic aberration, i.e., by using two lenses, one convergent and the other divergent. All modern telescopic lenses of good quality now employ the double object glass with the figures of the lenses and the separation between the components depending upon the ideas of the makers. For wide-angle, short-focus lenses, such as are used in modern hand cameras and in astrographic cameras, the simple pair of lenses does not provide sufficient correction for all of the aberrations, and three or more lenses are used in combination. Perhaps the most common is the so-called doublet, in which two pairs of lenses are used with a considerable separation between the pairs.

Spherical aberration may be corrected in the case of a mirror by grinding the concave surface in the form of a paraboloid of revolution instead of in the form of a sphere. This provides almost complete correction for rays entering the mirror parallel to the axis of revolution of the paraboloid, i.e., along the principal axis of the mirror; but for rays entering at a moderately large angle, spherical and various other aberrations make their appearance in the resultant image. Hence, while the reflecting type of telescope can be more easily corrected for the aberrations along the axis, nevertheless it cannot be used to obtain photographs of large areas with good definition throughout.

SPHERICAL HARMONICS. In analogy to harmonic functions in the plane, the solutions of the Laplace equation in spherical coordinates. Spherical surface harmonics are special sets taken over the surface of a sphere; therefore, the harmonic components are restricted to an integral number of waves over the sphere. Spherical harmonics have been applied in the study of the large-scale oscillations of the atmosphere.

SPHERICAL POLAR COORDINATES. A curvilinear coordinate system. Its parameters are: (1) the radius vector r from an origin or pole to the point; (2) the colatitude q, an angle made by r and a fixed axis, the polar axis; (3) the longitude f made by the plane of q with a fixed plane through the polar axis, called the meridian plane. The coordinate surfaces are: (1) concentric spherical surfaces about the origin, $r = \text{const.}$; (2) right circular conical surfaces with apex at the origin and axis along the Z-axis, $\phi = \text{const.}$; (3) planes from the Z-axis, $\phi = \text{const}$. The range of the variables is $0 \le r \le \infty$; $0 \le \pi$; $0 \le \phi\pi$. In terms of a right-handed rectangular system with the same origin:

$$x = r \sin\theta \cos\phi \quad r^2 = x^2 + y^2 + z^2$$
$$y = r \sin\theta \cos\phi \quad \theta = \cot^{-1} z/\sqrt{x^2 + y^2}$$
$$z = r \cos\theta; \qquad \phi = \tan^{-1} y/k$$

Synonymous terms are spherical coordinates or polar coordinates in space. If $\theta = \pi/2$, the point lies in the XY-plane and if the longitude ϕ is then called θ, as is customary, the system becomes that of polar coordinates in a plane.

See also **Conical Surface**; **Coordinate System and Polar Coordinates**.

SPHERICAL SURFACE. A surface all points of which are at a fixed distance, the *radius*, from a fixed point, the *center*. The term sphere is frequently used for this surface but it more properly means a solid bounded by a spherical surface.

In rectangular coordinates its general equation is

$$x^2 + y^2 + z^2 + Gx + Hy + Kz + L = 0$$

but if the center is taken at the origin of the coordinate system, the equation becomes $x^2 + y^2 + z^2 = r^2$, where r is the radius of the spherical surface.

The surface is measured in terms of the following parts: (1) *Zone*, a portion of the surface included between parallel planes. The bases of the zones are circumferences made by the planes but if one of the bounding planes is tangent to the surface, it is a zone of one base. The distance between the planes is the *altitude* of the zone. (2) *Lune*, a part of the surface bounded by the circumferences of two great circles. (3) Spherical *pyramid*, part of a sphere bounded by a spherical polygon and the planes of its sides. (4) Spherical *sector*, part of a surface generated by the revolution of a circular sector about any diameter of which the sector is a part. (5) Spherical *segment*, a portion of a spherical surface between two parallel planes. (6) Spherical *wedge*, a portion of the surface bounded by a line and two great semicircles.

If A is surface area, the various cases give for it: sphere, $4\pi r^2$; zone, $2\pi rh$; lune, $\pi r^2 a/90$; triangle or polygon, $\pi r^2 E/180$, where r is the radius of the surface, h is the altitude of the zone, a is the number of degrees in the angle, and E is the spherical excess, defined by $E = T - 180\ (n - 2)$, where T is the sum of the angles and there are n sides to the polygon.

See also **Sphere**.

SPHERICAL TRIGONOMETRY. A generalization of plane trigonometry, spherical trigonometry is primarily concerned with the solution of spherical triangles. It is used in many navigation and astronomical problems, as well as in the construction of certain kinds of maps.

Solution of a spherical triangle means the finding of unknown sides and angles from given values for other sides and angles. The right spherical triangle is the simplest case, but it, unlike the plane right triangle, can have two or even three right angles. If, however, it has two right angles, the sides opposite them are quadrants and the third angle has the same measure as its opposite side. If all three angles are right angles, the measure of each side is 90°. These cases are all relatively simple; hence, we will consider a triangle that has only one right angle, its opposite side in general not being 90°.

Let a, b, c be the sides of a right spherical triangle, measured by the angle subtended at the center of a sphere, and with opposite angles A, B, C, where $A = 90°$. Then 10 relations exist, as follows:

$$\begin{aligned}
\sin a &= \sin A \sin c & sinb &= \sin B \sin c \\
\sin a &= \tan b \cot B & \sin b &= \tan a \cot A \\
\cos A &= \cos a \sin B & \cos B &= \cos b \sin A \\
\cos A &= \tan b \cot c & \sin B &= \tan a \cot c \\
\cos c &= \cot A \cot B & \cos c &= \cos a \cos b
\end{aligned}$$

Since these equations are rather awkward. Napier's rules are convenient in actual use. They can be stated as follows: let co-A, co-c, co-B mean

the complements of the angles (co-$A = 90^\circ - A$) and arrange the parts as shown in the diagram. Then, calling any angle a middle part, it will have two parts adjacent to it and two parts opposite to it. Napier's rules are then: (i) the sine of a middle part equals the product of the tangents of the adjacent parts; (ii) the sine of part equals the product of the cosines of the opposite parts. See Fig. 1.

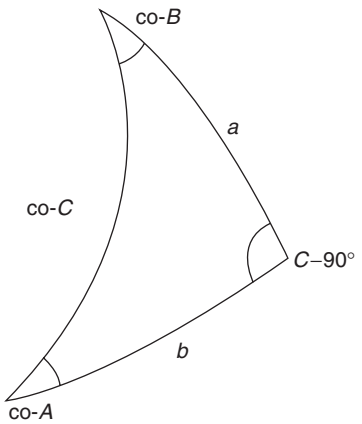

Fig. 1. Designation of angles in Napier's rules.

In the case of an oblique spherical triangle, the following relations may be obtained. (1) Law of sines:

$$\frac{\sin A}{\sin a} = \frac{\sin B}{\sin b} = \frac{\sin C}{\sin c}$$

(2) Law of cosines: $\cos a = \cos b \cos c + \sin b \sin c \cos A$ and $\cos A = -\cos B \cos C + \sin B \sin C \cos a$. (3) Haversine law: have $a = \text{hav}(b - c) + \sin b \sin c \text{ hav } A$. (4) Half-angle formulas:

$$\sin A/2 = \sqrt{\frac{\sin(s-b)\sin(s-c)}{\sin b \sin c}}$$

and

$$\tan A/2 = \frac{r}{\sin(s-a)},$$

where $2s = (a + b + c)$ and $r^2 \sin s = \sin(s-a)\sin(s-b)\sin(s-c)$. (5) Napier's analogies:

$$\frac{\tan(a+b)/2}{\tan c/2} = \frac{\cos(A-B)/2}{\cos(A+B)/2}.$$

(6) Gauss formulas:

$$\sin(A-B)/2 = \frac{\sin(a-b)/2 \cos C/2}{\sin c/2}.$$

(7) Rule of quadrants: in any spherical triangle, one-half the sum of two angles is in the same quadrant as one-half the sum of the sides opposite. (8) Spherical excess: $\tan^2 E/4 = \tan s/2 \tan(s-a)/2 \tan(s-b)/2 \tan(s-c)/2$. There are additional relations in several of these cases (for example, 3, 4, 5), obtainable by cyclic permutation of A, B, C and a, b, c.

In solving a spherical triangle there are six possible cases, depending on the parts given, as follows: (I) a, b, C; (II) A, B, c; (III) b, c, C; (IV) A, B, a; (V) a, b, c; (VI) A, B, C. Case (III) is an ambiguous case, since there may be two solutions or only one. Each of the six cases may be solved by several combinations of the relations given in the preceding paragraph.

See also **Trigonometry**.

SPHEROID. An ellipsoid. Also called ellipsoid of revolution, from the fact that it can be formed by revolving an ellipse about one of its axes. If the shorter axis is used as the axis of revolution, an *oblate spheroid* results, and if the longer axis is used, a *prolate spheroid* results. The earth is approximately an oblate spheroid.

See also **Ellipsoid**; and **Surface (Of Revolution)**.

SPHEROIDAL COORDINATE. A degenerate system of curvilinear coordinates obtained from ellipsoidal coordinates when two axes of the quadric surface are equal in length. There are two special cases: *oblate* and *prolate* spheroidal coordinates. In the oblate case, the coordinate surfaces are families of oblate ellipsoids of revolution around the Z-axis with semi-axes $a = c\sqrt{1+\xi^2}$, $b = c\xi$ ($\xi = \text{const.}$); hyperboloids of revolution of one sheet with $a = c\sqrt{1+\eta^2}$, $b = c\eta$ ($\eta = \text{const.}$) and planes from the Z-axis ($\phi = \text{const.}$). The following additional relations hold:

$$0 \le \xi \le \infty; \quad -1 \le \eta \le 1; \quad 0 \le \phi \le 2\pi$$
$$x = c\sqrt{(1+\xi^2)(1-\eta^2)}\cos\phi$$
$$y = c\sqrt{(1+\xi^2)(1-\eta^2)}\sin\phi$$
$$z = c\xi\eta$$

Alternative variables often used are $\xi = \sinh u$; $\eta = \cos v$; $0 \le u \le \infty$; $0 \le v \le \pi$.

For prolate spheroidal coordinates, the coordinate surfaces are families of prolate ellipsoids of revolution around the Z-axis with semi-axes $a = c\xi$, $b = v\sqrt{\xi^2 - 1}$), $\xi = \text{const.}$; hyperboloids of revolution of two sheets with $a = c\eta$, $b = c\sqrt{1-\eta^2}$, $\eta = \text{const.}$ and planes from the Z-axis, $\phi = \text{const.}$ The coordinates are limited in range: $-1 \le \eta \le 1$; $1 \le \xi \le \infty$; $0 \le \phi \le 2\pi$ and in terms of rectangular coordinates

$$x = c\sqrt{(1-\eta^2)(\xi^2-1)}\cos\phi$$

$y = c\sqrt{1-\eta^2)(\xi^2-1)}\sin\phi$; $z = c\xi\eta$. The variables $\xi = \cosh u$; $\eta = \cos v$; $0 \le u \le \infty$; $0 \le v \le \pi$ are often used.

This system is particularly useful in quantum mechanical two-center problems, for if the centers are taken at the foci of the system, the focal radii to a point where the surfaces of revolution intersect satisfy the relations $(r_1 + r_2) = 2c\xi$; $(r_1 - r_2) = 2c\eta$.

See also **Coordinate System**; **Curvilinear Orthogonal Coordinates**; **Ellipsoidal Coordinate**; and **Hyperboloid**.

SPHEROMETER. An instrument for measuring the curvature of solid spherical surfaces, either convex or concave, such as those of lenses; a measurement in which high precision is not easily attained. See Fig. 1. The most familiar mechanical device for this purpose is a form of micrometer. It resembles a small three-legged stool, the sharp steel points of whose legs form an equilateral triangle. The micrometer screw, also with a sharp point, is mounted at the center of this supporting trivet, and is adjusted to read zero when all four points are in one plane, as determined by standing the instrument on a flat plate of glass and screwing the micrometer point down to it. The distance from each of the legs to the central axis must be accurately known. It is called k, and if the elevation (or depression) of the micrometer point to fit a given spherical surface is a, then the radius of

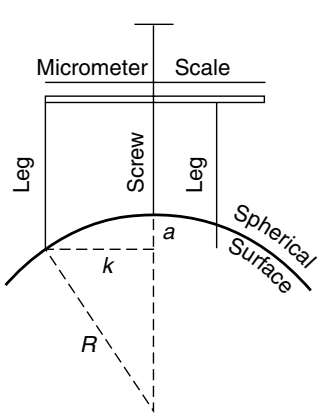

Fig. 1. Diagrammatic section of spherometer.

curvature of the surface is readily calculated as

$$R = \frac{k^2 + a^2}{2a}$$

The chief source of error are in determining just when contact takes place between micrometer point and surface, and in measuring k.

See also **Circular Curves**; and **Sphere**.

SPHYGMOMANOMETER. An apparatus for measuring blood pressure. It consists of a rubber-bag cuff, which is wrapped around the upper arm. This is inflated by a hand bulb. The cuff is connected by rubber tubing to a measuring device that is either a sealed column of mercury or a spring scale. Sufficient pressure is pumped into the rubber cuff to compress the brachial artery in the upper arm. A stethoscope is applied over the artery below the cuff and air is gradually allowed to escape from the cuff until the pulse can be heard. The reading on the scale or column of mercury at this point indicates the systolic pressure or the highest pressure in the arteries during contraction of the heart. The deflation of the cuff is continued, and that point on the scale when the last sound of the disappearing pulse is heard is the distolic pressure, or lowest pressure in the artery during diastole, or relaxation of the heart muscle between beats. The normal systolic reading of an adult varies from 110 to 130 or 140 millimeters of mercury. Normal diastolic readings vary from 60 to 90 millimeters of mercury. See also **Hypertension (High Blood Pressure)**.

SPICA (α Virginis). Ranking fifteenth in apparent brightness among the stars, Spica has a true brightness value of 2,800 as compared with unity for the sun. Spica is a blue-white, spectral type B star and is located in the constellation Virgo, a zodiacal constellation. Estimated distance from the earth is 260 light years.

Spica is particularly interesting in that it is believed to be the star that provided Hipparchus with the data that enabled him to discover the precession of the equinoxes. The temple at Thebes was oriented with reference to Spica in about 3200 B.C. Later temples which were oriented to this same star indicated the motion of the star due to precession and provided the necessary data.

See also **Constellations**.

SPICES. A spice is any aromatic, pungent, or colored vegetable product used in preparation or cooking to give zest and a piquant or pleasing flavor or color to foods; it is not a food of itself. The vegetable product may be fresh, dried, or ground. Examples of spices include ground dried cinnamon, whole dried cloves, ground fresh basil leaves, pressed garlic, and powdered paprika. Traditionally, what distinguished a spice was that it was used in the cooking process. This distinction was particularly applicable to the tropical or ancient spices. While modern cooking methods have made this difference somewhat less specific, it remains a reasonable distinction to maintain in the definition of spice.

A condiment is a vegetable or food product that has aroma, pungency, or color and is added to food after it is cooked and when it is served. By this definition, a spice or group of spices may be considered a condiment, depending on use. A condiment may be a single spice or composed of several spices, and often contains other food products such as oil or vinegar. Examples of condiments include ground black pepper, salad dressings, chutney, and ketchup. Tomatoes, since they are a food of themselves, are not spices but may be condiments. Salt, since it is neither a vegetable nor a food, is neither a spice nor a condiment, but is classified as a seasoning.

A seasoning is anything that enhances in flavor or appearance, or gives relish to foods. Spices, condiments, and salt or monosodium glutamate (MSG) [CAS: 32221-81-1] are all seasonings. See also **Bioprocess Engineering (Biotechnology)**.

In the 1990s, flavorists, traders, and culinary experts have expanded the term spice to include many vegetable products. Spices can be divided into four general categories. (1) The traditional or so-called *true or tropical spices*, eg, black and white pepper, cloves, cinnamon, ginger, nutmeg, and mace, may be buds, fruit, bark, roots, or other parts of tropical plants. (2) Herbs, e.g., sage, rosemary, marjoram, and oregano, are usually the leafy parts of plants that grow in the temperate zones. (3) Spice seeds, e.g., mustard, celery, caraway, dill, fennel, and anise, grow in both tropical and temperate zones. (4) Lastly, dehydrated aromatic vegetables, e.g., onion, garlic, parsley, and sweet pepper, are often dried to prevent spoilage.

The reduction of water limits mold formation, but only slightly affects the aroma or pungency. The dried product maintains its character and pound for pound is stronger in aroma and flavor than the fresh spice, since a nonessential component has been substantially removed. In areas where a spice is grown, the same product that is dried for storage and shipment is often used fresh for flavoring.

Many spices are processed to produce essential oils, oleoresins, essences, tinctures, extracts, resinoids, etc. These processes separate nonflavor components and further concentrate the aromatic or pungent principles of the spices. Such products allow a wider variety of uses and applications of the vital spice components. See also **Oils, Essential**; and **Oleoresin**.

A spice oleoresin is a concentrated form of the dried spice, processed by extraction, usually with a volatile nonaqueous solvent. The pharmacological herbs are usually processed by extraction with water or dilute alcohol, yielding powdered, fluid, or solid extracts. Oleoresins contain the odor and flavor of the spice including nonvolatile principles and, unlike spice essential oils, are usually viscous liquids, semisolid, or solid materials. Natural botanicals contain many components that make no contribution to the odor, flavor, or spice value of the item. Selection of the proper solvent removes such things as resins and resin acids, water, cellulose and pentosans, lignin, carbohydrates, sugars, starches, fiber, tannins, and minerals, while retaining such things as fixed oils (glycerides), essential oils, di- and triterpenoids, proteins, amides, phenols, and some waxes.

The oleoresin extraction process requires advanced technology which was accomplished prior to World War II only in industrialized countries that imported the dried spice. Modern factories now exist (ca) in countries that grow the spice as well as in many developing nations. Advantages to manufacturing the finished goods locally include reduced volume of the product with no loss of total flavor intensity, and reduced bulk and shipping costs. The product also is more stable to temperature and time, is bacteria-free and bacteria-stable, and is more uniform and easier to specify and control. Additionally, the raw spice need not pass the rigid scrutiny of international customs prior to extraction; thus broken spices, even perhaps some dustings, which do contain flavor but otherwise have little commercial value, can be extracted and salvaged.

History

The most ancient uses of spices appear to be therapeutic in nature. The use of spices was common in China but little, if any authentic Chinese records exist to confirm this. According to Chinese myths and legends, Shen Nung, the Divine Cultivator, founded Chinese medicine and discovered the curative powers of many herbs. He is said to have described more than 100 plants in a treatise reportedly written in 2700 BC. It has been shown, however, that no written language was available in China at that time. Although some of the herbal uses in the treatise go back several centuries BC, the work seems to have been produced by unknown authors in the first century AD. Other records on the use of cassia and ginger are known to have been written in the fifth and fourth centuries BC, in the latter case by Confucius.

The first authentic records of the applications of spices and herbs date from Egypt earlier than the twentieth century BC. Burial chambers and ancient temples show written proof of such products. An Egyptian medical scroll, dating from about 1515 BC, describes almost 800 medical drugs, herbs, and spices used not only in medicine, but also in embalming, purifications, cooking, and for fragrant ointments and perfumes. Cinnamon and cassia, available only from China and other parts of Asia, are among the spices recorded; this indicates a spice trade between the edge of the Mediterranean Sea and the Far East long before recorded history. Before the eighteenth century, control of the spice trade was one of the motivating economic forces of entire nations. From the ninth century BC to the fifteenth century AD, the spice trade was completely controlled by the Arabs in principal cities along the land and sea trade routes. The Greek, Roman, and later European civilizations increased the demand for spices, but despite European expansion eastward, the Arabs controlled the flow of products from the Orient.

In 1096 AD the Crusades opened up the northern Italian ports of Genoa and Venice to Oriental trade through Alexandria. When the Portuguese

found the sea route around the coast of Africa by way of the Cape of Good Hope, bypassing Alexandria, the Western spice centers were shifted from Alexandria and the ports of northern Italy to Portugal and Spain. Destruction of the Spanish Armada in 1588 removed Spain from competitive commercial shipping. By the 1620s the Dutch had driven the Portuguese from the Spice Islands and regulated the spice trade by creating artificial shortages and high prices.

By 1799, the British held northern Borneo, India, Ceylon, Singapore, and the mainland of Malay to the borders of Siam, and allowed the Dutch to retain the islands of the Malay Archipelago. The center of the spice trade in the West shifted to London.

From about 1815, fast vessels gave Salem, Massachusetts a virtual monopoly of the pepper trade with Sumatra. In the nineteenth and twentieth centuries, the spice trade began to play a secondary role in economic and political influence. The demand for spices in the United States directed the shift of the occidental spice center to New York while the oriental center was at Singapore.

Japanese expansion throughout the East Indian islands in the 1930s and 1940s, then anticolonialism and the emergence of the Third World nations, finally wrested control of the Spice Islands from the Dutch.

In the 1990s the United States is the leading factor in the spice trade. The western hemisphere has become a large producer of important spices, among them aromatic seeds and herbs, eg, mustard, capsicum, dehydrated onion and garlic, basil, tarragon, coriander, cardamom, ginger, and sesame seed. Brazil has become a factor in black pepper production.

Specifications, Analysis, and Quality

Spices are natural agricultural products and exhibit a range of variations of many specific characteristics. The most important quality assessment is the subjective physical observation of the whole or ground spice by an expert. The macroscopic and microscopic examination of spice is the criterion for the continued analysis of the product to determine adherance to specifications.

Physical appearance, as well as flavor quality and strength, can be influenced by soil conditions, rainfall, storms, blights, insects, growing and harvesting methods, storage, etc. All of these must be considered to evaluate a particular lot and to harvest, sell, or buy the lot and use it in a food product.

The FDA applies the Federal Food, Drug and Cosmetic Act, http://www.fda.gov/opacom/laws/fdcact/fdctoc.htm, to the spice industry and its products. The FDA has established a definition for spice which is somewhat general. It states, however, that vegetables such as onions, garlic, and celery are regarded as foods, not spices, even if dried.

The USDA considers most spices generally recognized as safe (GRAS). There are no standards of identity or legal definitions of spices. Spices used in drugs must meet the official standards of the *U.S. Pharmacoepia* in force. Advisory specifications may also be applied in commercial spice trading.

The American Spice Trade Association (ASTA), http://www.astaspice.org/, established by the industry, works with U.S. government organizations to set up specifications for spice products that conform specifically to the laws, however generalized they are.

Spices and herbs can play an important indirect role in good nutrition. They are not high in nutrient values, but they help to increase the appeal and satisfaction of foods that are highly nutritious. Spices do contain fat, protein and carbohydrates, electrolytic minerals, iron and B vitamins, and others, but even the highest calorie spice, poppy seeds, contains only two to three calories per serving in normal use.

Individual Spices

Allspice (Pimenta). Allspice is the dried, nearly ripe berry of the tree *Pimenta dioica* L., formerly called *Pimenta officinalis-Lindley* (Myrtaceae), which is a tropical evergreen growing semiwild in Jamaica and other Latin American countries. Allspice should not be confused with pimento or pimiento, a variety of red pepper. Allspice is the only significant commercial spice exclusive to the Western Hemisphere. *Pimenta* berries resemble black pepper corns; they are round and up to 0.65 cm ($\frac{1}{4}$ in) in diameter. The berries are hand-picked while green, then slightly fermented and sun-dried, turning them reddish brown. The aroma of *pimenta* berries resembles that of cloves, cinnamon, black pepper, and nutmeg, hence the name allspice or *quatre épices*. Allspice is used in seasonings, sauces, sausages, ketchup, jams, pumpkin, gravies, roasts, hams, baked goods, and teas. Caribbean cooking relies on Allspice as the main ingredient in jerk seasoning.

Most Allspice is produced in Jamaica. See also **Allspice**.

Ancho Chile. Ancho Chile Pepper is the dried, ground fruit of *Capsicum annum*. The product is made from poblano chile peppers grown in Mexico. Ancho has a mild paprika flavor, with sweet to moderate heat. The Ancho Chile together with the Mulato and Pasilla chiles form the "holy trinity" of chiles used to prepare mole sauces. Ancho is used to add flavor, heat, and color to sauces and moles.

Anise Seed. Anise seed is the dried, ripe fruit of *Pimpinella anisum* L. (Umbelliferea), a member of the parsley family indigenous to Asia Minor, Greece, and Egypt. Anise seed resembles caraway seed in appearance, but has a sweet, licorice flavor popular in Mediterranean and Latin countries, particularly in beverages, anisette, confectionery, salad dressings, and sausage flavors.

The star anise (*Illicium verum Hook* F.) is from a small evergreen tree, native to southwest China. When ripe, the hard brown fruits of this tree open up into an eight-pointed star, hence the name. The flavor and aroma of this spice is similar to that of *P. anisum*; the essential oils are of similar composition. The uses are similar but more localized.

Anise is used whole or crushed in cookies, cakes, breads, cheese, pickles, stews, fish, and shellfish. Roasting enhances the flavor. See also **Anise**.

Basil (Sweet Basil). Basil consists of the brown, dried leaves and tender stems of *Ocimum basilicum* L. (Labiatae), an annual native to India, Africa, and Asia. Basil is one of the oldest known herbs, and it is reported that there are perhaps 50–60 poorly defined *Ocimum* species which can only be identified according to their chemical components. The flavor of the *basilicum* type is warm, sweet, somewhat pungent, and peculiar, ie, methyl chavicol and linalool. It is used with meats, fish, certain cheeses, and tomato-based salads. The fresh leaves are ground and known as pesto with pastas. It is the main component of the liqueur Chartreuse.

Bay (Laurel) Leaves. These are the dried leaves of *Laurus nobilis* L. (Lauraceae), also called sweet bay or laurel tree, an evergreen with shiny green leaves up to 7.6 cm (3 inches) in length. It is not be confused with the bay rum tree (*Pimenta racimosa Mill* (Myrtaceae)) from Puerto Rico and neighboring islands, or California bay laurel (*Umbellularia californica Nutt*. (Lauraceae)). *L. nobilis* has been cultivated since antiquity in Mediterranean countries. The odor of the leaves is delicate but distinctly aromatic; the flavor is slightly bitter and burning. It is used extensively for meats, sauces, meat dishes, bouillabaisse, stews, and for pickling spice.

Capsicum. Several important condiments are derived from the dozens of spices and varieties of the genus *Capsicum* (Solanaceae), the nightshade family, particularly from *C. annum* L., ie, paprika, red pepper, and cayenne pepper. These plants are indigenous to Mexico, Central America, the West Indies, and much of South America. Capsicums are sensitive to climatic and soil conditions. Many horticultural varieties have been developed, differing in size, shape, taste, pungency, and color. Capsicum can be divided into two general groups, the sweet and the pungent.

Paprika, also called *sweet pepper* or *pimento* (pimiento, in Spanish), is the dried ripe fruit (stemless pod) of chiefly *Capsicum annum* L. The varieties of this annual herb, grown primarily for its bright red color, not pungency, are mild and slightly sweet. The odor is pleasant and somewhat aromatic. It is a rich source of vitamin C and serves as a garnish and flavorant in many foods, such as meats, soups, poultry, salad dressings, etc. It is an important constituent of ketchup and chili sauces.

Red pepper, cayenne pepper, and chilis belong to the pungent group of capsicums derived from the varieties of *C. annum* L. and *C. frutescens* L. They are usually small in size and exhibit a very hot, pungent flavor. They are cultivated primarily in tropical and subtropical latitudes, and occur in dozens of types. Often ground peppers are blended to arrive at a required or specified strength of flavor, pungency, and color. Red pepper serves where pungency is essential, e.g., in barbecue and spicy table sauces, chili powder, hot curries, and in medicinal preparations such as hair lotions and liniments. Capsicum is the main component of salsa, the best selling table sauce.

Caraway Seed. This spice is the dried ripe fruit of *Carum carvi* L. (Umbelliferae). It is a biennial plant cultivated extensively in the Netherlands and Hungary, Denmark, Egypt, and North Africa. The seed is brown and hard, about 0.48 cm (0.2 in) long, and is curved and tapered at the ends. It is perhaps the oldest condiment cultivated in Europe. The odor is pleasant and the flavor is aromatic, warm, and somewhat sharp (carvone). Caraway Seed is known for its flavor in rye bread, and it is used to flavor cakes, biscuits, cheese, carrot, and potato dishes, kuemmel liqueurs, applesauce, and cookies.

Cardamom Seed. The dried, ripe seed of *Elettaria cardamomum* M. (Zingiberaceae) is from this large perennial herb, indigenous to and cultivated in southeastern India and Sri Lanka. The seeds are removed from the capsules (pods) and when dried are irregularly round and about 0.23 cm (0.09 in) long. The aroma and flavor are pleasant, aromatic, and somewhat camphoraceous. It is a tropical spice, known since the fourth century BC. Throughout Arab countries, cardamom is the most popular spice, used in a coffee-like beverage, and is a symbol of hospitality. The spice is also used in baking pastries and pies in Nordic countries, and is used as well in ground meats. It is an ingredient of curry powder and pickle flavor. See also **Cardamom (Elettaria Cardamomum; Zingiberaceae)**.

Celery Seed. Celery spice is the dried ripe fruit of *Apium graveolens* L. (Umbelliferae) a biennial, sometimes annual, herb native to southern Europe. The seed is 0.42 cm (0.2 in) long and brown. The odor of the seed is characteristic and warm and the taste somewhat bitter. It is used in tomato ketchup, sauces, soups, pickles, pastries, salads, and certain cheeses. See also **Celery**.

Chili Powder. Chili powder is a commercial blend of several spices, i.e., chili peppers, oregano, cumin seed, onion and garlic powders, allspice, perhaps cloves, and others. Chili powder is the basic flavor for many highly spiced dishes, among them chili con carne, and is used in cocktail sauces and ground meats.

Cinnamon. There are two distinct types of cinnamon, each with its own varieties.

Cassia. (*Cinnamomum cassia Blum*). Lauraceae is the so-called cassia. It is native to southeastern China and has not been grown successfully outside of this area. The dried bark of this evergreen tree is stripped, ground, and sold almost exclusively in China. The leaves and twigs of the tree contain the same flavor components as the bark and are steam distilled to yield the cassia oil of commerce. Infrequently, small amounts of bark are bundled and exported as cassia lignea but cannot compete with the other varieties as bark spice. The Chinese prefer to sell the essential oil.

Other botanical varieties are called cassia, but the leaves of these varieties differ in flavor components from those of the bark.

Zeylanicum. The second type of cinnamon is the dried inner bark of the shoots of the tree *Cinnamonium zeylanicum* Nees, a moderately sized coppiced evergreen bush of the laurel family cultivated in Sri Lanka. The bark is stripped, rolled into quills, dried, and then shipped in large bundles. The aroma and flavor of the *zeylanicum* type, which contains eugenol as well as cinnamic aldehyde, is much milder than the *cassia* type. See also **Laurel Family (Lauraceae)**.

Cloves. The clove spice is the dried unopened buds of the evergreen tree, *Eugenia caryophyllus* Thumb (Myrtaceae). This tree is also called *Syzygium aromaticum* L. Other botanical names are used, but some discrepancies exist as to the proper nomenclature. The tree is indigenous to the Molucca Islands. In 1770, shoots were smuggled to the islands of Mauritius and Reunion, and eventually were cultivated on extremely large plantings in Zanzibar and the Pemba Islands in Tanzania, and Madagascar in Malagasy. The term clove is derived from the French *clou* for nail; the dried clove buds resemble round-headed nails, about 1.3 to 1.9 cm ($\frac{1}{2}$ to $\frac{3}{4}$ in) long. The color is dark reddish brown, the aroma is powerful, and the taste is hot and spicy. Cloves, both whole and ground, are widely used in baked goods, confectioneries, puddings, desserts, sweet syrups, pickling and pickled fruit, and spicy table sauces. About half of the world's clove production is mixed with tobacco to supply kretek cigarettes to Indonesia. See also **Clove Tree**.

Coriander Seed. This spice is the dried ripe fruit of *Coriandrum sativum* L. (Umbelliferae) and is indigenous to southern Europe and the Mediterranean. The seed is about 0.5 cm in diameter, yellowish to brown, and was one of the first herbs grown in the United States. The foliage and unripe fruit have a fetid, buggy odor, described by the Greeks as *koris* or bedbuggy. As the fruit ripens, the disagreeable odor fades away and is replaced by a warm, fragrant, and spicy odor. It is used in ground meats (sausage and frankfurters), cheeses, curry powders, and pickling spices; it has many medicinal uses as well.

Cumin Seed. Cumin spice is the dried ripe fruit of *Cuminum cyminum* L. (Umbelliferae). The seed-like fruit is elongated about 0.31 to 0.63 cm and is yellowish brown. It is native to upper Egypt and the eastern Mediterranean. It has a strong peculiar aroma and flavor, pleasing to some and offensive to others. Cumin seed is used in chutney and curry, chili powders, chili con carne, cheeses, and the pickling of cabbage.

Curry Powder. This powder is a commercial blend of many ground spices. The composition of curry varies in the East according to the region. It is used in the flavoring of exotic dishes, especially Indian, Indonesian, and Chinese specialties. Typical constituents of curry powder are coriander, ginger, nutmeg, clove, cinnamon, fenugreek, red pepper, onion salt, turmeric, etc.

Dill Seed. Dill spice is the dried ripe fruit of *Anethum graveolens* L. (Umbelliferae), a plant indigenous to the Mediterranean region and to the southern former Soviet Union. The seed is oval shaped, light brown, and up to 0.16 cm in length. The aroma resembles that of caraway seed, but is thinner. The herb is grown extensively in the United States, principally for the leaves which must be harvested before the plant flowers. The leaves, known as dillweed, are used mainly for essential oil production. Dill seed is used as a condiment, in soups, processed meats, sausages, spicy sauces, salads, and sauerkraut, and particularly in pickling.

Fennel Seed. Fennel is the dried ripe fruit of *Foeniculum vulgare* Mill. (Umbelliferae), a biennial or perennial aromatic herb native to India, southern Europe, and the Mediterranean, particularly in the vicinity of the sea. The seed is oblong–oval, straight or slightly curved, up to 0.80 cm in length, and yellowish brown. The flavor is aromatic and sweet and resembles that of anise seed. It is popular in Mediterranean countries for the flavoring of baked goods, soups, fish dishes, and sweet pickles. It is used in cordials and pharmaceutical preparations.

Fenugreek Seed (Foenugreek). This spice is the dried ripe fruit of the plant *Trigonella foenum graecum* L. (Leguminosae), an annual of the pea family native to western Asia and southern Europe. The seed is irregularly oval, up to 0.48 cm (0.20 in) in length, and is a brownish yellow. It has a slightly bitter, peculiar flavor and odor, somewhat pleasant, resembling maple or burnt sugar. It is used in curry powders, chutney, and imitation maple flavors. Medicinal uses continue from ancient times.

Garlic Powder. This powdered spice is the ground, selected dehydrated clove of *Allium sativum* (Liliaceae), a widely cultivated perennial herb with an underground compound segmented bulb. The aroma is powerful and offensive, developing by enzymatic action when the clove is crushed or moistened. In diluted form, it is attractive and indispensable in many Italian and French dishes, salad dressings, and sauces. Garlic is widely used in the United States for meat packing, sausages, frankfurters, and luncheon meats. One of the oldest of spices, it is indigenous to Egypt, China, and India and is grown throughout the world.

Ginger. This tuberous spice is the washed or peeled sundried rhizome (underground stem) of a perennial, *Zingiber officinale* Rose (Zingiberaceae). The color is an even, light buff and the tubers are referred to as hands because of their size and shape. Ginger was cultivated by the ancient Chinese and Hindus and is now grown throughout the world. The aroma and flavor is distinctively pleasant, aromatic, sweet, and pungent with a slight bite. African ginger is camphoraceous, Cochin ginger is lemon-like, and Jamaican ginger is perhaps the finest combination of both characteristics. Ginger is used in soft drinks, baked goods (gingerbread), confectionery, curry powders, meats, pickling, and certain cordials.

Mace. This unique spice is the dried aril or skin surrounding the kernel of *Myristica fragrans* Houtt (Myristicaceae), or nutmeg. It is grown and produced in Indonesia. The color is yellow orange; the flavor is similar to nutmeg, but softer, somewhat less pungent but fuller. Mace is used in a wide range of products, particularly baked goods, meats, and vegetables.

Marjoram (Sweet Marjoram). Marjoram spices are the dried leaves, with or without small portions of the flowering tops, of *Majorana hortensis*

Moench (Labiatae). It is a perennial herb. It may be confused, sometimes purposely, with oregano. Marjoram is a gray-green color and the flavor is highly aromatic, warm, and somewhat bitter. It is used in salad dressings, vegetables, meat stews, sausages, soups, and poultry stuffings.

Mint. The dried leaves of *Mentha spicata* L. (spearmint) and *Mentha piperita* L. (peppermint), hardy perennial herbs of the family Labiatae, are included in this spice category. These are indigenous to Europe and the Mediterranean but also are grown extensively in regions of the United States, ie, in the far west (Washington and Oregon) and the midwest (Michigan and Indiana). Although it has many medicinal uses, it is used particularly in toothpaste, mouth washes, chewing gum, and confectionery as well as sauces, desserts, salads, jellies, vinegars, and teas. See also **Mint Family (Labiatae)**.

Mustard. Mustard is composed of the dried, ripe seeds of several closely related genera, species, and varieties of herbaceous annuals of the family Cruciferae, eg, *Sinapsis alba* L. (syn. *Brassica hirta* Moench) known as white or yellow mustard; *Brassica nigra* L. Koch, black mustard; and *Brassica juncea* Coss and Czern, which is brown mustard. The first two are probably indigenous to southern Europe and the Mediterranean region, and *B. juncea* to the northern Himalayan area. The seed is extremely small, globular, and hard; at one time it was considered the smallest known seed. Within one growing season the plant may reach a height of 3 meters (9.8 ft) or more.

When ground and mixed with water, the seeds of black mustard ferment and yield a sharp, irritating odor and a pungent taste; white mustard does not react in this manner.

Mustard is marketed in three forms, ie, as a seed; as a prepared blend of ground mustard seed, vinegar, salt, sugar, and other spices; and as powdered dry mustard, also known as ground mustard or mustard flour. The seeds of the white or yellow mustard add pungency to any preparation, and that of the black mustard is required for aroma. Mustard is the largest volume spice imported into the United States and its use covers almost every flavor category except dessert items. See also **Brassica**.

Nutmeg. Derived from an apricot-like fruit of *Myristica fragrans* Houtt (Myristicaceae), nutmeg is an evergreen indigenous to the Moluccas and other East Indian islands. It is also cultivated in Indonesia and in Grenada in the West Indies. The fleshy fruit is globose, lemon-yellow to light brown, and when ripened splits in half exposing a beautiful scarlet reticulated areola (mace) investing the thin, hard, brown, and shiny shell which contains the seed (nutmeg). The oval nutmegs range in size up to 4 cm in diameter.

The flavor of nutmeg is pleasant, warm, spicy, and aromatic. Nutmeg is used to flavor baked goods, processed meats, curries, and beverages. See also **Nutmeg Tree**.

Onion Powder. Dehydrated onions, *Allium cepa* L. and other *Allium* species (Liliaceae), are ground to produce this spice. These botanicals are cultivated throughout the world. They generate their odor and flavor by enzymatic action in the presence of moisture. A sharp, pungent odor and flavor develops which is desirable on dilution. It is widely used in meats, sausages, vegetables, and many dishes. See also **Onion**.

Origanum (Oregano). Origanum is the dried leaves of *Lippia graveolens* (Verbenaceae) and *Origanum*, mostly *vulgare* species (Labiatae). The *lippia* species are grown in Mexico and the *origanum* in the Mediterranean countries, Greece, and Turkey. The light green leaf is about 1.59 cm ($\frac{1}{2}$ in) long having a strong and aromatic odor. The flavor is pungent, warm, and slightly bitter. The aroma resembles marjoram. Oregano is used in chili powders, Italian specialties, gravies, salad dressings, vegetables, and various meats.

Parsley (Parsley Flakes). The dried leaves of *Petroselinum hortense*, syn. *P. crispum* (Mill) (Umbelliferae), are from a hardy biennial, native to the Mediterranean region. The aroma is green and the flavor is pleasant, characteristic, and mild. Parsley is used for the seasoning of fish, meats, soups, salads, etc. Parsley seed, the dried ripe fruit of the parsley herb, has an aroma and flavor less pronounced than the leaves.

Pepper, Black. Black pepper spice consists of the dried immature berries (fruit) of *Piper nigrum* L. (Piperaceae). This vine-like perennial is native to the Malabar coast of southern India and is now commercially cultivated in the tropics of both hemispheres. There are many varieties of pepper, differing in appearance, size, and flavor. Dried black pepper consists of a light-colored kernel surrounded by a dark-colored, shriveled outer hull. There are about 3926 kernels to the kilogram. It has a strong characteristic fragrant odor, a hot, biting flavor, and is the most extensively used seasoning known.

Pepper, White. This spice is derived from the same plant as black pepper except that the berries are allowed to ripen fully. The dark outer hulls are removed by rubbing and washing after soaking and fermentation. White pepper has generally the same flavor and aroma as black pepper; however, it is milder and has a slight fecal odor.

Poppy Seed. The tiny dried seed of *Papaver somniferum* L. (Papaveraceae) is the poppy seed spice. The plant is an annual cultivated widely in Turkey, Iran, India, and China mostly for the preparation of opium. Poppy seed is one of the most ancient of spices, found among the ruins of the prehistoric lake dwellings in Switzerland. The black, kidney-shaped seeds, about 0.12 cm (0.05 in) long, are not narcotic and have an agreeable nutty flavor when roasted. Poppy seeds are used in whole form as a topping for bread, rolls, and pastries, and also in pasta, salads, and some vegetables. See also **Poppy (Papaver Somniferum; Papaveraceae)**.

Rosemary. The dried leaves of *Rosmarinus officinalis* L. (Labiatae) are from an evergreen shrub growing wild in the Mediterranean countries. The leaves are brownish green and resemble curved pine needles in shape, seldom exceeding 2.5 cm in length. Te odor is strong, fragrant, and aromatic, and the taste is somewhat bitter and camphoraceous. Rosemary is used to flavor stuffings, poultry, beef, lamb, fish, stews, and soups.

Saffron. Saffron spice is the dried stigmas of *Crocus sativus* L. (Iridaceae), a bulbous perennial native to southern Europe and Asia Minor and cultivated in the Mediterranean countries, particularly Spain. True saffron should not be confused with either meadow saffron, ie, *Colchicum autumnale* L. (Liliaceae) also called safflower, or bastard saffron, ie, *Carthamus tinctorius* L. (Compositae), both of which are occasionally used to adulterate true saffron.

Saffron is the world's most expensive spice. As the flower blooms the stigmas from 75,000 flowers (three per flower) must be hand picked to obtain about 500 grams (18 ounces) of spice after drying. The color is bright yellow-red and the aroma is powerful, somewhat bitter, peculiar, and exotic. It is used in exotic dishes, and is also used in cheese, pastry, and confectionery. See also **Saffron (Crocus Sativus; Iridaceae)**.

Sage. This spice consists of the dried leaves of *Salvia officinalis* L. (Labiatae), a perennial, low shrub which grows spontaneously in Mediterranean countries. Of the numerous sage species, the Dalmatian variety is considered the finest for flavoring. The color of the dried spice is grayish green or silver-gray and the aroma is strong, fragrant, warm, and slightly bitter with no camphoraceous or piney off-notes. Sage is used in the flavoring of meat, poultry, fish, certain cheeses, salad dressings, and sausages as well as poultry seasonings.

Savory (Summer Savory). This spice is the dried leaves and flowering tops of *Satureia hortensis* L. (Labiatae), an annual plant. The leaves are brown-green and up to 0.95 cm (0.4 in) in length. The spice odor is strong, warm, and highly aromatic; the flavor is sharp and somewhat resinous. Savory is used in poultry seasoning, meats, soups, eggs, salads, and sauces and is sometimes substituted for parsley.

Seasame Seed (Benne, Benni, Bene Seed). Sesame seed is the whole dried seed of *Sesamum indicum* L. (Pedaliaceae), an annual plant now cultivated in Mexico and Central America, although indigenous to Indonesia and tropical Africa. It may be the oldest condiment known. The seed is small, shiny, and oval shaped, about 0.32 cm (0.13 in) long. The unhulled seeds are dark and the hulled seeds are pearly white. Sesame seeds, when baked, have a pleasant, roasted, nutty flavor. They are used in baked goods and in confections, e.g., halvah.

Tarragon (Estragon). Tarragon spice is the dried leaves and flowering tops of *Artemisia dracunculus* L. (Compositae), a perennial herb indigenous to the southern former Soviet Union and western Asia. The aroma and flavor of the spice are warm, aromatic, and reminiscent of anise, although bittersweet. It is used in the flavoring of vinegar and in salads, soups, stews, and sauces such as bearnaise, tartare, etc.

Thyme. This spice is the dried leaves and flowering tops of *Thymus vulgaris* L. and *T. zygis* L. (Labiatae), small, perennial shrubs native to the Mediterranean area and Asia Minor. The tiny brown-gray-green, narrow, curled leaves rarely exceed 0.63 cm ($\frac{1}{4}$ in) in length. The flavor of the spice is aromatic, warm, and pungent. Thyme is used to flavor fish chowders, sausages, meats, poultry dressings, fish sauces, and in the liqueur Benedictine.

Turmeric (Curcuma). Turmeric is the cleaned, sound, dried rhizome of *Curcuma longa* L. (Zingiberaceae), a herbaceous perennial indigenous to southern Asia. Turmeric has a thick round rhizome or underground stem with blunt fingers. The flavor is distinctly aromatic, earthy, and somewhat bitter. Turmeric is used as much for its orange-yellow color as it is for flavor. It is used in curry powder, for coloring pickles, and for flavoring poultry, seafood, and rice dishes.

Vanilla. Vanilla is the dried, cured, full-sized, but not fully ripe fruit pods (beans) of *Vanilla planifolia* And. and *V. tahitensis*, J. W. Moore (Orchidaceae). The vine is native to the tropical rain forests of southern Mexico, Central America, the West Indies, and northern South America. Plantings were started in Madagascar, Reunion, Java, Mauritius, and Zanzibar in 1840. The Madagascar-type bean is still the most important, but Indonesia produces more than Malagasy. The structure of the flower prevents self-pollination and therefore, where insects are not prevalent, hand pollination is necessary.

A large portion of beans go to make extracts and tinctures, which are then used for ice cream, bakery goods, liqueurs, and many other items. See also **Bean**.

SPICULES. Bright spikes extending into the chromosphere of the Sun from below. They are several hundred miles in diameter and extend outward 5000 to 10,000 miles. Spicules have a lifetime of several minutes and may be related to granules.

SPIDER *(Arachnida, Araneida)*. Arthropods of almost exclusively terrestrial habits, known commonly for their ability to spin silken webs. They differ from other arthropods in one or more of the following characters: The body is divided into cephalothorax and abdomen, and the latter is unsegmented. The head bears a group of simple eyes. Four pairs of legs are present. The jaws are perforated by the ducts of poison glands. The ventral surface of the abdomen bears the openings of the lung books, respiratory organs of peculiar form, and a group of spinnerettes through which the ducts of the silk glands open.

Spiders are among the most interesting of all animals, and with few exceptions, e.g., the black widow spider, are harmless. Even though they secrete poison most of them are too small to bite a human being unless on a very thin fold of tissue, and most seem to have no inclination to bite. Even the large hairy species commonly called banana spiders or tarantulas are mild-mannered creatures.

To what extent the bad reputation of the black widow, *Latrodectus mactans*, is deserved seems difficult to establish. See Fig. 1. Apparently its bite is severely poisonous and occasionally fatal, and apparently it is vicious in its habits. There is contradictory evidence, however, so the case is not wholly settled.

Spiders vary greatly in habits. Some spin funnel-like webs in which they hide to await their prey, others form irregular webs, and still others make the orb webs so beautifully demonstrated in our gardens on dewy mornings. Other forms spin no web but capture their prey by pouncing on it from concealment or by open chase. Among these forms are the crab spiders, named from their short broad form, which lie in wait on plants and are sometimes almost perfectly hidden in flowers by their concealing coloration. The wolf spiders are stout hairy species, often black in color. They hunt like the predators for which they are named.

Fig. 1. Black widow spider. (*A.M. Winchester.*)

The spiders that capture prey without the use of webs have other uses for silk, such as the formation of cocoons or egg-sacs in which the eggs are deposited, and the construction of a smooth lining for their hiding places. The most remarkable example of the latter use is the nest of the trapdoor spiders of warm regions. These nests consist of a silk-lined burrow with a beveled margin at the surface of the ground. A lid hinged with tough silk fits perfectly into this beveled depression and can be held shut by the spider, which provides in its lining two depressions to be gripped by the claws.

The mating habits of spiders are also remarkable. The male, in many species much smaller than the female, goes through a courting procedure as complex as that of the birds, and is often killed by his consort. Reproductive adaptations are also peculiar in the males, in that the palpi are modified to convey the seminal fluid to the genital passages of the female. When sexually mature the male spins a web in which the contents of the reproductive organs are discharged, to be taken up into the cavities in the palpi. When the individual is successful in securing a mate he thrusts the palpi one at a time into her genital aperture.

SPIDER MONKEY. See **Monkeys and Baboons**.

SPILLWAY. One of the important adjuncts of a dam of the overflow type is a spillway, which is simply an opening through or over which

excess water may flow when the reservoir is full. The spillway may be a certain overflow section of the dam, or it may be located at one side of the dam.

SPINACH. Of the family *Chenopodiacea* (goosefoot family), spinach (*Spinacia oleracea*) is a pot herb, cooked and eaten much as other greens, such as chard, turnip greens, and mustard greens. Not all greens, of course, are members of the same botanical family. Many are brassicas, members of the *Cruciferae* (mustard) family. Spinach is a hardy cool-weather plant that withstands winter conditions in the southern United States. In most of the northern states, spinach is primarily an early-spring or late-fall crop, but in some areas, where summer temperatures are mild, spinach may be grown continuously from early spring until late fall. Winter culture of spinach is possible only where moderate temperatures, as found in California, prevail.

It is believed that the cultivation of spinach commenced in Persia (Iran) about A.D. 300 or 400. There is no mention of spinach in very ancient records. One writing in China, dating back to A.D. 647, refers to spinach as the "herb of Persia." The vegetable was introduced into Spain by the Moors in about A.D. 1100. By the late 1200s, spinach was known and consumed throughout most of Europe. An English writer referred to the vegetable as "spynoches" in 1390. There are no records, but it is assumed that spinach was brought to the United States by the early colonists. By 1806, three varieties were listed in seed catalogs. The first savoyed-leaf variety was introduced in 1828.

There are two principal variations of spinach: (1) the *savoy* or *wrinkled-leaf* kind; and (2) the *semisavoy* or *flat-leafed* kind. For the fresh market, the savoy type is usually preferred. The semisavoy kind is used for processing. Some botanists also classify spinach in terms of whether a variety is *prickly seeded* or *smooth seeded*. Modern growers greatly prefer the smooth-seeded varieties for ease and precision of planting. A savoy-type plant is shown in Fig. 1. One further classification distinguishes the *long-standing* varieties. Long-standing refers to the fact that the plant is slow in bolting — that is, it does not go to seed early, a desirable characteristic for growers.

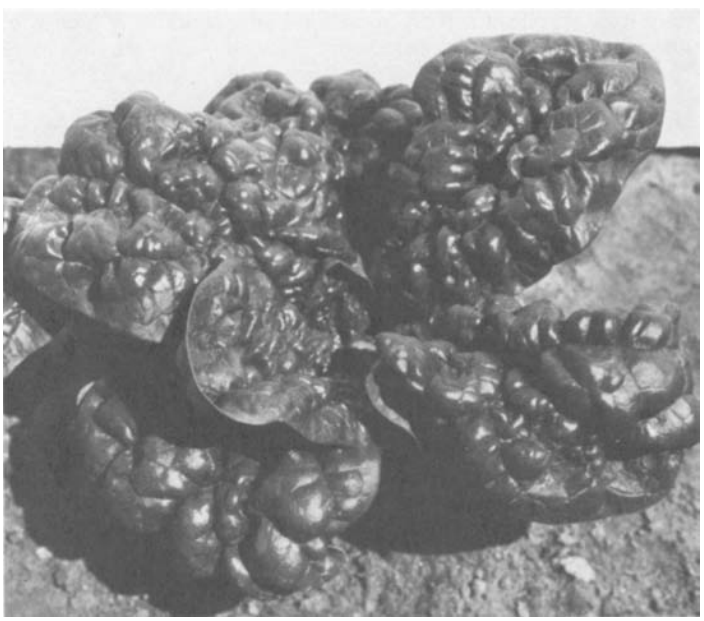

Fig. 1. A healthy spinach plant of *Long Standing Bloomsdale variety. (Spinacia oleracea). (Ferry Morse Seed Co.)*

SPINACH LEAF MINER *(Insecta, Diptera)*. One of several leaf-mining flies and maggots that attack a variety of plants. The spinach leaf miner (*Pegomya hyoscyami*, Panzer) attacks beet, chard, mango, spinach, and sugarbeet, as well as a number of weeds, such as chickweed and lamb's quarters. The insect is of much greater economic importance in Europe than in North America. It is believed that the insect was introduced into North America in the early 1880s. The small maggots produce blister-like blotches on the leaves of the aforementioned plants, rendering them unfit for market. Even where the leaves of such plants may not be used, the roots and seeds do not develop properly if the plant is vigorously attacked by this insect. The adult is a slender, grayish-black, two-winged fly, about $\frac{1}{4}$ inch (6 millimeters) long. The adult emerges in mid-spring and mating and egg-laying occur almost immediately. The eggs are laid on the underside of leaves. The very small maggots immediately commence feeding on leaves when hatched. They migrate from one leaf to the next and thus destruction is not localized. There are from 3 to 4 generations of the insect per year. Effective control can be achieved by destroying nearby host weeds. Screening of the plant beds with cheese-cloth also can be an effective control measure. Spinach planted in early spring or late fall usually is not affected. Where cultural methods are not sufficient, chemical controls, such as spraying or dusting parathion or diazinon in the affected areas will bring about control. Care must be exercised to avoid using chemicals near the time of harvest because of the possible presence of poisonous residuals on the leaves.

SPIN-DEPENDENT FORCE. The force between two particles which depends on their relative spin orientations and possibly on their spin directions relative to the line joining the particles. Physical basis could be the interaction between the magnetic moments of the particles, or in the case of nuclear forces, to the exchange of π-mesons between the nucleons.

SPINE. The vertebral column or backbone, in humans composed of 33 vertebrae which, grouped according to regions, are: 7 cervical; 12 thoracic; 5 lumbar, 5 sacral, and 4 coccygeal vertebrae. See also **Skeletal System**.

SPINEL. The mineral spinel is one of a group of minerals which crystallize in the isometric system with an octahedral habit, and whose chemical compositions are analogous. These minerals are combinations of bivalent and trivalent oxides of magnesium, zinc, iron, manganese, aluminum, and chromium, the general formula being represented as $R''O \cdot R_2''O_3$. The bivalent oxides may be MgO, ZnO, FeO, and MnO, and the trivalent oxides Al_2O_3, Fe_2O_3, Mn_2O_3, and Cr_2O_3. The more important members of the spinel group are spinel, $MgAl_2O_4$; gahnite, zinc spinel, $ZnAl_2O_4$, franklinite $(Zn, Mn^{2+}, Fe^{2+})(Fe^{3+}, Mn^{3+})_2O_4$, and chromite, $FeCr_2O_4$. True spinel has long been found in the gem-bearing gravels of Sri Lanka and in limestones of Burma and Thailand.

Spinel usually occurs in isometric crystals, octahedrons, often twinned. It has an imperfect octahedral cleavage; conchoidal fracture; is brittle; hardness, 7.5–8; specific gravity, 3.58; luster, vitreous to dull; transparent to opaque; streak white; may be colorless, rarely through various shades of red, blue, green, yellow, brown, or black. These colors are doubtless due to small amounts of impurities. The clear red spinels are called spinel-rubies or balas-rubies and were often confused with genuine rubies in times past. Rubicelle is a yellow spinel. A violet-colored manganese-bearing spinel is called almandine spinel.

Spinel is found as a metamorphic mineral, and also as a primary mineral in basic rocks, because in such magmas the absence of alkalies prevents the formation of feldspars, and any aluminum oxide present will form corundum or combine with magnesia to form spinel. This fact accounts for the finding of both ruby and spinel together. In addition to the localities mentioned above, which yield beautiful specimens, spinel is found in Italy and Sweden and in Madagascar. Also in the United States in Orange County, New York, and in Sussex County, New Jersey, are many well-known spinel localities. Spinel is found also in Macon County, North Carolina, and in Canada in Quebec and Ontario.

The name spinel is derived from the Greek, meaning a spark, in reference to the fire-red color of the sort much used for gems. Balas ruby is derived from Balascia, the ancient name for Badakhshan, a region of central Asia situated in the upper valley of the Kokcha River, one of the principal tributaries of the Oxus.

ELMER B. ROWLEY, F.M.S.A., formerly Mineral Curator,
Department of Civil Engineering, Union College,
Schenectady, NY

SPINNERET. A spinning organ of spiders. The spinnerets are located on the ventral surface of the abdomen, near or at its tip, and vary from one to

three pairs. They are conical to cylindrical in form. Each has a membranous terminal portion called the spinning field, through which run many minute spinning tubes from the silk glands. The nature of the spinning tubes varies, different tubes producing different kinds of silk.

In the act of spinning the liquid silk is forced through the spinning tubes, to harden on exposure to the air as silk. The spinnerets bear spines, some of them apparently tactile, and are moved by muscles, so that the spider is able to form and place its threads with precision.

Glass fibers and various synthetic fibers, such as polyesters, are also spun in a process known as *melt spinning*. In modern spinning plants, the polymer is heated and conveyed to the spinning head by means of a melt extruder. If the polymer is initially in the form of quenched chips, it must be thoroughly dried before melting or the molten resin will degrade by ester hydrolysis during the spinning process. The molten polymer in its passage from extruder to jet has a viscosity of the order of 1,000 poises. Pressures in the area range from 1,000 to 5,000 psi (6.9 to 34.5 mPa). The spinneret is made of stainless steel with a number of holes ranging from 14 to several hundred, depending upon the filament count of the yarn to be spun. The holes have diameters ranging from 0.008 to about 0.025 inch (0.2 to 0.6 millimeter), in accordance with the denier being spun. The depth of the holes is 1.3 to 3 times the diameter. See also **Fibers**.

SPIN (Nuclear). The total angular momentum of an atomic nucleus, when it is considered as a single particle.

SPIN STATE. A system is said to be in a definite spin state when the quantum mechanical wave function describing the system is an eigenfunction of the various spin operators corresponding to the square of the total spin angular momentum and the component(s) of the spin angular momentum being used to designate the system. For example, the spin state of a single particle might be designated by specifying the particle's spin projection on its direction of motion. The operator corresponding to this dynamical variable is $\mathbf{s} \cdot \mathbf{p}$ where $\mathbf{s}$ is the vector operator corresponding to the spin angular momentum of the particle and $\mathbf{p}$ is the vector operator corresponding to the linear momentum. For a particle to be in a definite spin state according to this method of designation, it must be described by a wave function which is an eigenfunction of $\mathbf{s} \cdot \mathbf{p}$. As another example, the spin state of a two particle system might be specified in one of two ways — either by specifying S^2 and S_z, the square of the total spin angular momentum and its z-component respectively, or by specifying S_{1z} and S_{2z}, the z-components of the spin angular momentum of each particle. If the case for the two particle system are considered in detail, using nonrelativistic quantum mechanics and the Pauli spin operators, one has

$$\mathbf{S}_1^2 = \tfrac{1}{4}\hbar^2\boldsymbol{\sigma}_1^2$$
$$\mathbf{S}_2^2 = \tfrac{1}{4}\hbar^2\boldsymbol{\sigma}_2^2$$
$$\mathbf{S}^2 = (\mathbf{S}_1 + \mathbf{S}_2)^2 = \mathbf{S}_1^2 + \mathbf{S}_2^2 + \mathbf{S}_1 \cdot \mathbf{S}_2$$
$$= \tfrac{1}{2}\hbar^2(\boldsymbol{\sigma}_1^2 + \boldsymbol{\sigma}_2^2 + \boldsymbol{\sigma}_1 \cdot \boldsymbol{\sigma}_2)$$

and

$$S_z = S_{1z} + S_{2a}$$

with

$$S_{1z} = \tfrac{1}{2}\sigma_{1z} \text{ and } S_{2z} = \tfrac{1}{2}\sigma_{2z}$$

Then letting α represent the column matrix $\binom{1}{0}$ and β represent the column matrix $\binom{0}{1}$, one has

$$S_1^2\alpha_1 = \tfrac{1}{2}\left(\tfrac{1}{2} + 1\right)\hbar^2\alpha_1$$
$$S_{1z}\alpha_1 = \tfrac{1}{2}\hbar\alpha_1$$
$$S_1^2\beta_1 = \tfrac{1}{2}(\tfrac{1}{2} + 1)\hbar^2\beta_1$$
$$S_{1z}\beta_1 = -\tfrac{1}{2}\hbar\beta_1$$

Thus $\alpha_1\alpha_2$, $\alpha_1\beta_2$, $\beta_1\alpha_2$, and $\beta_1\beta_2$ represent spin states with, respectively,

$$S_{1z} = \tfrac{1}{2}\hbar, \quad S_{2z} = \tfrac{1}{2}\hbar$$
$$S_{1z} = \tfrac{1}{2}\hbar, \quad S_{2z} = -\tfrac{1}{2}\hbar$$
$$S_{1z} = -\tfrac{1}{2}\hbar, \quad S_{2z} = \tfrac{1}{2}\hbar$$
$$S_{1z} = -\tfrac{1}{2}\hbar, \quad S_{2z} = -\tfrac{1}{2}\hbar$$

Also $\alpha_1\alpha_2$; $\frac{1}{2}(\alpha_1\beta_2 + \beta_1\alpha_2)$; and $\beta_1\beta_2$ all represent spin states with $S^2 = 2^{\smile 2}$ but $S_z = {}^{\smile}$; $S_z = 0$, and $S_z = -^{\smile}$ respectively. The state $\frac{1}{2}(\alpha_1\beta_2 - \beta_1\alpha_2)$ is one with $S^2 = 0$ and $S_z = 0$.

SPINY ANTEATER. See **Monotremeta**.

SPIRACLE. 1. A small opening on the surface of the insect body, leading into an air tube of the respiratory system. Insect spiracles are simple openings in some species, but usually they are guarded by some structure that prevents the entrance of foreign particles. This guard varies from a fringe of hairs to an elaborate sieve-like plate. Some insects depend on a closing apparatus of the associated trachea for the exclusion of particles.

In the primitive condition, spiracles apparently were paired and metameric, one opening on each side of each segment. This arrangement is only slightly modified in some species, which are said to be peripneustic. In other cases the number of openings is greatly restricted, only one or two pairs providing the sole entrance to the respiratory apparatus. Insects with a single pair at the anterior end of the body are called propneustic, those with a pair at the posterior end metapneustic, and those with a pair at each end amphipneustic. The spiracles may also be associated with tubes, either extending the tracheae beyond the general surface of the body or forming external conduits for air, by which the insect may reach the air from within the water or decaying matter in which it lives. 2. The greatly reduced external opening representing the first of the series of gill slits in elasmobranch fishes.

SPIRAL CURVE. In railway or highway alignments a spiral curve, sometimes called an easement or transition curve, is one which provides a gradual change of curvature when passing from a tangent (straight line) to a circular curve. See Fig. 1. The cubic parabola and cubic spiral are curves well suited for this purpose. The former is used when spirals are to be laid out by offsets from the tangent, since the offset to any point on the curve varies as the cube of the distance along the tangent from the point where the curve begins. When the curve is to be laid out by deflection angles the cubic spiral is used. In this curve the offset from the tangent is proportional to the cube of the distance along the curve measured from the point of tangency. Spiral curves are particularly well adapted for the use of superelevation since they furnish a means for gradually increasing this quantity from zero to the amount required on the circular portion of the curve. Railroads use a combination of spiral and circular curves to connect the tangents on their main lines. The value of the spiral is now recognized in modern highway design for high-speed traffic.

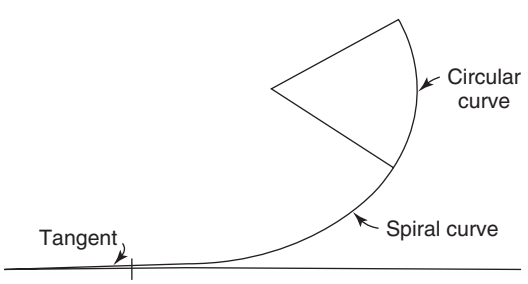

Fig. 1. Spiral curve.

See also **Superelevation**.

SPIRAL (Mathematics). A transcendental plane curve, for which the equation in many cases can be written in polar coordinates and in general form as $r = a_0\theta^n + a_1\theta^{n-1} + \cdots + a_n$. A spiral can also be defined as the locus of a point that moves about a fixed pole, while its radius vector **r** and its vectorial angle θ continually increases or decreases according to some law. The best-known cases have special names as follows: Archimedes spiral, Cornu spiral, Sici spiral, hyperbolic spiral, lituus, logarithmic spiral, parabolic spiral.

See also **Curve (Plane)**.

SPIRAL VALVE. A thin ridge projecting from the lining of the intestine of elasmobranch fishes to the center of the cavity and following a spiral course through the length of the tube. The structure provides greatly increased surface for the digestion and absorption of food. It is so arranged that the food must follow a spiral course, but beyond this regulating effect is not a valve in the usual sense. It merely slows the passage of food.

SPITTLE BUG *(Insecta, Homoptera)*. Of the family *Cercopidae*, the spittle insects, also commonly called frog hoppers because of their remote resemblance to frogs, are quite damaging to certain crops. The immature spittle bug sucks the sap and juices of plants and secretes a protective frothy mass about itself. Control chemicals must be applied at just the right time — about one week after the first appearance of the nymphs. There are no apparent natural enemies to these insects. When infestations are severe, reaching the proportion of several hundred nymphs per plant, as much as 30–40% of a leguminous hay crop and nearly all of an alfalfa seed crop can be lost. Infested strawberry plants also show great reductions in yield as the result of the spittle bug.

The insect winters over as an egg, only about 1 millimeter long. Masses of up to 30 eggs will be deposited in grain stubble several inches above ground level. The eggs hatch from early spring to early summer and the first instar nymphs migrate to host plants and attempt to find locations where the humidity will be relatively high. Immediately, the nymph covers itself with the aforementioned secretion, a procedure that is highly effective against desiccation. There are 5 nymphal instars in the cycle, which ranges from 1 to 3 months, largely depending upon temperature.

SPITZER, LYMAN JR. (1914–1997). Lyman Spitzer, Jr. was one of the 20th century's great scientists. A renowned astrophysicist, he made major contributions in the areas of stellar dynamics, plasma physics, thermonuclear fusion, and space astronomy. Lyman Spitzer, Jr. was the first person to propose the idea of placing a large telescope in space and was the driving force behind the development of the Hubble Space Telescope.

Lyman Spitzer, Jr. was born on June 26, 1914 in Toledo, Ohio. He attended Yale University where he earned his Bachelor's degree in physics in 1935 and then spent a year at Cambridge University. In 1936, Spitzer entered Princeton University where he earned his Master's degree in 1937 and a Doctorate in astrophysics in 1938 while working under the famous astronomer Henry Norris Russell. After receiving his doctorate, he spent a year as a postdoctoral fellow at Harvard University and then joined the faculty of Yale University in 1939.

During World War II, Spitzer did underwater sound research, working with a team that led the development of sonar. When the war was over, Lyman Spitzer returned to teach at Yale for a brief time. Then, in 1946, more than a decade before the first satellite was launched into space and twelve years before NASA was formed, Spitzer proposed that an observatory be placed in space where it would be able to detect a wide range of wavelengths and not have to deal with the blurring effects of our atmosphere. He proposed that a telescope in space would reveal much clearer images, of even far-off objects, than any ground-based telescope. He wrote a paper entitled "Astronomical Advantages of an Extra-Terrestrial Observatory" which described in detail the advantages of putting a telescope in space. He would work for the next 50 years on making this vision a reality.

In 1947, at the age of 33, Lyman Spitzer, Jr. was appointed chairman of Princeton's astrophysical sciences department, succeeding Henry Norris Russell. He also became the director of Princeton's Observatory. Along with Martin Schwarzschild, he built the department into a major research facility.

While at Princeton, Spitzer made many contributions to the field of astrophysics. Lyman Spitzer, Jr. is considered the founder of study of the interstellar medium — the gas and dust between the stars from which new stars are formed. See also **Interplanetary Medium**. Spitzer studied in detail interstellar dust grains and magnetic fields as well as the motions of star clusters and their evolution. He studied regions of star formation and was among the first to suggest that bright stars in spiral galaxies formed recently from the gas and dust there. He also accurately predicted the existence of a hot galactic halo surrounding our Milky Way galaxy.

In 1951, Spitzer founded the Princeton Plasma Physics Laboratory (originally called Project Matterhorn) which was Princeton's pioneering program in controlled thermonuclear research. He pioneered efforts to harness nuclear fusion as a clean source of energy and remained the Laboratory's director until 1967. A year later, in 1952, Spitzer was named the Charles A. Young Professor of Astronomy at Princeton, a title that he would keep for the rest of his life.

From 1960 to 1962, Lyman Spitzer, Jr. served as president of the American Astronomical Society. With the development of the U.S. space program in the 1960's, Spitzer's idea of astronomy from space was finally beginning to look more promising. In 1962, he led a program to design an observatory which would orbit the Earth and study the ultraviolet light from space, which is normally blocked by our atmosphere. This observatory became NASA's successful Copernicus satellite which operated between 1972 and 1981.

In 1965, the National Academy of Sciences established a committee to define the scientific objectives for a proposed Large Space Telescope. Lyman Spitzer, Jr. was chosen to head this committee. Many astronomers did not support the idea of a space telescope and were concerned that the cost would reduce support for ground-based astronomy. Spitzer put great effort into convincing the scientific community, as well Congress, of the great value of placing a large telescope into space. In 1968, Spitzer's dream of putting a telescope in space began to come true, with the launch of the highly successful Orbiting Astronomical Observatory.

Between 1973 and 1975, Lyman Spitzer, Jr. was awarded several prestigious honors. In 1973 he was awarded the Catherine Wolfe Bruce gold medal by the Astronomical Society of the Pacific. In 1974, the National Academy of Sciences awarded him the Henry Draper Medal "for his vision and distinguished achievements in space astronomy and for his many outstanding contributions to the physics of plasmas on earth and in the interstellar medium." In 1975, he was awarded the first James Clerk Maxwell Prize for Plasma Physics by the American Physical Society for "his pioneering investigations of the behavior of plasma" and guiding and inspiring "a generation of plasma physicists through his research and leadership in the controlled thermonuclear program."

Spitzer continued to lobby NASA and Congress to develop a space telescope. Finally, in 1975, NASA, along with the European Space Agency, began development of what would become the Hubble Space Telescope (HST). See also **Hubble Space Telescope (HST)**. A year later, in 1976, NASA awarded him its Distinguished Public Service Medal for "his pioneering efforts in rocket and high altitude balloon astronomy, his outstanding contributions to space astronomy as principal investigator on the highly successful Orbiting Astronomical Observatory, Copernicus, and his vision and leadership in articulating the advantages and benefits to be realized from the Space Telescope Program." In 1977, due in large part to Spitzer's continuous efforts, Congress approved funding for the construction of the Space Telescope.

Between 1978 and 1985, Spitzer was again awarded several high honors including the Gold Medal of the Royal Astronomical Society (1978), National Medal of Science (1979), Jules Janssen Medal of the Societe Astronomique de France (1980), and the Crafoord Prize of the Royal Swedish Academy (1985), which is the equivalent of the Nobel Prize in fields excluded from those awards.

The Hubble Space Telescope, was delivered into space by the Space Shuttle in 1990, 54 years after Spitzer first proposed placing a large telescope into space. The Hubble Space Telescope still orbits the Earth today, providing stunning images of the Universe and amazing new discoveries.

Lyman Spitzer, Jr. passed away suddenly on March 31, 1997 at the age of 82. He had just completed a normal working day at Princeton University, discussing astronomy with his colleagues and analyzing results

from the Hubble Space Telescope, the instrument he dreamed of in 1946. He left behind his wife, Doreen Canaday Spitzer, four children, and ten grandchildren.

In addition to being an outstanding scientist and leader in the development of space telescopes, Lyman Spitzer, Jr. was an outstanding teacher who was extremely well-respected by both his colleagues and students. He was an author whose books include "Physics of Fully Ionized Gases" (1956) which became a valuable reference in the fields of plasma and fusion research, and "Diffuse Matter in Space" (1968) which described the field of interstellar matter. He was also a member of numerous scientific organizations including the American Academy of Arts and Sciences, the National Academy of Sciences, the American Astronomical Society, the Astronomical Society of the Pacific, the Royal Astronomical Society (London), the American Physical Society, the American Geophysical Union, the American Association of the University Professors, and the American Philosophical Society.

Lyman Spitzer, Jr. was considered to be a man of "incredible discipline, diligence and politeness." He loved mountain-climbing and skiing and was a member of the American Alpine Club to which he contributed a grant which promoted "state-of-the-art, cutting-edge climbing through financial support of small, lightweight climbing teams attempting bold first ascents or difficult repeats of the most challenging routes in the world's great mountain ranges."

On August 25, 2003, NASA launched a new space telescope. The observatory consists of a large and lightweight telescope, and three cryogenically-cooled science instruments capable of studying the Universe at near- to far-infrared wavelengths. Incorporating state-of-the-art infrared detector arrays, and launched into an innovative Earth-trailing solar orbit, the observatory is orders of magnitude more capable than any previous space-borne infrared telescope. NASA has named this new facility the Spitzer Space Telescope, to honor the vision and contributions of Lyman Spitzer, Jr. See also **Spitzer Space Telescope (SST)**.

SPITZER SPACE TELESCOPE (SST). In December 2003, four months after its launch, NASA formally gave the Spitzer Telescope its new name finally retiring the old **SIRTF, the Space Infrared Telescope Facility**. NASA named this new facility, to honor the vision and contributions of Lyman Spitzer, Jr. The Spitzer Space Telescope (SST) is a space-borne, cryogenically-cooled infrared observatory capable of studying objects ranging from our Solar System to the distant reaches of the Universe. Spitzer is the final element in **NASA's Great Observatories Program**, and an important scientific and technical cornerstone of the new **Astronomical Search for Origins Program**. See also **Origins Program**.

To grasp the wonders of the cosmos, and understand its infinite variety and splendor, we must collect and analyze radiation emitted by phenomena throughout the entire electromagnetic (EM) spectrum. Towards that end, NASA proposed the concept of Great Observatories, a series of four space-borne observatories designed to conduct astronomical studies over many different wavelengths. An important aspect of the Great Observatory program was to overlap the operations phases of the missions to enable astronomers to make contemporaneous observations of an object at different spectral wavelengths.

The first element of the program, and the best known, is the Hubble Space Telescope (HST). The Hubble telescope was deployed by the Space Shuttle *Discovery* on April 24, 1990. A subsequent Shuttle mission in 1993 serviced HST and recovered its full capability. A second successful servicing mission took place in 1997. Subsequent servicing missions have added additional capabilities to HST, which observes the Universe at ultraviolet, visual, and near-infrared wavelengths. See also **Hubble Space Telescope (HST)**.

The second Great Observatory was launched and deployed by the Space Shuttle *Atlantis* on April 5, 1991: the Compton Gamma-Ray Observatory (CGRO). This mission collected data on some of the most violent physical processes in the Universe, characterized by their extremely high energies. The CGRO was safely de-orbited and re-entered the Earth's atmosphere on June 4, 2000 after nine years in service. See also **Gamma-Ray Astronomy**; and **Compton Gamma-Ray Observatory (CGRO)**.

The third member of the Great Observatory family, the Chandra X-Ray Observatory (CXO), was deployed from the Space Shuttle *Columbia* and boosted into a high-Earth orbit, on July 23, 1999. This observatory is observing such objects as black holes, quasars, and high-temperature gases throughout the x-ray portion of the EM spectrum. See also **X-Ray Astronomy**; and **Chandra X-Ray Observatory**.

The Spitzer Space Telescope represents the fourth and final element in NASA's Great Observatory program. The Spitzer Space Telescope was launched into space by a Delta rocket from Cape Canaveral (Fig. 1), Florida on 25 August 2003. During its mission, Spitzer will obtain images and spectra by detecting the infrared energy, or heat, radiated by objects in space between wavelengths of 3 and 180 microns (1 micron is one-millionth of a meter). Most of this infrared radiation is blocked by the Earth's atmosphere and cannot be observed from the ground.

Fig. 1. On 24 August 2003, the mobile service tower is rolled back at Launch Pad 17-B, Cape Canaveral Air Force Station, to reveal NASA's Spitzer Space Telescope (formerly Space Infrared Telescope Facility (SIRTF) ready for launch aboard a Delta II Heavy launch vehicle. (*NASA*).

Mission Overview

Spitzer will explore the birth and evolution of the universe and the objects within it with unprecedented sensitivity, viewing phenomena not seen through other astronomical techniques. The Spitzer mission is managed for NASA by the Jet Propulsion Laboratory (JPL), a division of the California Institute of Technology. Infrared wavelengths, redder than the human eye can see, can be thought of as heat radiation. The colder infrared detectors are, the better they can "see" objects in the sky that glow in the infrared. In space, infrared telescopes are above the warmth of Earth's atmosphere, and can be cooled to very low temperatures, enabling studies of objects that range from far below room temperature to many thousands of degrees.

Spitzer will be the first space observatory to combine such a highly sensitive cryogenically cooled telescope with the imaging and spectroscopic power of a new generation of infrared detector arrays. Spitzer will see through clouds of dust and gas that obscure much of the universe from view. It will sense the infrared radiation, or heat, emitted by objects from the oldest galaxies to forming stars and emerging planetary systems. Scientists expect the observatory to help them discover the answers to important questions about the origin and evolution of the universe, its galaxies and stars, and to seek out stars like the Sun that may hold planets like Earth orbiting about them.

Spitzer's specially designed orbit will completely remove the spacecraft from the heat of the Earth and from the obscuring atmosphere that blocks our view of most of the infrared light from celestial sources. The observatory will see wavelengths of light critical to NASA's quest for an understanding of our origins, allowing astronomers to discover the basic processes underlying the formation of planets and the birth of stars and galaxies.

Data received through NASA's Deep Space Network from Spitzer will be processed and disseminated to the science community at the JPL/Caltech Infrared Processing and Analysis Center located at the Caltech campus. http://www.ipac.caltech.edu/

The National Academy of Sciences designated Spitzer the highest priority major mission for all of U.S. astronomy in the 1990s. With U.S. technology developments, innovative engineering and streamlined mission planning, Spitzer has undergone radical redesign to be consistent with the new NASA paradigm of faster/better/cheaper. The result is an affordable yet enormously powerful observatory.

Spitzer's Telescope and Spacecraft Overview

Cryogenic Telescope Assembly. Spitzer's Cryogenic Telescope Assembly (CTA) consists of four main parts: a superfluid helium cryostat, a light-weight 85 centimeter (33.5 inch) Ritchey-Chretien telescope, an Outer Shell Group, and a Multiple Instrument Chamber which houses the Science Instruments. Everything that is cold is part of the CTA. The CTA is mechanically mounted to, but thermally isolated from, the spacecraft by means of low conductivity struts and thermal radiation shields. The solar array and spacecraft shields block the CTA from the sun and spacecraft components at all times, helping to keep the CTA as cold as possible.

Telescope. The Spitzer telescope fabricated by Hughes Danbury Optical Systems is a lightweight reflector of Ritchey-Chrétien design. It weighs less than 50 kilograms (110 pounds) and is designed to operate at an extremely low temperature. The telescope has an 85 centimeter (33.5 inch) diameter aperture. All of its parts, except for the mirror supports, are made of light-weight beryllium. Beryllium is a very strong material, which works well in the construction of infrared space telescopes because it has a low heat capacity at very low temperatures. The telescope is attached to the top of the vapor-cooled cryostat vacuum shell, which keeps the science instruments very cold. See Fig. 2.

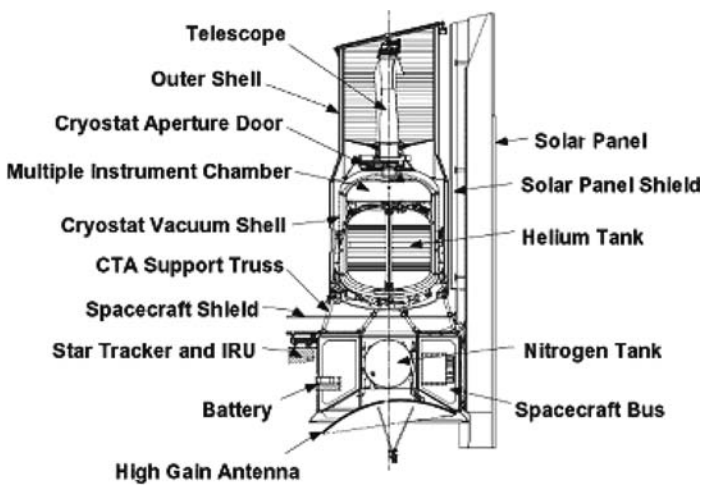

Fig. 2. Outline of Spitzer Space Telescope. (*Image courtesy of NASA/Caltech*).

The design philosophy of the telescope assembly is based on the following guidelines:

- Maximize the use of materials with a very high stiffness/density ratio, high thermal conductivity, and low cryogenic specific heat.
- Build the entire telescope of the same material to prevent thermal expansion mismatch complications, and to make the telescope assembly, as dimensionally stable as possible.
- Select a configuration that minimizes the size of the major elements of the telescope assembly.
- Strive for the simplest possible design to minimize the number of parts, thereby reducing the time and cost for design, fabrication, and integration.

Multiple Instrument Chamber. Spitzer's Multiple Instrument Chamber (Fig. 2.) contains the cold parts of Spitzer's three science instruments, IRAC, IRS, and MIPS, as well as the pointing calibration reference sensor which is part of the pointing control system. The Multiple Instrument Chamber is built to be so tight that no light can get through it except that which is allowed to be detected directly by the instruments. The chamber is 84 centimeters (33.1 inches) in diameter by 20 centimeters (7.9 inches) high. It has an aluminum baseplate and cover and is mounted directly to the helium tank.

Infrared Array Camera (IRAC). The Infrared Array Camera (IRAC) is one of Spitzer's three science instruments, and provides imaging capabilities at near- and mid-infrared wavelengths. It is a general-purpose camera that will be used by observers on SIRTF for a wide variety of astronomical research programs.

IRAC is a four-channel camera that provides simultaneous 5.12×5.12 arcmin images at 3.6, 4.5, 5.8, and 8 microns. Each of the four detector arrays in the camera are 256×256 pixels in size. IRAC uses two sets of detector arrays. The two short-wavelength channels are imaged by composite detectors made from indium and antimony. The long-wavelength channels use silicon detectors that have been specially treated with arsenic. The only moving part in IRAC is the camera shutter. See Fig. 3 and 4.

Infrared Spectrograph (IRS). The Infrared Spectrograph (IRS) is one of the three instruments onboard Spitzer and provides both high- and low-resolution spectroscopy at mid-infrared wavelengths. Spectrometers are instruments, which spread light out into its constituent wavelengths creating a spectra. Within this spectra, astronomers can study emission and absorption lines: which are the fingerprints of atoms and molecules. See Fig. 5.

The IRS has four separate modules: a low-resolution, short-wavelength mode covering the 5.3-14 micron interval; a high-resolution, short-wavelength mode covering 10-19.5 microns; a low-resolution, long-wavelength mode for observations at 14-40 microns; and a high resolution, long-wavelength mode for 19-37 microns. Each module has its own entrance slit to let infrared light in. See Fig. 6. The detectors are 128×128 arrays. The shorter-wavelength silicon detectors are treated with arsenic; the longer-wavelength silicon detectors are treated with antimony.

The IRS instrument consists of two physically separated parts, the cold assemblies which are located within the Spitzer multiple instrument chamber and the warm electronics, which are located in the Spitzer spacecraft bus. The IRS has no moving parts!

Multiband Imaging Photometer (MIPS). The Multiband Imaging Photometer for Spitzer (MIPS) is one of the three science instruments that will fly on the Observatory and will provide imaging and limited spectroscopic data at far-infrared wavelengths. It has three detector arrays. A 128×128 array for imaging at 24 microns is composed of silicon, specially treated with arsenic. A 32×32 array for imaging at 70 microns, and a 2×20 array for imaging at 160 microns both use germanium, treated with gallium. The 32×32 array will also take spectra from 50–100 microns. The MIPS field of view varies from about 5×5 arcmin at the shortest wavelength to about 0.5×5 arcmin at the longest wavelength. See Fig. 7.

The three arrays, calibrators, scan mirror, and optics compose the cryogenic part of the MIPS. This assembly is mounted in the Spitzer cold instrument chamber. In addition, the MIPS and the IRS share warm electronics that controls their operation. The only moving part in MIPS is a scan mirror used to efficiently map large areas of the sky.

Cryostat. In general, Spitzer's science payload needs to be kept very cold to work properly. This is because it uses infrared detectors that are very sensitive to heat. If the instruments are not very cold, the heat from the instruments themselves will interfere with the study of the faint infrared radiation from objects in space. Spitzer's cryostat will keep the science instruments at temperatures as low as 1.4 degrees Kelvin ($-272\,^{\circ}$C or $-457\,^{\circ}$F) for up to 5 years. See Fig. 8.

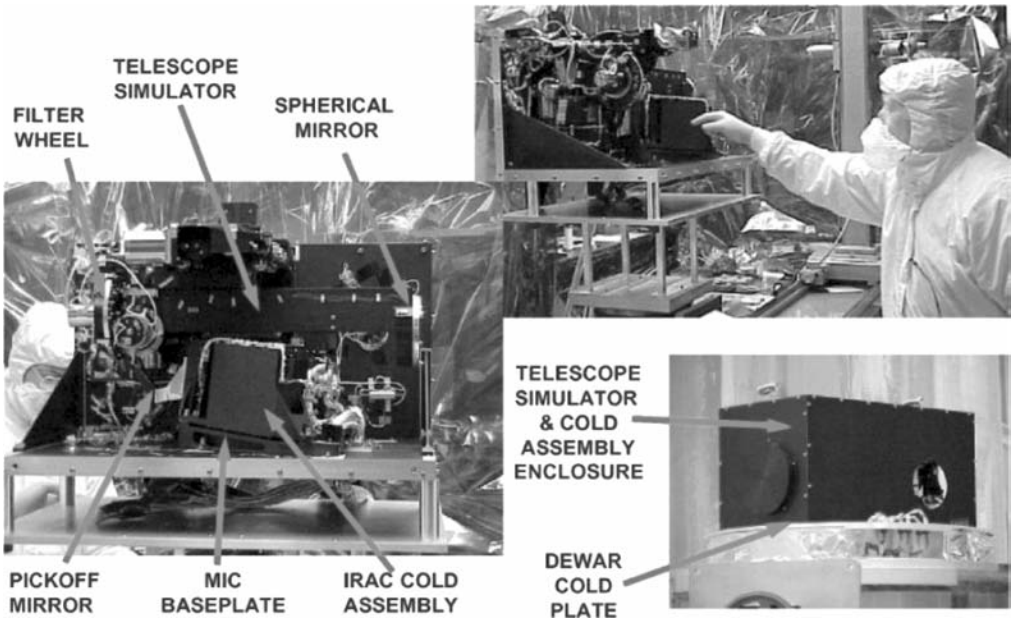

Fig. 3. Looking inside IRAC. (*Image courtesy of NASA/Caltech*).

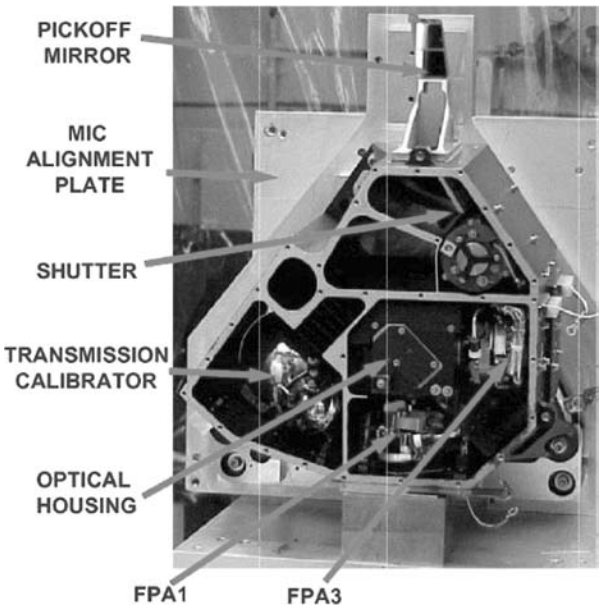

Fig. 4. Image of IRAC Assembled. (*Image courtesy of NASA/Caltech*).

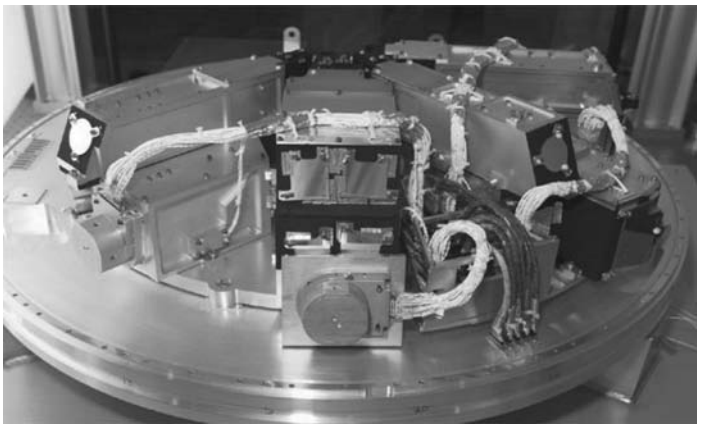

Fig. 5. IRS on the MIC Baseplate. (*Image courtesy of NASA/Caltech*).

Spitzer's cryostat will keep the instruments cold by venting helium vapor from a liquid helium tank. The cryostat consists of the vacuum shell, inner and middle vapor cooled shields, helium tank, and the fluid management system. The tank holds about 360 liters (95 gallons) of superfluid helium.

The telescope is attached to the top of the vapor-cooled cryostat. The telescope and cryostat shell is launched warm, and cool down to about 35 degrees Kelvin ($-238\,^{\circ}$C or $397\,^{\circ}$F) once in orbit. The cryostat vacuum shell must be sealed during ground operations and launch. Once the cryostat is cooled and in the vacuum of space, a cryostat door on the top of the shell is opened to allow light into the Multiple Instrument Chamber.

CTA Outer Shell. Spitzer's outer shell is made up of a dust cover, outer shield (cooled by helium vapor), thermal shields (which block radiation from space), and the solar panels. The telescope and cryostat are surrounded by the outer shell. See Fig. 9. The shell keeps exterior heat from reaching the telescope and instruments by radiating it out into cold space.

The outer shell is made of lightweight, aluminum honeycomb sandwich construction. It is painted black on the anti-sun side, for efficient thermal radiation to cold space, and is shiny on the sun-facing side, for efficient rejection of heat from the sun and solar panels. To maximize the helium lifetime, the outer shell temperature must be as low as possible. The sources of heat to the outer shell are the spacecraft bus, solar panel, and star trackers.

The outer shell is closed at the top by an ejectable cover, which lets out unwanted dry nitrogen which, if left in, could contaminate the telescope's mirrors and other surfaces. The thermal shields are sized and shaped such that the observatory is shaded at all times when pointed properly.

Spacecraft. Spitzer's spacecraft refers to the warm portion of the Observatory, including the solar panel, the bus structure, and the components mounted in the bus that provide the Observatory engineering functions. These components include: the solar arrays, the command and data handling unit, the reaction control subsystem, the telecommunications subsystem, the power generation and distribution subsystem, the pointing control subsystem, and the flight software. See Fig. 10.

The spacecraft consists of an octagonal bus structure in which the avionics and the science instrument's warm electronics are housed, and a solar panel that provides electrical power to the vehicle and serves to shade the cryo-telescope assembly from direct exposure to the sun. The spacecraft provides electrical power to the science instruments, orients and stabilizes the boresight of the telescope, collects and compressed data from the science instruments for later transmission to the ground, executes stored commands to direct science instrument activities, and communicates with the ground system. All communications with Spitzer are conducted

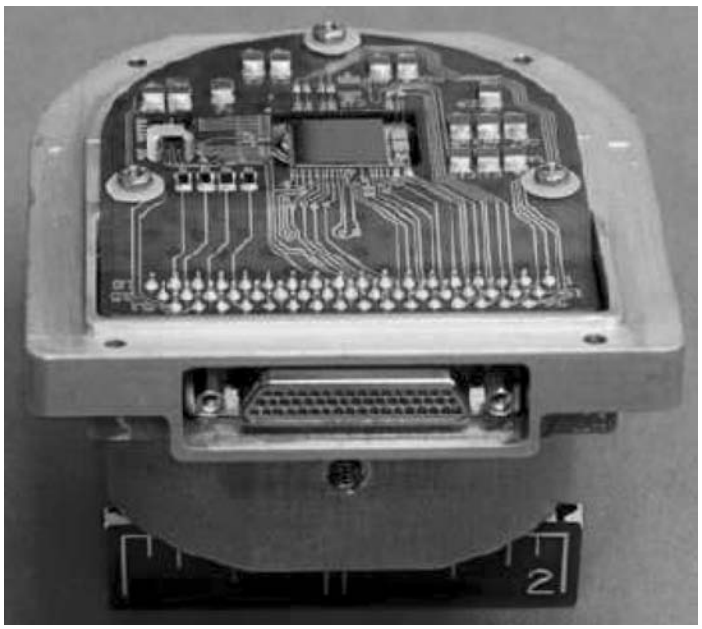

Fig. 6. One of the 4 IRS detector arrays. (*Image courtesy of NASA/Caltech*).

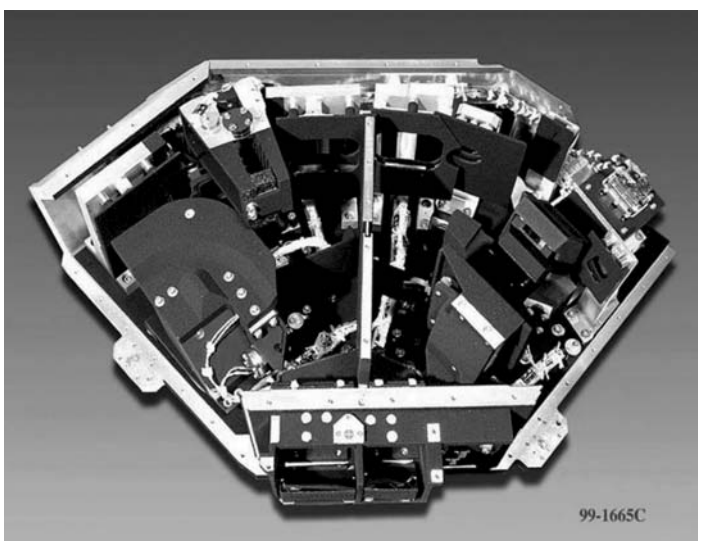

Fig. 7. The inside of MIPS. (*Image courtesy of NASA/Caltech*).

through NASA's Deep Space Network. The spacecraft is responsible for the safe operation of the Observatory.

Solar Panel Assembly. Spitzer's Solar Panel Assembly is designed to provide the electrical power needed to operate Spitzer for up to 5 years. The Solar Panel Assembly is made up of two solar panels each of which has 392 solar cells. See Fig. 11. Each solar cell is 5.5 centimeters (2.2 inches) by 6.5 centimeters (2.6 inches) in area. Together, these cells will convert radiation from the Sun into a total of 427 Watts of electrical energy. Spitzer cannot point more than 120 degrees away from the sun. If it does, sunlight will not hit the solar panels properly.

The solar panel has 50 percent of its area covered with solar cells and 50 percent covered with optical solar reflectors. These reflectors reduce the solar panel temperature to about 330 K (26.85 °C or 80.33 °F). The wedge shaped solar panel shield is angled away from the outer shell in order to improve its view factor to space and to improve the thermal isolation between it and the outer shell.

Spacecraft Bus. Spitzer's Spacecraft Bus is an octagonal structure in which the avionics and the science instrument warm electronics are housed. The Spacecraft Bus provides electrical power to the science instruments, orients and stabilizes the boresight of the telescope, collects

Fig. 8. Cryostat after assembly. (*Image courtesy of Ball Aerospace*).

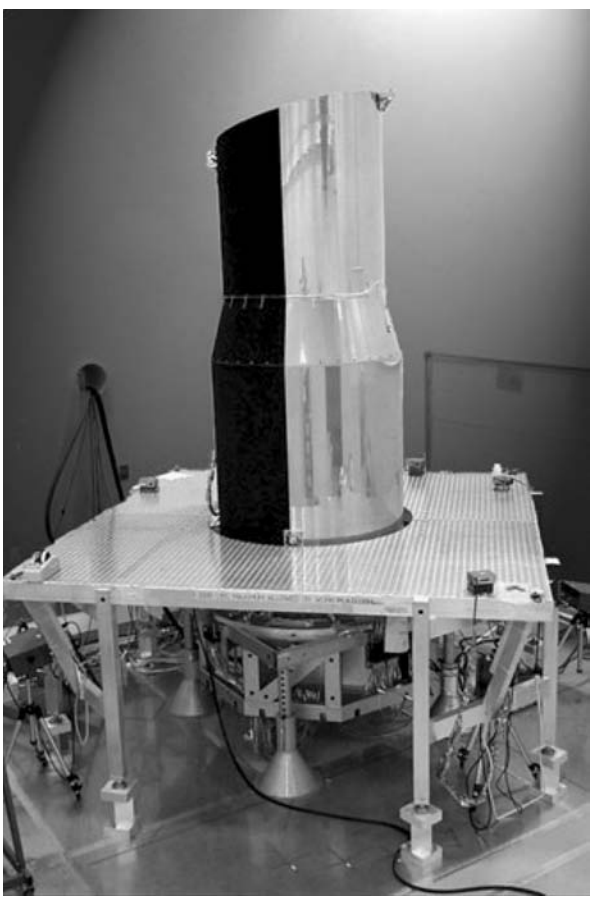

Fig. 9. The assembled CTA outer shell. (*Image courtesy of NASA/Caltech*).

and compresses data from the science instruments for later transmission to the ground, executes stored commands to direct science instrument activities, and communicates with the ground system. See Fig. 12.

The bus structure makes up the nine bays within which the bus equipment is housed. Four side modules, four corner modules, two heatpipe equipment panels, and six equipment panels make up the nine bays. The equipment panels are sandwiched between the modules and are bolted and bonded together for maximum stiffness and structural integrity. On the outside of the bays, panels are bolted to the modules. These panels are

removable and provide access to the outer bays during integration and test. The center bay is accessible from the top.

Innovations. An important breakthrough in the redesign of Spitzer was to abandon the idea of placing the observatory into Earth orbit and instead to insert it into an Earth-trailing heliocentric orbit. In other words, the Observatory will be launched into an orbit where it will simply drift behind Earth as it circles the Sun.

Spitzer has drifted away from Earth at the rate of ~0.1 AU/year. [An AU, or Astronomical Unit, is the average distance between the Sun and Earth, or about 150 million kilometers]. Since the Observatory must be cooled to within a few degrees of absolute zero, this orbit choice offers a more benign thermal environment than any geocentric orbit. Earth not only reflects visible light from the Sun, but it also emits warm infrared radiation. Any satellite in a reasonable geocentric orbit would therefore be bathed in temperatures exceeding 250 Kelvin (K). The drifting heliocentric orbit places Spitzer in "deep space," where the ambient temperatures are about 30 to 40 K. By using Nature to assist in cooling the Observatory, Spitzer can carry much less liquid helium cryogen than it would need in an Earth orbit.

A consequential benefit of the solar orbit is that Spitzer will have a large instantaneous view of the celestial sky. Sensitive observatories such as Spitzer and the Hubble Space Telescope must avoid looking at (or anywhere near) extremely bright objects such as the Sun, Earth, and Moon. Spitzer's view of the sky will be limited by only two pointing constraints. See Fig. 13. First, the Observatory cannot point closer than 80 degrees in the direction of the Sun, in order to minimize the thermal heating of the telescope by solar radiation. Second, it cannot point more than 120 degrees away from the direction of the Sun, because of need to illuminate the solar panels and produce electricity to power the Observatory.

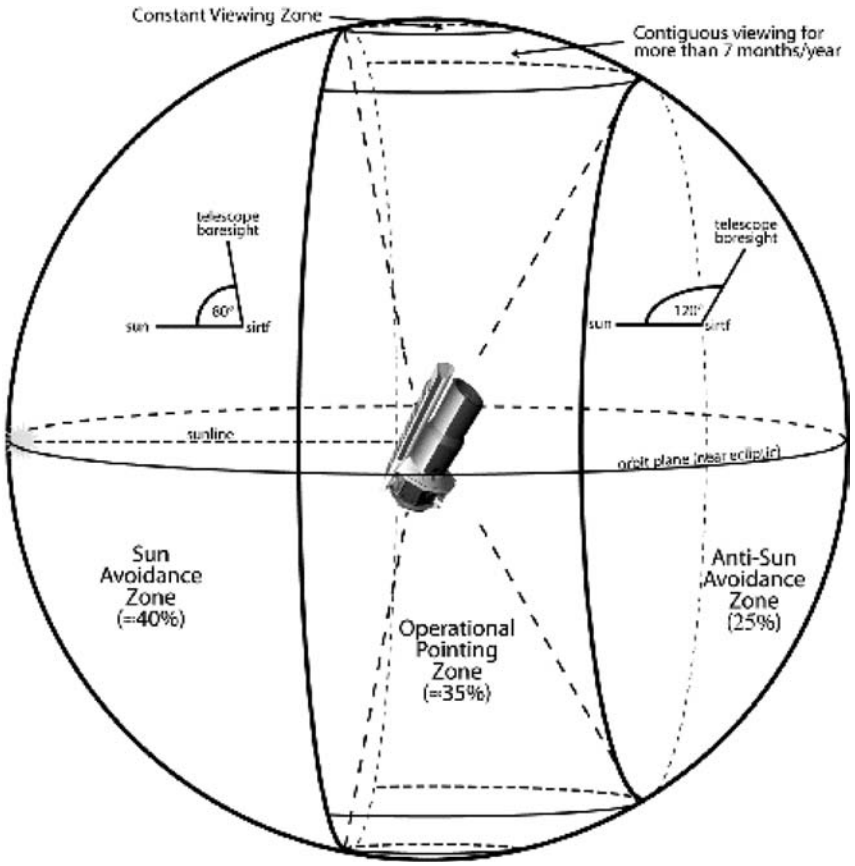

Fig. 13. Spitzer's sky viewing geometry. (*Image courtesy of NASA/JPL*).

Spitzer's window of visibility on the celestial sky forms an annulus, perpendicular to the ecliptic plane, of 40-degree width. A region of the sky will be minimally visible to the Observatory twice a year, for about 40 days each period (at the ecliptic equator). The visibility periods increase to about 120 days per year at an ecliptic latitude of 30 degrees, to about 200 days at latitudes of 60 degrees, and reach constant viewing at the ecliptic poles. About a third of the sky will be instantaneously visible to Spitzer at any given time. This broad window on the sky will simplify scheduling and operations of Spitzer, and will allow it to achieve very high astronomical observing efficiency.

Cryogenic Architecture. Previous infrared telescopes in space have been enshrouded within a giant cryostat containing the super-fluid liquid helium necessary to refrigerate the telescope to operating temperatures near absolute zero. This system configuration has come to be known as the "cold-launch" architecture (Fig. 14). Unlike IRAS and ISO, however, Spitzer adopts an innovative "warm-launch" cryogenic architecture (Fig. 14.). The Observatory is launched at ambient temperature and radiatively (or passively) cooled in the deep recesses of space. Only the focal-plane instruments and the liquid helium cryostat are enclosed in a vacuum shell containing the cryostat.

It is important to recognize that the warm-launch architecture is enabled by the choice of orbit. With Spitzer inserted into a relatively cold space environment (i.e., away from the warm Earth), the ambient temperature of deep space passively cools the Observatory to less than 40 K within a few weeks of launch. At that time, the telescope is thermally de-coupled from the cryogenic telescope assembly (CTA) outer shell. The boil-off of liquid helium produces a vapor that cools the CTA to the operational temperature of 5.5 K.

This innovative launch architecture, combined with 360 liters of liquid helium, yields an estimated mission lifetime of about five years. For the sake of comparison, IRAS used 520 liters of cryogen during its 10-month mission and ISO used 2140 liters for to achieve a mission lifetime of nearly 2.5 years.

The most obvious benefit of this architecture is the substantial reduction in the size of the Observatory, and its resultant launch costs. Spitzer will be launched on a modified Boeing Delta-II rocket (Fig. 1) rather than a larger (and more costly) Titan or Atlas rocket.

A secondary benefit of the warm-launch architecture is that it simplifies pre-launch ground-based testing and integration. Without the need to enclose the entire Observatory in a cryostat, it is easier and less costly to test various sub-systems during the integration of the Observatory prior to launch.

The warm-launch architecture and passive cooling in deep space is the future of space-based infrared observatories. This cost-effective approach is also being adopted, with variations, in the design of future large-aperture infrared telescopes, such as the James Webb Space Telescope. See also **Infrared Astronomy**.

Store-and-Dump Telemetry. Employing onboard, solid-state memory and lossless data compression software, Spitzer utilizes a store-and-dump philosophy of data transfer to the ground. The high-gain antenna on the back end of Spitzer is fixed, so the spacecraft will interrupt its science program once or twice a day to re-point the Observatory to Earth and downlink the data. Telemetry will be provided through NASA's Deep Space Network, with nominal one-hour communication windows scheduled every 12 to 24 hours. See also **Deep Space Network**.

New observing schedules will typically be uplinked to the spacecraft on a weekly basis, although the telemetry design offers the opportunity for more frequent contact (especially early in the mission). The average data acquisition rate is 85 kilobits per second (kbps). Onboard storage capability of 8 Gigabits permits ground operations to downlink a full day of science in the event of a missed telemetry pass.

Taken together, the choice of orbit and the telemetry requirements suggest that Spitzer will spend the vast majority of its precious lifetime conducting valuable scientific observations. It is estimated that Spitzer will make 100,000 or more observations during its predicted five-year life.

Program Management. In most previous flight development programs, the design and requirements of the mission were completed first, and then the contractors were brought in to bid on development. In an effort to constrain costs, the Spitzer Project embarked on an experimental approach. The Project Team members, including the industrial contractors, were

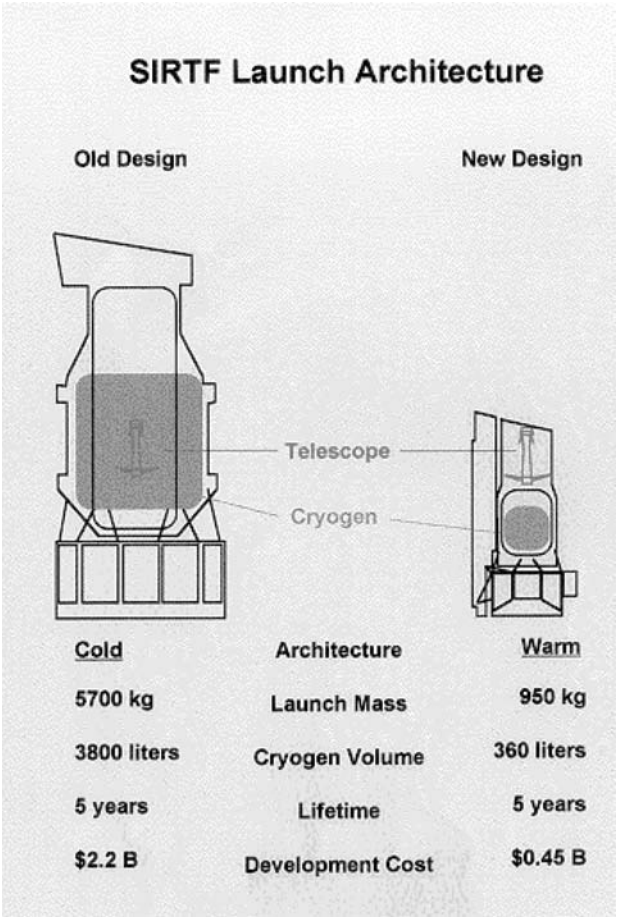

Fig. 14. The "warm-launch" cryogenic architecture adopted by Spitzer (right) substantially reduces mass and development costs. Note that the size of the telescope, depicted in red, is identical in the two designs. The reduction in the size of the cryogenic "packaging" (in blue) enables the entire Observatory to be vastly reduced in size. (*Image courtesy of NASA/JPL*).

solicited early enough to enable full participation in the preliminary design process. The entire Spitzer team worked closely together during the design and the development phases of Spitzer.

Caltech's Jet Propulsion Laboratory http://www.jpl.nasa.gov/ in Pasadena, California retains responsibility for overall project management, systems engineering, and flight operations. Lockheed Martin Space Systems Company http://www.lmaeronautics.com/redirects.html (Sunnyvale, California) is responsible for the spacecraft and for the system integration and testing. Ball Aerospace and Technologies Corporation (Boulder, Colorado) http://www.ballaerospace.com/sirtf.html is responsible for the cryogenic telescope assembly (CTA). The three science instruments, part of the CTA, were designed and built by university-based research teams. Development of the InfraRed Array Camera was managed by the Smithsonian Astrophysical Observatory (Cambridge, Massachusetts) http://cfa-www.harvard.edu/cfa/oir/Research/irac/firstpage.html and built at the NASA Goddard Space Flight Center (Greenbelt, Maryland) http://www.gsfc.nasa.gov/. The Infrared Spectrograph was designed and built at Cornell University (Ithaca, New York) http://isc.astro.cornell.edu/SIRTF//, while the Multiband Imaging Photometer for Spitzer was designed and fabricated at the University of Arizona (Tucson, Arizona) http://mips.as.arizona.edu/mipspage/. Science operations for Spitzer are based at the Spitzer Science Center on the campus of the California Institute of Technology in Pasadena.

Science Overview

Spitzer will study a wide variety of astronomical phenomena, extending from our Solar System to the distant reaches of the early Universe. Providing coverage at infrared wavelength between 3 and 180 microns, Spitzer provides an important scientific complement to the Hubble Space Telescope and the Chandra X-Ray Observatory. The shortest IR wavelengths will pierce through the heavy obscuration of dust and allow astronomers to study newly formed stars. The longer IR wavelengths are well suited to studying the distribution of dust, an important ingredient of future planet and star formation, throughout the Milky Way Galaxy. See also **Hubble Space Telescope (HST)**; and **Chandra X-Ray Observatory**.

Nearly 80 percent of the observing time on Spitzer will be available to the scientific community-at-large through competitive proposals solicited by the Spitzer Science Center; http://ssc.spitzer.caltech.edu/. To date, over half of the Spitzer mission (assuming a 5-year mission) has been defined through the Legacy Science Program; http://ssc.spitzer.caltech.edu/legacy/, the First-Look Survey; http://ssc.spitzer.caltech.edu/fls/, and the Guaranteed Time Observations; http://ssc.spitzer.caltech.edu/geninfo/gto/.

One consequence of the re-designs of Spitzer in the early 1990s was the decision to design Spitzer such that it would make important and lasting contributions in these four science themes:

Planets. Spitzer will study some of the well-known planets and their moons, in addition to the comets, asteroids and dust scattered throughout our Solar System. The Observatory will also devote considerable time to studies of the circumstellar ("surrounding a star") disks of dust and gas found around nearby stars, which are thought to eventually form "extrasolar" planetary systems.

The Outer Planets. Objects like the Sun and Moon are too bright and would saturate the sensitive solid-state detectors on Spitzer. The primary planetary targets in the Solar System will be the outer planets, where no robotic exploration is anticipated in the foreseeable future. Spitzer will barely resolve details on Uranus and Neptune, but imaging and spectroscopic observations should be able to detect temperature variations and chemical compositions within their atmospheres. The diameter of Pluto is smaller than a Spitzer pixel, and hence the planet will be spatially unresolved. Observations will be limited to global characterizations of the icy planet's thermal properties.

Spitzer will be able to study and characterize the largest moons of Jupiter, Saturn and the other outer planets. Particular emphasis will be directed towards Titan, the largest natural satellite of Saturn. This intriguing moon has an atmosphere visited by the Cassini spacecraft in 2004, during the Spitzer prime mission. Observations by Spitzer will help to establish the global context for the results from Cassini and its Huygens probe, and will help scientists understand the composition and large-scale changes in the Titan atmosphere. Observations of Neptune's largest moon, Triton, will also be undertaken with Spitzer.

Moons. Spitzer will be able to study and characterize the largest moons of Jupiter, Saturn and the other outer planets. Particular emphasis will be directed towards Titan, the largest natural satellite of Saturn. This intriguing moon has an atmosphere and was visited by the Cassini spacecraft in 2004, during the Spitzer prime mission. Observations by Spitzer will help to establish the global context for the results from Cassini and its Huygens probe, and will help scientists understand the composition and large-scale changes in the Titan atmosphere. Observations of Neptune's largest moon, Triton, will also be undertaken with Spitzer. See also **Cassini Mission to Saturn**.

Comets. Since comets are reservoirs for primeval material surviving from the time of Solar System formation, they offer an intriguing target for Spitzer. The Observatory will examine comets at large distances from the Sun. Studies will include the structure and composition of cometary dust and ices and their comparison with similar dust grains and ice particles found in other astrophysical realms. In 2003, comet Encke passed within 0.2 AU of Spitzer, (Fig. 15.) offering an unusual opportunity for the Observatory to conduct infrared observations that can be integrated with other measurements obtained from Earth and from the CONTOUR spacecraft.

Asteroids. There are 11,000 named asteroids with known orbits, and four times as many with preliminary orbit determinations. However, only 2,000 have measured diameters and albedos, mostly with diameters in excess of 10 km (6.2 miles). It is estimated that up to a few million kilometer-sized asteroids exist in the Main Belt between Mars and Jupiter. The large variation in reflected (visible) light from asteroids complicates any attempt to characterize their size distribution. Therefore, Spitzer will

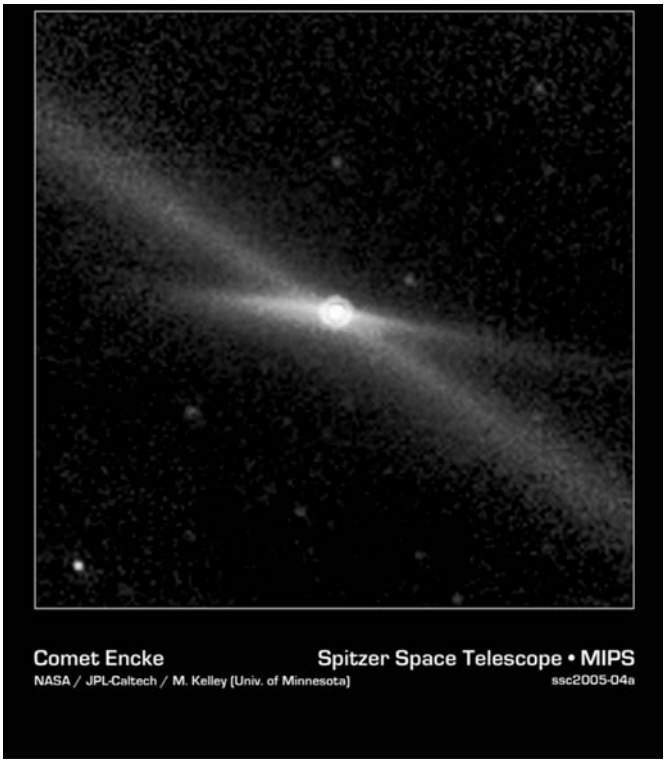

Fig. 15. This image taken by NASA's Spitzer Space Telescope shows the comet Encke riding along its pebbly trail of debris (long diagonal line) between the orbits of Mars and Jupiter. This material actually encircles the solar system, following the path of Encke's orbit. Twin jets of material can also be seen shooting away from the comet in the short, fan-shaped emission, spreading horizontally from the comet.

Encke, which orbits the Sun every 3.3 years, is well traveled. Having exhausted its supply of fine particles, it now leaves a long trail of larger more gravel-like debris, about one millimeter in size or greater. Every October, Earth passes through Encke's wake, resulting in the well-known Taurid meteor shower.

This image was captured by Spitzer's multiband imaging photometer when Encke was 2.6 times farther away than Earth is from the Sun. It is the best yet mid-infrared view of the comet at this great distance. The data are helping astronomers understand how rotating comets eject particles as they circle the Sun. (*Image courtesy of NASA/JPL-Caltech/M. Kelley (Univ. of Minnesota*.)

rely on measurements of thermal infrared emission to obtain better data for asteroids with diameters smaller than 10 km (6.2 miles).

Kuiper Belt Objects. The Kuiper Belt is found beyond the orbit of Neptune and contains perhaps 100,000 faint and icy bodies. This distant reservoir is the source of comets with short orbital periods and highly eccentric orbits. Astronomers have discovered only a few hundred of these Kuiper Belt Objects (KBOs) to date. Due to their faintness, KBOs are difficult to detect through reflected sunlight. Spitzer will instead directly detect their faint thermal emission and determine their albedos and thermal/physical properties.

Dust. Interplanetary dust is found throughout the Solar System and is the result of comets and asteroid collisions. This zodiacal dust is found within the same ecliptic plane in which planets orbit the Sun. Studies of this dust are not only intrinsically interesting, but are necessary in order to "filter out" its foreground thermal infrared emission when studying faint objects outside the Solar System. A unique feature of the Spitzer orbit is that the Observatory will traverse through a dust cloud that is trailing the Earth as it circles the Sun, providing an unusual opportunity to characterize the structure and evolution of the dust. Moreover, studying the influence of larger bodies (such as planets) on the dust cloud morphology is important in interpreting results from observations of circumstellar disks around nearby stars.

Circumstellar Disks and Extrasolar Planets. The InfraRed Astronomical Satellite (IRAS) discovered the presence of dust disks surrounding a handful of nearby stars. These circumstellar disks are thought to be a common feature of stellar evolution and of planetary system formation. No single telescope currently in operation has adequate spatial resolution (or visual acuity) to directly detect planets around other stars. [JPL is developing concepts for a Terrestrial Planet Finder capable of directly imaging planets within ten years.] http://msc.caltech.edu/tpf.html.

Spitzer will be able to detect and characterize circumstellar disks around nearby stars, providing key information about the formation of 'extrasolar' planetary systems. Attempting to see the faint disk at visible wavelengths is extremely difficult because of the bright light from the parent star. However, the relative difference is reduced in the infrared, where Spitzer will conduct its measurements. The Observatory will study hundreds of nearby stars in order determine the frequency of these disks. It will also use imaging and spectroscopy to search to characterize the spatial structure and composition of the disks. These data will prove invaluable in addressing the frequency and nature of planetary systems outside our own.

Stars. Spitzer will provide new and important insights into the formation and evolution of stars, and their immediate ("circumstellar") environment. The discovery and characterization of circumstellar disks of gas and

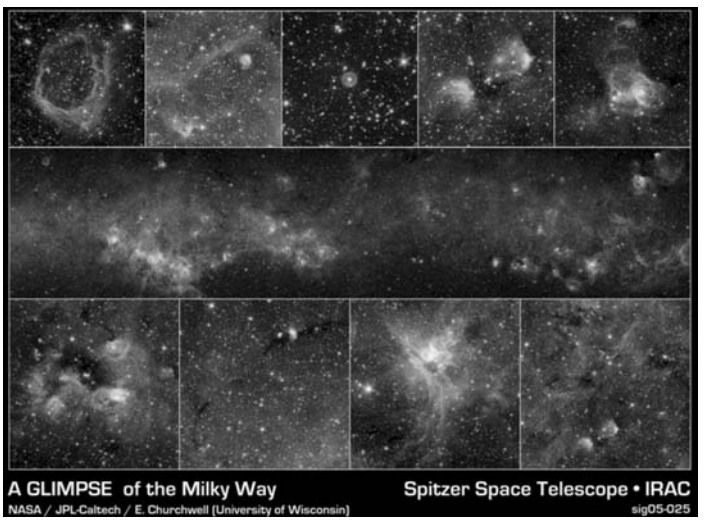

Fig. 16. In visible light, the bulk of our Milky Way galaxy's stars are eclipsed behind thick clouds of galactic dust and gas. But to the infrared eyes of NASA's Spitzer Space Telescope, distant stars and dust clouds shine with unparalleled clarity and color.

In this panoramic image (center row) from the Galactic Legacy Infrared Mid-Plane Survey Extraordinaire (GLIMPSE) project, a plethora of stellar activity in the Milky Way's galactic plane, reaching to the far side of our galaxy, is exposed. This image spans 9 degrees of sky (approximately the width of a fist held out at arm's length).

The red clouds indicate the presence of large organic molecules (mixed with the dust), which have been illuminated by nearby star formation. The patches of black are dense obscuring dust clouds impenetrable by even Spitzer's super-sensitive infrared eyes. Bright arcs of white throughout the image are massive stellar incubators.

With over 160 megapixels, the full detail in this panorama cannot be appreciated without zooming in to various areas of interest (top and bottom rows). Bubbles, or holes, in the red clouds are formed by the powerful outflows from massive groups of forming stars. Wisps of green indicate the presence of hot hydrogen gas. Star clusters can also be seen as the groupings of blue, yellow, and green specks inside some of the red nebulae, or star-forming clouds. In contrast to the plentiful examples of stellar youth in this montage, Spitzer also sees an object called a planetary nebula (top row, middle). Such nebulae are the final gasp of dying stars like our sun, whose outer layers are blown into space, leaving a burnt -out core of a star, called a white dwarf, behind.

Although this panoramic image captures a large range of the galaxy, it represents only 7.5 percent of the primary GLIMPSE survey, which will image most of the star formation regions in our galaxy.

The infrared images were captured with the Spitzer's Infrared Array Camera (IRAC). The pictures are 4-channel false-color composites, showing emission from wavelengths of 3.6 microns (blue), 4.5 microns (green), 5.8 microns (orange), and 8.0 microns (red).

(*Image courtesy of NASA/JPL-Caltech/E. Churchwell (Univ. Wisconsin*)

dust, the signatures of extra-solar planetary systems, is one of the core scientific goals of the Spitzer mission.

Molecular Clouds. Giant molecular clouds, comprised primarily of hydrogen, provide the reservoir of raw materials from which stars are born. These clouds, scattered throughout the interstellar medium of our Milky Way Galaxy, contain enough dense gas and dust to form hundreds of thousands of Sun-like stars. See Fig. 16. Spitzer will study the temperature and density of molecular clouds in order to characterize the physical conditions and chemical compositions from which protostars are formed. See also **Interplanetary Medium**.

Star Formation. Stars are born within cocoons of dust and dense molecular gas, and are mostly hidden from view at visible wavelengths. Near-infrared light, at wavelengths of a few microns, can pierce through the dusty veil to provide astronomers with a peek at a newborn star. Spitzer will use its short-wavelength camera to probe the formation and early evolution of young stellar objects in the first million years of their life. (In astronomical terms, a million years is a brief period of time. Many stars live for *billions* of years.) Spitzer observations will also reveal the extent to which new stars are formed in clusters, rather than in isolation. See Fig. 17.

Circumstellar Disks. A substantial amount of Spitzer observing time will be devoted to the study of circumstellar ("surrounding star") dust disks. These flat disks enshrouding young stars are thought to be a common feature of stellar evolution and of planetary system formation. Primordial protoplanetary disks contain gas and dust and provide the raw materials from which future planetary systems can form. See Fig. 18 and 19. Planetary debris disks represent a later stage of evolution, with most of the gas having been dissipated. These disks are comprised mostly of small

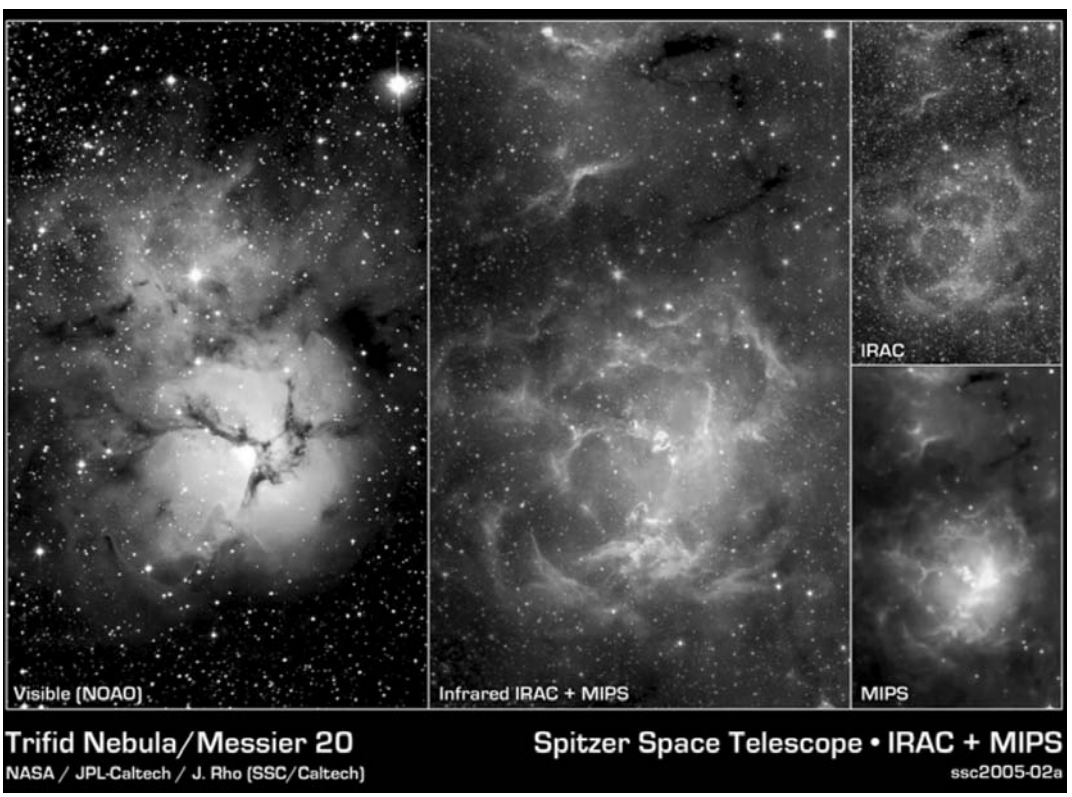

Fig. 17. This image composite compares the well-known visible-light picture of the glowing Trifid Nebula (left panel) with infrared views from NASA's Spitzer Space Telescope (remaining three panels). The Trifid Nebula is a giant star-forming cloud of gas and dust located 5,400 light-years away in the constellation Sagittarius.

The false-color Spitzer images reveal a different side of the Trifid Nebula. Where dark lanes of dust are visible trisecting the nebula in the visible-light picture, bright regions of star-forming activity are seen in the Spitzer pictures. All together, Spitzer uncovered 30 massive embryonic stars and 120 smaller newborn stars throughout the Trifid Nebula, in both its dark lanes and luminous clouds. These stars are visible in all the Spitzer images, mainly as yellow or red spots. Embryonic stars are developing stars about to burst into existence. Ten of the 30 massive embryos discovered by Spitzer were found in four dark cores, or stellar "incubators," where stars are born. Astronomers using data from the Institute of Radioastronomy millimeter telescope in Spain had previously identified these cores but thought they were not quite ripe for stars. Spitzer's highly sensitive infrared eyes were able to penetrate all four cores to reveal rapidly growing embryos.

Astronomers can actually count the individual embryos tucked inside the cores by looking closely at the Spitzer image taken by its infrared array camera (top right). This instrument has the highest spatial resolution of Spitzer's imaging cameras. The Spitzer image from the multiband imaging photometer (bottom right), on the other hand, specializes in detecting cooler materials. Its view highlights the relatively cool core material falling onto the Trifid's growing embryos. The middle panel is a combination of Spitzer data from both of these instruments.

The embryos are thought to have been triggered by a massive "type O" star, which can be seen as a white spot at the center of the nebula in all four images. Type O stars are the most massive stars, ending their brief lives in explosive supernovas. The small newborn stars probably arose at the same time as the O star, and from the same original cloud of gas and dust.

The Spitzer infrared array camera image is a three-color composite of invisible light, showing emissions from wavelengths of 3.6 microns (blue), 4.5 microns (green), 5.8 and 8.0 microns (red). The Spitzer multiband imaging photometer image shows 24-micron emissions. The Spitzer mosaic image combines data from these pictures, showing light of 4.5 microns (blue), 8.0 microns (green) and 24 microns (red). The visible-light image is from the National Optical Astronomy Observatory, Tucson, Ariz. (*Image courtesy of NASA/JPL-Caltech/J.Rho (SSC/Caltech*)

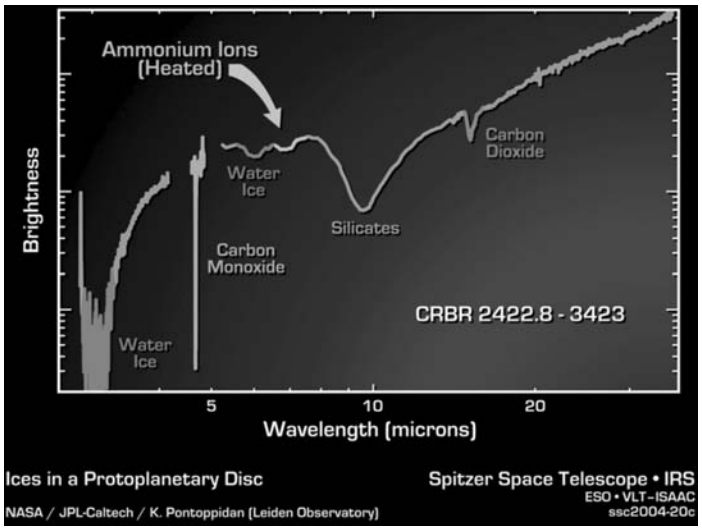

Fig. 18. Astronomers have made the first clear detection of a variety of ices — water, ammonium, and carbon dioxide — in the inner planet-forming region near a young star about 120 light years away. Such an observation is only possible by combining the unique sensitivity of NASA's Spitzer Space Telescope with the fortunate alignment of this particular system.

Planet-forming discs are seen in a variety of orientations, ranging from edge-on (where the discs block the light of the star entirely) to face-on (where the disc is lost in the glare of the star). In this system, known to astronomers as CRBR 2422.8−3423, the disc lies at a unique angle. The light from the star just peeks out over the disc, like a distant sunrise, and contains clues about the disc material through which it has passed.

These observations use Spitzer's infrared spectrograph which acts much like a prism, spreading light out into its component parts, or spectrum. Astronomers study this infrared rainbow, measuring how much light from the star reaches us at different wavelengths. From this they can determine the composition of the disc.

Different ices in the disc each have their own unique infrared "colors" and will block the light in different parts of the star's spectrum. For example, the dip in the spectrum around 6 microns indicates the presence of water ice. The feature at 7 microns is caused by warmed ammonium ions and therefore must be close to the star, within the inner planet-forming region of the disc.

This result has given astronomers a new tool in probing the inner workings of planet-forming discs. By looking for other young stars with discs lined up at just the right angle, they can learn more about the stuff that formed our own solar system almost 5 billion years ago. (*Image courtesy of K. Pontoppidan (Leiden Observatory)*)

dust grains presumably formed from collisions between small planetesimals and larger rocky bodies.

Spitzer will be able to detect and characterize circumstellar disks around nearby stars, providing key information about the formation of planetary systems. See Fig. 20. Attempting to see the faint disk at visible wavelengths is extremely difficult because of the bright light from the parent star. However, the relative difference is reduced in the infrared, where Spitzer will conduct its measurements. The Observatory will study hundreds of nearby stars in order determine the frequency of these disks. It will also use imaging and spectroscopy to search to characterize the spatial structure and composition of the disks. These data will prove invaluable in addressing the frequency and nature of planetary systems beyond our own.

Dwarfs and Low-Mass Stars. While bright and massive stars may dominate the night sky, most of the stellar mass in galaxies is found in low-luminosity, low-mass stars. These stars live for billions of years, but are dimmer and cooler than our Sun, and hence can be difficult to detect at visible wavelengths. Spitzer will use its infrared capabilities to detect and characterize these objects. Particular attention will be devoted to the discovery and characterization of brown dwarfs. These objects are too small to ignite the thermonuclear reactions that define a star, and hence radiate primarily in the infrared. Brown dwarfs were a theoretical concept only when Spitzer was first proposed. Since the mid-1990s, various telescopes and surveys such as 2MASS have identified a few hundred of these objects, with temperatures extending below 2000 K. Spitzer will detect thousands of brown dwarfs, including those only slightly larger than Jupiter, thereby providing a sufficiently large sample for statistical analyses.

Star Clusters. Spitzer observations in this realm will focus primarily on open (or galactic) clusters, gravitationally bound systems of thousands of young stars typically found within the plane of our Galaxy. Clusters are thought to be a natural location for discovering faint brown dwarfs. See Fig. 21. Spitzer will conduct detailed imaging studies of the Pleiades and Hyades clusters, in part to search for previously unseen cluster members as small as ten Jupiter masses.

Evolved Stars. Spitzer will carry out various programs of research into the late evolutionary phases of stars. Once it has exhausted most of its thermonuclear fuel over tens of millions to billions of years, a star like our Sun will enter a rapidly changing stage of its life, with its behavior and ultimate fate depending on the initial mass of the star. During the late stages of its life, a star typically ejects gaseous material from its outer layers, either through gentle periodic processes (such as a nova), or through a violent cataclysmic explosion (supernova). Spitzer will study the stellar ejecta in planetary nebulae, providing information about the temperature and chemical composition of the ejected material, and on the mass loss rates of the parent star. The gas and dust thrown off dying stars is an important constituent of the interstellar medium, and its study is essential for understanding not only stellar death, but the birth of the next generation of stars. See Figs. 22, 23, 24, 25, 26 and 27.

Interstellar Medium. Interspersed between stars is a tenuous interstellar medium (ISM) comprised of dust grains and atomic and molecular gas. Dust absorbs visible and ultraviolet light, increases in temperature, and re-radiates in the infrared. Moreover, many of the most important spectral lines produced by gas in the ISM falls within infrared wavelengths. Spitzer will exploit these fundamental physical traits by conducting spectroscopic studies of the ISM. Among these research investigations will be the important study of water, ices and organic molecules throughout the ISM. Spitzer observations at near-infrared wavelengths will map the inner regions of our Milky Way, yielding important new information that is otherwise obscured by heavy concentrations of dust at visible wavelengths.

Galaxies. Spitzer will conduct extensive imaging and spectroscopic studies of galaxies, ranging from the local neighborhood of our Milky Way Galaxy to the far reaches of the observable universe. See Figs. 28, 29, 30, 31, 32 and 33.

Ultraluminous Infrared Galaxies (ULIRGs). The IRAS satellite revealed a class of ultraluminous galaxies that radiate more than 90 percent of their light in the infrared. Combined infrared and optical studies reveal that the majority of these objects are found in merging and interacting galaxy systems. Understanding the nature of ULIRGs and their relationship to active galaxies (see paragraph below) remains one of the most compelling problems in astrophysics. Spitzer will study their properties and evolution of ULIRGs out to great cosmological distances, and determine the relationship between these galaxies and AGN discovered by other techniques. Spectroscopic measurements will determine the physical conditions in the optically obscured interiors of these galaxies, providing insight into the ultimate power source for these bright beacons.

Active Galaxies / Active Galactic Nuclei. An active galaxy is characterized by extremely intense non-thermal emission, typically at radio and x-ray wavelengths, the signature that a high-energy process is at the core of the intense radiation (the active galactic nuclei, or AGN). The source of the incredible energies released by such a galaxy may be a giant black hole in the galaxy nucleus. Quasars, radio galaxies and Seyfert galaxies are all active galaxies. Many of these objects are enshrouded in dust, in which case they emit large amount of infrared light also. Spitzer will observe AGN at great distances in an effort to understand the relationship between various AGN types, the evolution of their observable properties over time, and the physical processes underlying their energy outputs.

Starburst Galaxies. Starburst galaxies exhibit unusually high rates of star formation on large scales, and are therefore dominated by infrared and visible-light emission from young and massive stars. The starburst phenomenon may be localized near the galaxy center, or may appear throughout the galactic disk. The enhanced star formation is thought to be the result of galaxy mergers or a gravitational encounter with an interacting

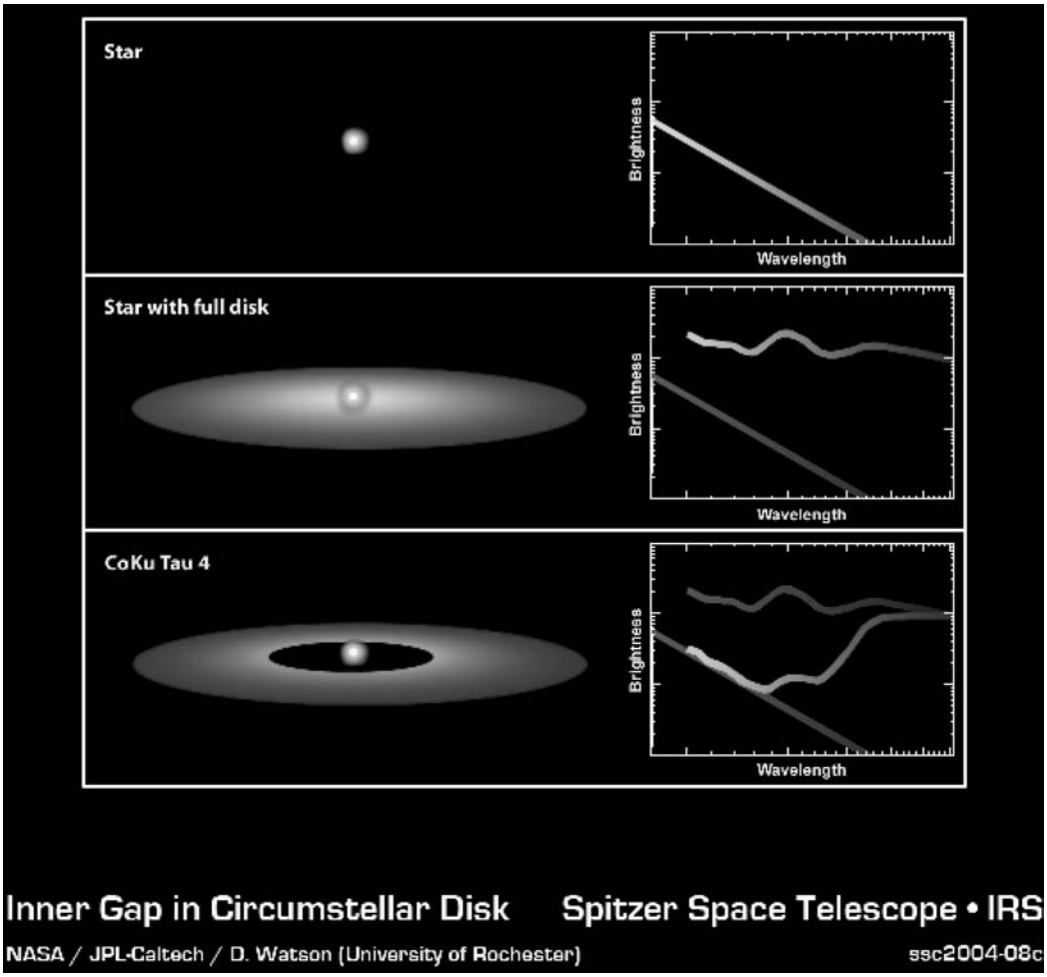

Fig. 19. How can you tell if a star has a protoplanetary disk around it, when the disk is too small to image directly? Using the technique of spectroscopy, scientists can deduce the temperature and chemical composition of material around a star, even if they cannot see the disk itself. Spectroscopy involves spreading the light from a star into a spectrum (in visible light, we are familiar with white light being spread out into a rainbow when it passes through a prism), and then measuring exactly how much light is present in each wavelength. The top illustration represents the spectrum of a star with no circumstellar disc or other surrounding material. The distribution of light at any given wavelength follows a specific and well-known line, determined by the laws of physics and the temperature of the star. In the case of a star, most of the light is produced at shorter wavelengths (the left side of the diagram), due to the high temperature of the star's surface. Moving to the right-hand side of the diagram, the wavelengths increase to lower energies (indicating lower temperatures) and, the starlight drops off.

In the second diagram, we see the spectrum of a star with a disc of dust and gas around it. The warm dust and gas disc around the star produces its own infrared light, which changes the shape of the spectrum. The circumstellar material is cooler than the surface of the star, so it emits most of its light at longer infrared wavelengths, closer to the right-hand side of the diagram. Now, there is an excess of infrared emission, which can not be coming from the star itself. The disk is revealed.

Going a step further, in the third diagram we see the spectrum of a star with a circumstellar disk around it, but in this case, the inner part of the disc has been swept away, perhaps by the formation of a planet. The dust closest to the star was also the hottest, so its absence means that there is less emission from the disk at higher temperatures. The only dust producing infrared light is much cooler than the star, and radiates only at long wavelengths. This low temperature "bump" on the spectrum indicates a disk with a missing center, and may be the first clue that planets have formed inside the disk. (*Image courtesy of NASA/JPL-Caltech/D. Watson (University of Rochester)*.

galaxy. Spitzer will take advantage of the fact that starburst galaxies emit huge amounts of infrared radiation to conduct comprehensive studies of their distribution and evolution over cosmological timescales.

Normal Galaxies. Most of the extragalactic (external to our galaxy) stellar systems are normal galaxies, which display none of the unusual characteristics of active galaxies. Astronomers classify such galaxies by their geometrical appearance: spiral, elliptical, or irregular. The unprecedented sensitivity and spatial resolution of Spitzer at mid- and far-infrared wavelengths will allow astronomers to conduct extensive studies of normal galaxies, extending from the local environs of the Milky Way to the distant and early Universe. Systematic measurements of the dust, gas and stellar content of galaxies within a few tens of millions of light years will provide astronomers with valuable templates for interpreting Spitzer observations of galaxies that are far more distant (and hence smaller in angular extent). Other programs will seek to detect the faint halos that are inferred from dynamical studies of spiral galaxies, map the distribution of molecular hydrogen gas within galaxy disks, and study how the formation and evolution of stars depends on the metallicity of a galaxy.

Galaxy Clusters. Galaxies are often found in large gravitationally bound clusters that are many times larger than their analogous stellar cousins. A rich cluster contains thousands of galaxies and a hot, clumpy intracluster gas detected in x-rays. Spitzer will investigate the extent to which cooling flows of gas, gravitationally attracted to the cluster center, produces low-mass stars and brown dwarfs. In a bizarre confirmation of Einstein's

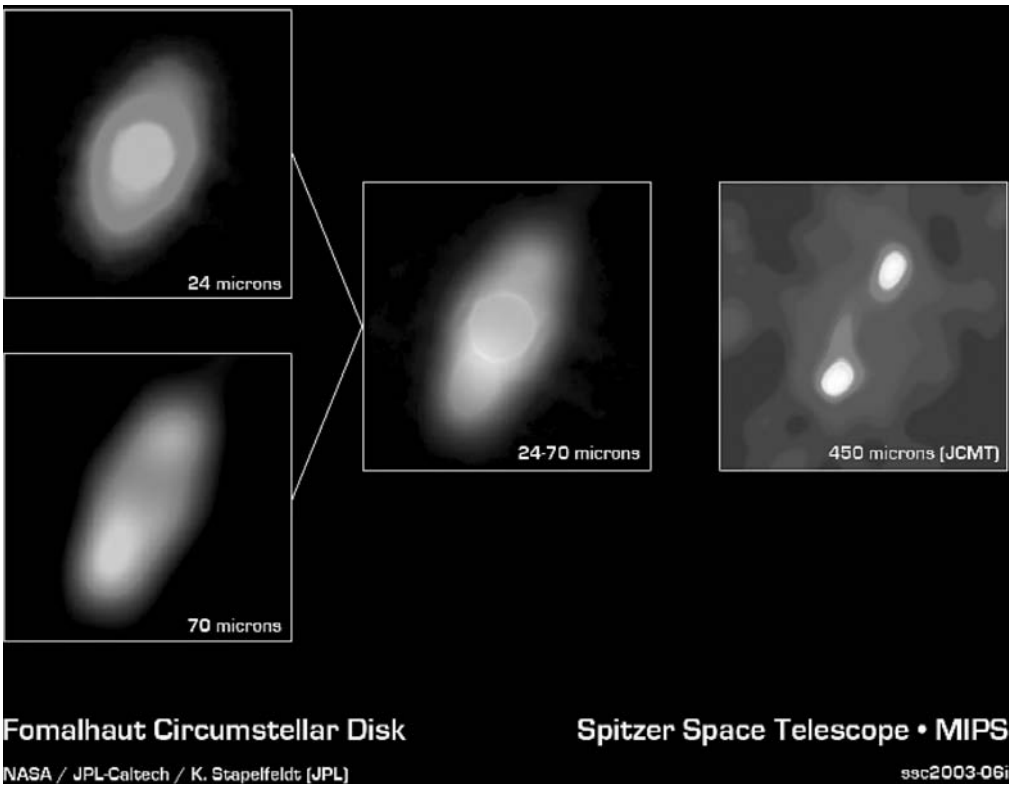

Fig. 20. The NASA Spitzer Space Telescope has obtained the first infrared images of the dust disk surrounding Fomalhaut, the 18th brightest star in the sky. Planets are believed to form from such a flattened disk-like cloud of gas and dust orbiting a star very early in its life. The Spitzer telescope was designed in part to study these circumstellar discs, where the dust particles are so cold that they radiate primarily at infrared wavelengths. Located in the constellation Piscis Austrinus, the parent star and its putative planetary system are found at a distance of 25 light-years.

Twenty years ago, the Infrared Astronomical Satellite, the first orbiting infrared telescope, detected much more infrared radiation coming from Fomalhaut than was expected for a normal star of this type. The dust is presumed to be debris left over from the formation of a planetary system. However, the satellite did not have adequate spatial resolution to image the dust directly. Subsequent measurements with sub-millimeter radio telescopes suggested that Fomalhaut is surrounded by a huge dust ring 370 astronomical units (an astronomical unit is the average distance between the Sun and Earth), or 34 billion miles (56 billion kilometers) in diameter. This corresponds to a size of nearly five times larger than our own solar system. Moreover, the sub-millimeter observations (far right image) revealed that the ring was inclined 20 degrees from an edge-on view.

The new images obtained with the multiband imaging photometer onboard Spitzer confirm this general picture, while revealing important new details of Fomalhaut's circumstellar dust. The 70-micron image (lower left) clearly shows an asymmetry in the dust distribution, with the southern lobe one-third brighter than the northern. Such an unbalanced structure could be produced by a collision between moderate-sized asteroids in the recent past (releasing a localized cloud of dust) or by the steering effects of ring particles by the gravitational influence of an unseen planet.

At 24 microns (upper left), the Spitzer image shows that the center of the ring is not empty. [Note that an image of a reference star was subtracted from the Fomalhaut image to reveal the faint disc emission.] Instead, the 'doughnut hole' is filled with warmer dust that extends inward to within at least 10 astronomical units of the parent star. This warm inner disc of dust occupies the region that is most likely to be occupied by planets and may be analogous to our solar system's 'zodiacal cloud' — but with considerably more dust. One possible explanation for this warmer dust is that comets are being nudged out of the circumstellar ring by the gravitational influence of massive planets. These comets then loop in toward the central star, releasing dust particles just as comets do in our own solar system. (*Image courtesy of NASA/JPL-Caltech/K. Stapelfeldt (JPL), James Clerk Maxwell Telescope*.)

general theory of relativity, massive galaxy clusters are observed to act as gravitational lenses, whereby background (more distant) objects are magnified by the mass of the intervening cluster. Spitzer will utilize such fortuitous alignments to image distant galaxies that would otherwise be too faint to be seen.

ISM in External Galaxies. Astronomers know that galaxies contain much more than stars. An interstellar medium (ISM) of dust and both atomic and molecular gas permeates the regions between stars. It is this ISM that provides the seeds for future star formation. Spitzer will not only conduct exhaustive studies of the ISM in our Milky Way Galaxy, but will also obtain valuable data from external galaxies. Measurements of H II regions in nearby galaxies will yield important data on how star formation is related to the general properties of the host galaxy.

Universe. ***Extragalactic Surveys.*** The unprecedented sensitivity and efficiency of Spitzer makes the observatory an ideal tool for conducting surveys of the extragalactic (external to our Milky Way) infrared sky. Early in its mission, Spitzer will conduct a variety of mid- and far-infrared imaging surveys. Deep and small-area surveys, including one centered on the northern Hubble Deep Field, will probe the early and distant Universe at redshifts approaching 5, corresponding to a distance of about 12 billion light years. Shallower surveys will also be conducted over larger areas, vastly increasing the number of cataloged infrared galaxies. One survey will cover about 70 square degrees, or 350 times the area of the full Moon, out to redshifts of 2.5 (about 10 billion light years). This survey will reveal more than two million galaxies, or nearly 30,000 galaxies per square degree. As with any extragalactic survey, the utility

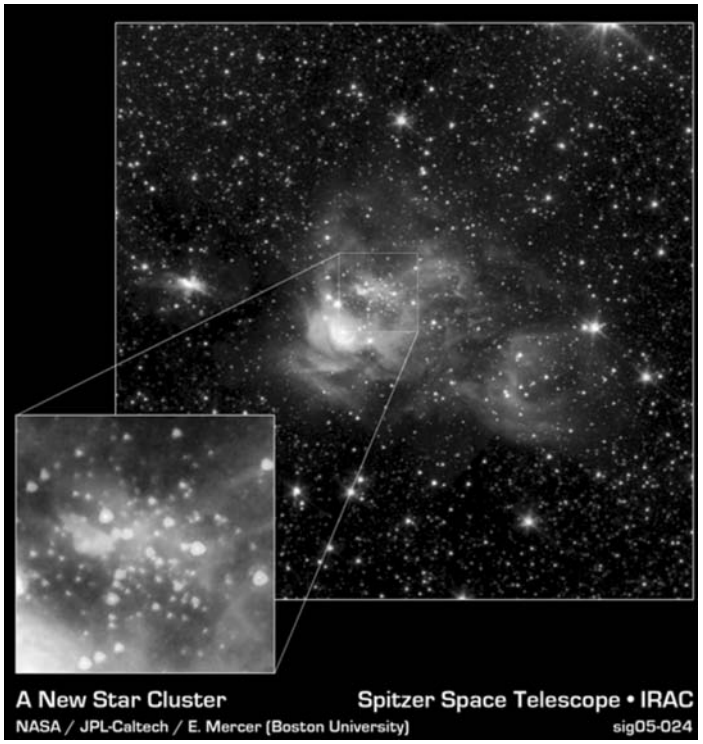

Fig. 21. Using an automated computer method to sift through data collected by NASA's Spitzer Space Telescope, astronomers on the Galactic Legacy Infrared Mid-Plane Survey Extraordinaire (GLIMPSE) team found a new star cluster (inset) in our Milky Way galaxy, in the northern constellation Aquila (main image).

The new cluster is seen in the center of the red nebula, or star-forming cloud, as the grouping of small blue, yellow, and green stars. The wisps of red are organic molecules within the dust which have been illuminated by nearby star formation. Green indicates the presence of hot hydrogen gas. Blue predominantly reveals older stars. The bright white arc located to the lower left side of the central star cluster shows the area where a massive star is forming.

For years, dense obscuring clouds of dust have blocked the central cluster from optical view. The high density of the stars triggered the GLIMPSE team's automatic cluster-finding computer program to the presence of this cluster. There are still some dust clouds even in the heart of this cluster, as seen in the inset, indicating, that stars are probably still being formed today. With time, these clouds will disappear as more stars form.

The infrared image was captured with the Spitzer's infrared array camera (IRAC). The picture is a 4-channel false-color composite, showing emission from wavelengths of 3.6 microns (blue), 4.5 microns (green), 5.8 microns (orange) and 8.0 microns (red). (*Image courtesy of NASA/JPL-Caltech/E. Mercer* (*Boston University*)

Fig. 22. The Crab Nebula is the shattered remnant of a massive star that ended its life in a massive supernova explosion. Nearly a thousand years old, the supernova was noted in the constellation of Taurus by Chinese astronomers in the year 1054 AD.

This view of the supernova remnant obtained by the Spitzer Space Telescope shows the infrared view of this complex object. The blue region traces the cloud of energetic electrons trapped within the star's magnetic field, emitting so-called "synchrotron" radiation. The yellow-red features follow the well-known filamentary structures that permeate this nebula. Though they are known to contain hot gasses, their exact nature is still a mystery that astronomers are examining.

The energetic cloud of electrons are driven by a rapidly rotating neutron star, or pulsar, at its core. The nebula is about 6,500 light-years away from the Earth, and is 5 light-years across.

This false-color image presents images from Spitzer's Infrared Array Camera (IRAC) and Multiband Imaging Photometer (MIPS) at 3.6 (blue), 8.0 (green), 24 (red) microns. (*Image courtesy of NASA/JPL-Caltech/R. Gehrz* (*University of Minnesota*)

of the Spitzer data will be greatly enhanced by companion observing programs at other wavelengths and with other space-borne and ground-based telescopes.

Origin and Evolution of Galaxies. At a cosmological redshift of 5, the visible light emitted by young galaxies is redshifted to near-infrared wavelengths, placing them within Spitzer's observational regime. Astronomers will exploit this capability to observe dusty protogalaxies being born in the young and distant Universe. By examining galaxy properties at different redshifts, or cosmological ages, scientists will trace the history of star formation as a function of environment, and try to explain why the global star formation rate was much higher seven billion years ago. These data will also enable studies of the spatial distribution and clustering of galaxies. Moreover, Spitzer data (when combined with x-ray data) will permit astronomers to ascertain the extent to which starburst galaxies and dusty active galactic nuclei contribute to the global infrared luminosity. See also **Galaxy**.

Cosmic Infrared Background. The cosmic infrared background (CIRB) is a very faint infrared glow in the distant Universe, presumably produced by the juxtaposition of countless unseen galaxies that are too faint to be detected individually. By studying the intensity of the CIRB at different wavelengths, astronomers can interpret the history of star formation, the history of galaxy formation, and the presence or absence of dust in the earliest primeval galaxies. Spitzer should not only confirm the recent detections of this background light, but will characterize the sources(s) of this radiation.

Optically Unidentified IR Sources. It is a well-known observation that some celestial sources emit more (if not most) of their radiation at particular wavelengths. It is certain that Spitzer will discover unusual infrared sources with no known optical counterpart. Spectroscopic measurements with Spitzer will allow astronomers to obtain the redshift, and hence the inferred distance, of these mysterious objects. The Spitzer data will be combined with observations at other wavelengths, such as x-ray and radio, to aid in the interpretation of the unidentified infrared sources.

Serendipity. Spitzer's powerful combination of great sensitivity, high observing efficiency, large-format detector arrays, and a long cryogenic lifetime represents a giant leap beyond current capabilities. This potent combination will produce a rich legacy of scientific results that will be studied for decades. As history has repeatedly shown, astronomers can also expect the unexpected: serendipitous discoveries of unanticipated phenomena.

See also **Astronomy**; and **Infrared Astronomy**.

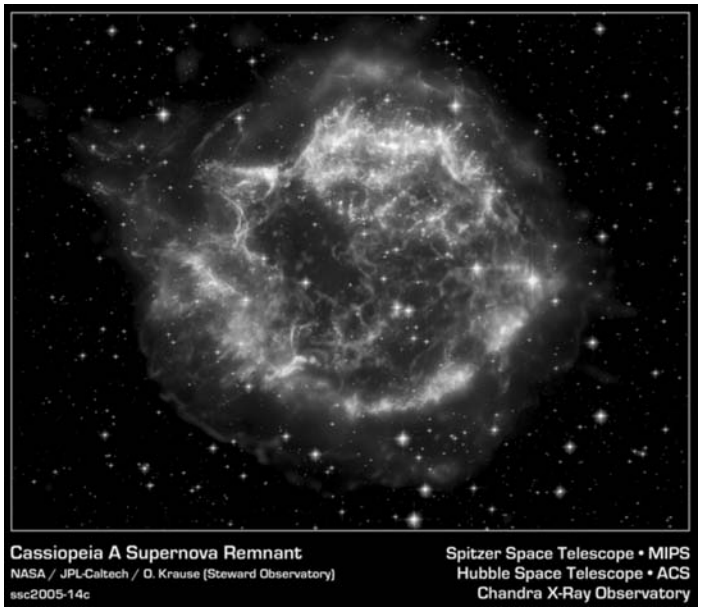

Fig. 23. This stunning false-color picture shows off the many sides of the supernova remnant Cassiopeia A. It is made up of images taken by three of NASA's Great Observatories, using three different wavebands of light. Infrared data from the Spitzer Space Telescope are colored red; visible data from the Hubble Space Telescope are yellow; and X-ray data from the Chandra X-ray Observatory are green and blue.

Located 10,000 light-years away in the northern constellation Cassiopeia, Cassiopeia A is the remnant of a once massive star that died in a violent supernova explosion 325 years ago. It consists of a dead star, called a neutron star, and a surrounding shell of material that was blasted off as the star died. This remnant marks the most recent supernova in our Milky Way galaxy, and is one of the most studied objects in the sky.

Each Great Observatory highlights different characteristics of this celestial orb. While Spitzer reveals warm dust in the outer shell about a few hundred degrees Kelvin (80 degrees Fahrenheit) in temperature, Hubble sees the delicate filamentary structures of hot gases about 10,000 degrees Kelvin (18,000 degrees Fahrenheit). Chandra probes unimaginably hot gases, up to about 10 million degrees Kelvin (18 million degrees Fahrenheit). These extremely hot gases were created when ejected material from Cassiopeia A smashed into surrounding gas and dust. Chandra can also see Cassiopeia A's neutron star (turquoise dot at center of shell).

Blue Chandra data were acquired using broadband X-rays (low to high energies); green Chandra data correspond to intermediate energy X-rays; yellow Hubble data were taken using a 900 nanometer-wavelength filter, and red Spitzer data are from the telescope's 24-micron detector. (*Image courtesy of NASA / JPL-Caltech / O. Krause* (*Steward Observatory*)

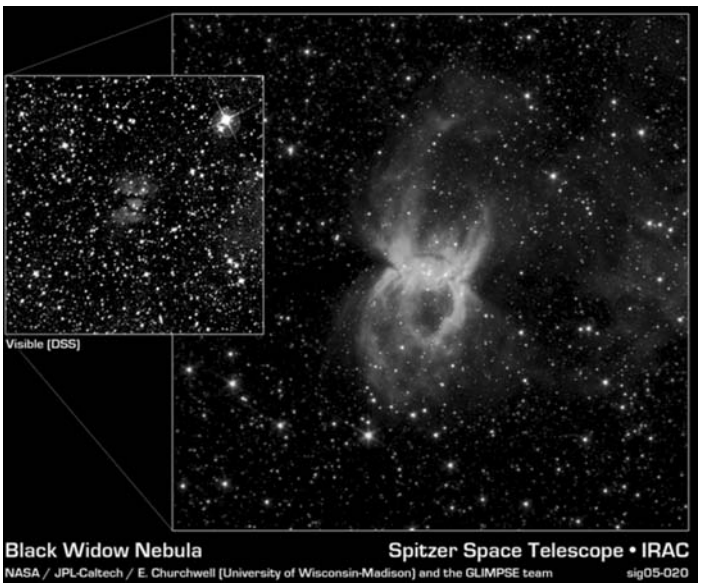

Fig. 24. In the constellation Circinus, where previous visible-light observations by the Digital Sky Survey (left) saw only a faint hourglass-shaped patch of obscuring dust and gas, NASA's Spitzer Space Telescope's dust-piercing eyes see a big "Black Widow Nebula" teeming with clusters of massive young stars (right).

In the Spitzer image, the two opposing bubbles are being formed in opposite directions by the powerful outflows from massive groups of forming stars. The baby stars can be seen as specks of yellow where the two bubbles overlap.

When individual stars form from molecular clouds of gas and dust they produce intense radiation and very strong particle winds. Both the radiation and the stellar winds blow the dust outward from the star creating a cavity or, bubble.

In the case of the Black Widow Nebula, astronomers suspect that a large cloud of gas and dust condensed to create multiple clusters of massive star formation. The combined winds from these groups of large stars probably blew out bubbles into the direction of least resistance, forming a double bubble.

The infrared image was captured by the Galactic Legacy Infrared Mid-Plane Survey Extraordinaire (GLIMPSE) Legacy project. The Spitzer picture is a four-channel false-color composite, showing emission from wavelengths of 3.6 microns (blue), 4.5 microns (green), 5.8 microns (orange) and 8.0 microns (red). (*Image courtesy of NASA/JPL-Caltech/E. Churchwell* (*University of Wisconsin-Madison*) *and the GLIMPSE Team*).

More information on the Spitzer mission is available from the project's home page at http://www.spitzer.caltech.edu/spitzer/index.shtml.

Jet Propulsion Laboratory (JPL), California Institute of Technology, Pasadena, CA

SPLEEN. An organ of vertebrates derived from mesenchyme and lying in the mesentery. It is closely associated with the circulatory system. The organ consists of masses of tissue of granular appearance, known as lymphoid tissue, located around fine terminal branches of veins and arteries. According to one interpretation, these vessels are connected through the spleen pulp by modified capillaries called splenic sinuses. The pulp is supported by a reticular tissue foundation and contains blood cells of all kinds in addition to the characteristic mesenchymal cells. The functions of the organ are the formation of blood cells, the destruction of old red cells, the removal of other debris from the blood stream, and as a reservoir for blood. It is estimated that the spleen can store from one-fifth to one-third of the total volume of blood. By undergoing periodic contractions during severe exercises, lowering of barometric pressure, and in cases of carbon monoxide poisoning, asphyxia, and hemorrhage, the organ can accommodate emergency calls for blood to be added to the circulatory system.

In humans, the spleen is situated in the left upper part of the abdomen, behind the stomach, just below the diaphragm. The organ, in an adult human, measures about $5 \times 3 \times 2$ inches ($12.5 \times 7.5 \times 5$ centimeters) in size. In some diseases, it enlarges (*splenomegaly*) and may even fill a large portion of the left side of the abdomen. Enlargement occurs in certain pathological conditions, such as Banti's disease, Gaucher's disease, and certain anemias. *Splenectomy* (surgical removal of the spleen) frequently gives favorable results in these cases. Enlargement also occurs in malaria, bacterial endocarditis, leukemia, and Hodgkin's disease, among others. In these latter cases, removal of the spleen is medically contraindicated. In persons who have undergone a splenectomy, or who are functionally asplenic (such as in sickle cell disease), there are attendant risks of overwhelming bacterimias with certain microorganisms, such as *Streptococcus pneumoniae* and *Haemophilas influenzae* Type B. This is particularly true of children.

The spleen is classified as a ductless gland and is also regarded as one of the centers of activity of the reticuloendothelial system. Its presence is not necessary for life. It may be removed surgically and often is, following abdominal injuries with rupture and hemorrhage from the spleen, or in the treatment of certain blood diseases (hemorrhagic purpura, familial jaundice, etc.), or for the removal of splenic tumors or cysts. Congenital anomalies such as accessory spleens occur, and rarely has the spleen been found to be completely absent.

Fig. 25. Located 1,000 light-years from Earth in the constellation Perseus, a reflection nebula called NGC 1333 epitomizes the beautiful chaos of a dense group of stars being born. Most of the visible light from the young stars in this region is obscured by the dense, dusty cloud in which they formed. With NASA's Spitzer Space Telescope, scientists can detect the infrared light from these objects. This allows a look through the dust to gain a more detailed understanding of how stars like our sun begin their lives.

The young stars in NGC 1333 do not form a single cluster, but are split between two sub-groups. One group is to the north near the nebula shown as red in the image. The other group is south, where the features shown in yellow and green abound in the densest part of the natal gas cloud. With the sharp infrared eyes of Spitzer, scientists can detect and characterize the warm and dusty disks of material that surround forming stars. By looking for differences in the disk properties between the two subgroups, they hope to find hints of the star- and planet-formation history of this region.

The knotty yellow-green features located in the lower portion of the image are glowing shock fronts where jets of material, spewed from extremely young embryonic stars, are plowing into the cold, dense gas nearby. The sheer number of separate jets that appear in this region is unprecedented. This leads scientists to believe that by stirring up the cold gas, the jets may contribute to the eventual dispersal of the gas cloud, preventing more stars from forming in NGC 1333.

In contrast, the upper portion of the image is dominated by the infrared light from warm dust, shown as red. (*Image courtesy of NASA/JPL-Caltech/R. A. Gutermuth* (*Harvard-Smithsonian CfA*).

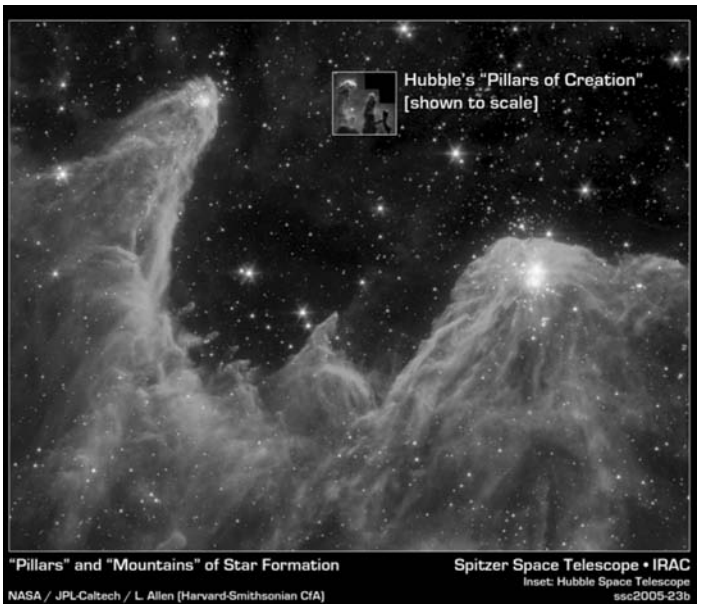

Fig. 26. This majestic false-color image from NASA's Spitzer Space Telescope shows the "mountains" where stars are born. Dubbed "Mountains of Creation" by Spitzer scientists, these towering pillars of cool gas and dust are illuminated at their tips with light from warm, embryonic stars.

The new infrared picture is reminiscent of Hubble's iconic visible-light image of the Eagle Nebula (inset), which also features a star-forming region, or nebula, that is being sculpted into pillars by radiation and winds from hot, massive stars. The pillars in the Spitzer image are part of a region called W5, in the Cassiopeia constellation 7,000 light-years away and 50 light-years across. They are more than 10 times in the size of those in the Eagle Nebula (shown to scale here).

The Spitzer's view differs from Hubble's because infrared light penetrates dust, whereas visible light is blocked by it. In the Spitzer image, hundreds of forming stars (white/yellow) can seen for the first time inside the central pillar, and dozens inside the tall pillar to the left. Scientists believe these star clusters were triggered into existence by radiation and winds from an "initiator" star more than 10 times the mass of our Sun. This star is not pictured, but the finger-like pillars "point" toward its location above the image frame.

The Spitzer picture also reveals stars (blue) a bit older than the ones in the pillar tips in the evacuated areas between the clouds. Scientists believe these stars were born around the same time as the massive initiator star not pictured. A third group of young stars occupies the bright area below the central pillar. It is not known whether these stars formed in a related or separate event. Some of the blue dots are foreground stars that are not members of this nebula.

The red color in the Spitzer image represents organic molecules known as polycyclic aromatic hydrocarbons. These building blocks of life are often found in star-forming clouds of gas and dust. Like small dust grains, they are heated by the light from the young stars, then emit energy in infrared wavelengths.

This image was taken by the Infrared Array Camera (IRAC) on Spitzer. It is a 4-color composite of infrared light, showing emissions from wavelengths of 3.6 microns (blue), 4.5 microns (green), 5.8 microns (orange), and 8.0 microns (red). (*Image courtesy of NASA/JPL-Caltech/L. Allen* (*Harvard-Smithsonian CfA*).

SPODUMENE. The mineral spodumene is a lithium aluminum silicate [CAS: 12068-40-5] corresponding to the formula $LiAlSi_2O_6$ and occurs in monoclinic prismatic crystals, occasionally of very large size. It also occurs massive. Spodumene has a perfect prismatic cleavage often very noticeable; uneven to splintery fracture; brittle; hardness, 6.5–7.5; specific gravity, 3–3.2; luster, vitreous to dull; color, grayish- to greenish-white, green, yellow and purple. Its streak is white; it is transparent to translucent. Spodumene is characteristically a mineral of the pegmatites, and it is found in Sweden, Ireland, Madagascar and Brazil. In the United States it is found especially in the pegmatites of Oxford County, Maine; in the towns of Goshen, Huntington and Chesterfield in western Massachusetts; at Branchville, Connecticut; in North Carolina; in South Dakota in huge crystals and in San Diego and Riverside Counties in California.

The name spodumene is derived from the Greek meaning ash-colored, particularly appropriate for the slightly weathered varieties. Hiddenite, the beautiful emerald-green or yellow-green spodumene that is used as a gem,

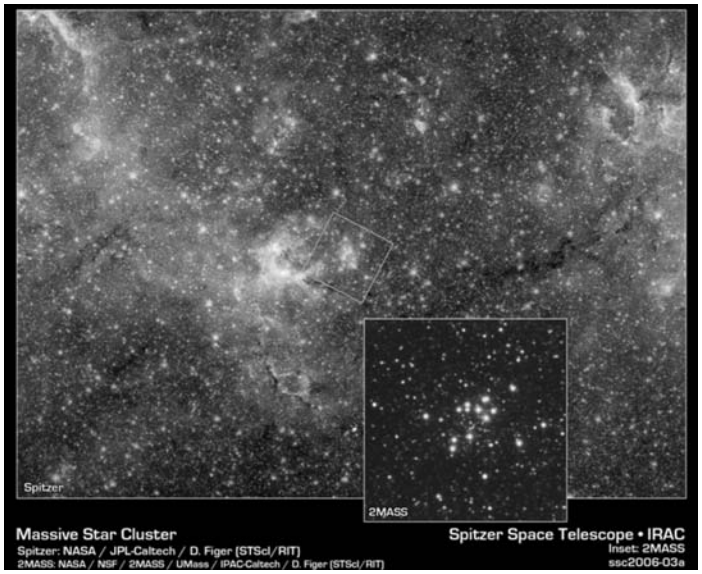

Fig. 27. The sky is a jewelry box full of sparkling stars in these infrared images. The crown jewels are 14 massive stars on the verge of exploding as supernovae.

These hefty stars reside in one of the most massive star clusters in the Milky Way Galaxy. The bluish cluster is inside the white box in the large image, which shows the star-studded region around it. A close-up of the cluster can be seen in the inset photo.

These large stars are a tip-off to the mass of the young cluster. Astronomers estimate that the cluster is at least 20,000 times as massive as the Sun. Each red supergiant is about 20 times the Sun's mass.

The larger color-composite image was taken by the Spitzer Space Telescope for the Galactic Legacy Infrared Mid-Plane Survey Extraordinaire (GLIMPSE) Legacy project. The survey penetrates obscuring dust along the thick disk of our galaxy to reveal never-before-seen stars and star clusters.

The false colors in the image correspond to infrared-light emission. The stars in the large color-composite image all appear blue because they emit most of their infrared light at shorter wavelengths.

The inset image, a false-color composite, was captured by the Two Micron All Sky Survey (2MASS). Astronomers identified the cluster as a potential behemoth after spotting it in the 2MASS catalogue. They then used the Infrared Multi-object Spectrograph at the Kitt Peak National Observatory in Arizona to analyze the cluster's colors. From that analysis, they discovered the red supergiants. They confirmed the red supergiants' pedigree by studying the colors of other red supergiants in data taken by the Spitzer Space Telescope.

The cluster lies 18,900 light-years away in the direction of the constellation Scutum. It is the first in a survey of 130 potentially massive star clusters in the Milky Way that astronomers will study over the next five years using a variety of telescopes, including the Spitzer and Hubble space telescopes.

The Spitzer image was taken April 4, 2004; the 2MASS image on July 4, 1999.

The science team that studied the star cluster consists of Don Figer, Space Telescope Science Institute/Rochester Institute of Techology; John MacKenty, Massimo Robberto, and Kester Smith, Space Telescope Science Institute; Francisco Najarro, Instituto de Estructura de la Materia in Madrid, Spain: Rolf Kudritzki, University of Hawaii in Honolulu; and Artemio Herrero, Universidad de La Laguna in Tenerife, Spain. (*Image courtesy of NASA/JPL-Caltech, D. Figer (Space Telescope Science Institute/Rochester Institute of Technology) and the GLIMPSE Legacy team of E. Churchwell, B. Babler, M. Meade, and B. Whitney (University of Wisconsin), and R. Indebetouw (University of Virginia).*

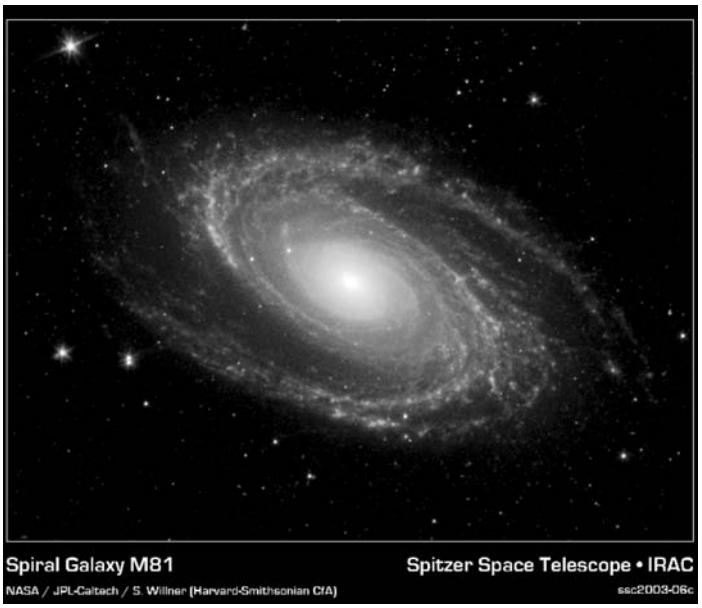

Fig. 28. The magnificent spiral arms of the nearby galaxy Messier 81 are highlighted in this NASA Spitzer Space Telescope image. Located in the northern constellation of Ursa Major (which also includes the Big Dipper), this galaxy is easily visible through binoculars or a small telescope. M81 is located at a distance of 12 million light-years.

Because of its proximity, M81 provides astronomers with an enticing opportunity to study the anatomy of a spiral galaxy in detail. The unprecedented spatial resolution and sensitivity of Spitzer at infrared wavelengths show a clear separation between the several key constituents of the galaxy: the old stars, the interstellar dust heated by star formation activity, and the embedded sites of massive star formation. The infrared images also permit quantitative measurements of the galaxy's overall dust content, as well as the rate at which new stars are being formed.

The infrared image was obtained by Spitzer's infrared array camera. It is a four-color composite of invisible light, showing emissions from wavelengths of 3.6 microns (blue), 4.5 microns (green), 5.8 microns (yellow) and 8.0 microns (red). Winding outward from the bluish-white central bulge of the galaxy, where old stars predominate and there is little dust, the grand spiral arms are dominated by infrared emission from dust. Dust in the galaxy is bathed by ultraviolet and visible light from the surrounding stars. Upon absorbing an ultraviolet or visible-light photon, a dust grain is heated and re-emits the energy at longer infrared wavelengths. The dust particles, composed of silicates (which are chemically similar to beach sand) and polycyclic aromatic hydrocarbons, trace the gas distribution in the galaxy. The well-mixed gas (which is best detected at radio wavelengths) and dust provide a reservoir of raw materials for future star formation.

The infrared-bright clumpy knots within the spiral arms denote where massive stars are being born in giant H II (ionized hydrogen) regions. The 8-micron emission traces the regions of active star formation in the galaxy. Studying the locations of these regions with respect to the overall mass distribution and other constituents of the galaxy (e.g., gas) will help identify the conditions and processes needed for star formation. With the Spitzer observations, this information comes to us without complications from absorption by cold dust in the galaxy, which makes interpretation of visible-light features uncertain.

The white stars scattered throughout the field of view are foreground stars within our own Milky Way galaxy. (*Image courtesy of NASA/JPL-Caltech/S. Willner* (*Harvard-Smithsonian Center for Astrophysics*).

was named for W.E. Hidden. Kunzite, named in honor of George F. Kunz, is a transparent lilac to rose-colored spodumene from Madagascar and California, and recently as magnificent, large gem crystals of both purple and yellow color from the Hindu-Kush Mountains, Nuristan Province in Afghanistan. Beautiful gem stones are cut from such crystals, but its easy cleavage discourages its use as a wearable gem. Spodumene alters rather readily to a mass of albite and muscovite. The commercial use of spodumene is chiefly as a source of lithium compounds.

See also **Lithium**.

SPONDYLARTHROPATHIES. During the early part of the twentieth century, all inflammatory diseases of or in the region of the joints were called "rheumatoid arthritis." Differences, such as the variations in sites involved, were simply assumed to be a reflection of the rather random character of a single disease. Dissatisfaction with this oversimplified view developed over the years and new names for specific manifestations of such conditions appeared. Rheumatoid spondylitis, for example, came into vogue to identify rheumatoid arthritis of the spine. Today there is an entire group of rheumatic diseases that are not directly related to rheumatoid arthritis. These diseases are called the *spondylarthropathies*. Ankylosing spondylitis is the most common disease of this group,

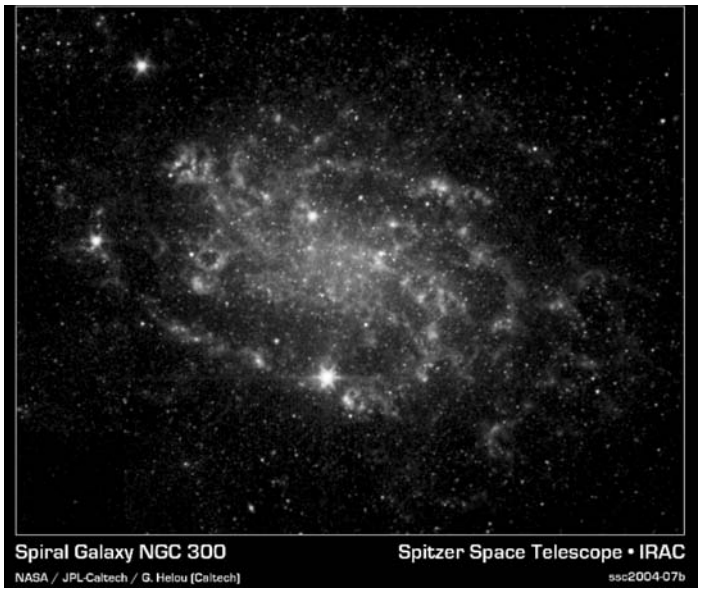

Fig. 29. Sometimes, the best way to understand how something works is to take it apart. The same is true for galaxies like NGC 300, which NASA's Spitzer Space Telescope has divided into its various parts. NGC 300 is a face-on spiral galaxy located 7.5 million light-years away in the southern constellation Sculptor.

This false-color image taken by the infrared array camera on Spitzer readily distinguishes the main star component of the galaxy (blue) from its dusty spiral arms (red). The star distribution peaks strongly in the central bulge where older stars congregate, and tapers off along the arms where younger stars reside.

Thanks to Spitzer's unique ability to sense the heat or infrared emission from dust, astronomers can now clearly trace the embedded dust structures within NGC 300's arms. When viewed at visible wavelengths, the galaxy's dust appears as dark lanes, largely overwhelmed by bright starlight. With Spitzer, the dust — in particular organic compounds called polycyclic aromatic hydrocarbons — can be seen in vivid detail (red). These organic molecules are produced, along with heavy elements, by the stellar nurseries that pepper the arms.

The findings provide a better understanding of spiral galaxy mechanics and, in the future, will help decipher more distant galaxies, whose individual components cannot be resolved.

This image was taken on Nov. 21, 2003 and is composed of photographs obtained at four wavelengths: 3.6 microns (blue), 4.5 microns (green), 5.8 microns (orange) and 8 microns (red). (*Image courtesy of NASA/JPL-Caltech/G. Helou* (*Caltech*).

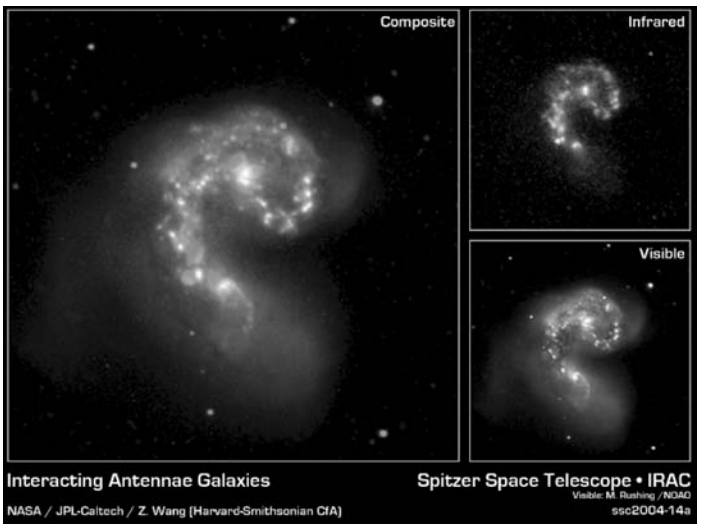

Fig. 30. This false-color image from NASA's Spitzer Space Telescope reveals hidden populations of newborn stars at the heart of the colliding "Antennae" galaxies. These two galaxies, known individually as NGC 4038 and 4039, are located around 68 million light-years away and have been merging together for about the last 800 million years. The latest Spitzer observations provide a snapshot of the tremendous burst of star formation triggered in the process of this collision, particularly at the site where the two galaxies overlap.

The main image is a false-color composite of infrared data from Spitzer and visible-light data from Kitt Peak National Observatory, Tucson, Ariz. Visible light from stars in the galaxies (blue and green) is shown together with infrared light from warm dust clouds heated by newborn stars (red).

The two nuclei, or centers, of the merging galaxies show up as yellow-white areas, one above the other. The brightest clouds of forming stars lie in the overlap region between and left of the nuclei.

The upper right panel shows the Spitzer image by itself. This picture was taken by the infrared array camera and is a combination of infrared light ranging from 3.6 microns (shown in blue) to 8.0 microns (shown in red). The dust emission (red) is by far the strongest feature in this image. Starlight was systematically subtracted from the longer wavelength data (red) to enhance dust features.

The lower right panel shows the true-color, visible-light image by itself. Here, we find a strikingly different view, with the bright star-forming features seen in the Spitzer image buried within dark clouds of dust.

Throughout the sky, astronomers have identified many of these so-called "interacting" galaxies, whose spiral discs have been stretched and distorted by their mutual gravity as they pass close to one another. The distances involved are so large that the interactions evolve on timescales comparable to geologic changes on Earth. Observations of such galaxies, combined with computer models of these collisions, show that the galaxies often become forever bound to one another, eventually merging into a single, spheroidal-shaped galaxy.

In the Spitzer image, wavelengths of 3.6 microns are represented in blue, 4.5 microns in green and 5.8-8.0 microns in red. In the composite image, wavelengths of .44 microns are represented in blue, .70 microns in green and 8.0 microns in red. The Spitzer image was taken on Dec. 24, 2003. (*Image courtesy of NASA/JPL-Caltech/Z. Wang* (*Harvard-Smithsonian CfA*).

which also includes Reiter's syndrome. Findings during and since the early 1970s have shown an immunogenetic connection between the spondylarthropathies and indeed a relationship with several other diseases. As one authority has observed, the group typified by ankylosing spondylitis may be distinguished from rheumatoid arthritis on historic, geographic, epidemologic, genetic, immunogenetic, clinical, immunologic, pathologic, radiologic, and therapeutic grounds.

In research in this area, human leukocyte antigen (HLA-B27) has been the key to developing the relationship of ankylosing spondylitis, for example, with certain other diseases. Statistics indicate that 90–100% of patients with ankylosing spondylitis are B27-positive; 70–90% of patients with endemic Reiter's syndrome (combination of urethritis, conjunctivitis, and arthritis, first discovered by Reiter in 1916); 80–90% with *Salmonella*-reactive arthropathy; 80% with epidemic Reiter's syndrome; 80% with *Yersinia*-reactive arthropathy; 50–70% with inflammatory bowel disease with sacroiliitis; 50–60% with psoriatic arthropy with sacroiliitis; 40–60% with juvenile chronic polyarthropathy; among other striking comparisons.

Ankylosing spondylitis, one time regarded as an uncommon disease, is now believed to occur at about the same rate as rheumatoid arthritis. Although the B27 gene occurs in about 7% of white people, only about 1.5% develop the disease. The disease is rare among black people. It is believed that available statistics may be low because of earlier misdiagnosis and inaccurate reporting. At one time, the disease was considered predominant among white males under 40 years of age, but it is now suggested that there may be a reasonable balance of occurrence in males and females.

If left untreated, ankylosing spondylitis ultimately renders the spine rigid. Fortunately, based upon the recently collected knowledge pertaining to the nature of the disease and, in combination with early treatment, the prognosis is quite good. Medication is directed toward relieving pain and decreasing inflammation. As of the early 1980s, because of the relative unavailability of detailed controlled studies defining the treatment of the disease, current therapy may be altered as new information is gained.

Psoriatic Arthropathy. The association of psoriasis with psoriatic arthropathy ("psoriatic arthritis") has been a subject of debate for many years. The disease is frequently seen and it is estimated that possibly 20% of individuals with psoriasis (principally with psoriatic nail disease) may develop psoriatic arthropathy. The occurrence in men significantly exceeds that in women. The disease may take the form of asymmetric involvement

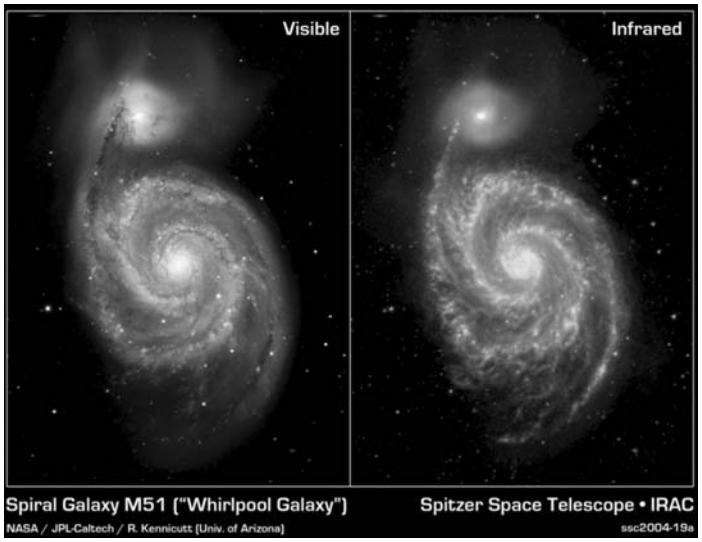

Fig. 31. NASA's Spitzer Space Telescope has captured these infrared images of the "Whirlpool Galaxy," revealing strange structures bridging the gaps between the dust-rich spiral arms, and tracing the dust, gas and stellar populations in both the bright spiral galaxy and its companion.

The Spitzer image is a four-color composite of invisible light, showing emissions from wavelengths of 3.6 microns (blue), 4.5 microns (green), 5.8 microns (orange) and 8.0 microns (red). These wavelengths are roughly 10 times longer than those seen by the human eye.

The visible light image comes from the Kitt Peak National Observatory 2.1 m telescope, and has the same orientation and size as the Spitzer infrared image, measuring 9.9 by 13.7 arcminutes (north up). Also a four-color composite, the visible light image shows emissions from 0.4 to 0.7 microns, including the H-alpha nebular feature (red in the image).

The light seen in the images originates from very different sources. At shorter wavelengths (in the visible bands, and in the infrared from 3.6 to 4.5 microns), the light comes mainly from stars. This starlight fades at longer wavelengths (5.8 to 8.0 microns), where we see the glow from clouds of interstellar dust. This dust consists mainly of a variety of carbon-based organic molecules known collectively as polycyclic aromatic hydrocarbons. Wherever these compounds are found, there will also be dust granules and gas, which provide a reservoir of raw materials for future star formation.

Particularly puzzling are the large number of thin filaments of red emission seen in the infrared data between the arms of the large spiral galaxy. In contrast to the beady nature of the dust emission seen in the arms themselves, these spoke-like features are thin and regular, and prevalent in the gaps all over the face of the galaxy.

Also of interest is the contrast in the distributions of dust and stars between the spiral and its faint companion. While the spiral is rich in dust, bright in the longer infrared wavebands, and actively forming new stars, its blue companion shows little infrared emission and hosts an older stellar population. The spectacular whirlpool structure and star formation in M51 are thought to be triggered by an ongoing collision with its companion. Understanding the impact on star formation by the interaction of galaxies is one of the goals of these observations.

The targeted galaxy is known by various names: M51 from its Messier catalog designation, and also as NGC 5194. M51 was one of the original discoveries of Charles Messier, found in October 1773 while he was observing a faint comet. The Messier catalogue of galaxies is named after him. Colloquially, M51 is also known as the "Whirlpool Galaxy", or "Rosse's Galaxy," after Lord Rosse, who first detected galaxy spiral structure in his observations of M51. The companion, NGC 5195, was discovered in 1781 by Pierre Mechain.

The Whirlpool galaxy is a favorite target for amateur and professional astronomers, alike, and was the first light target for the Infrared Space Observatory. Found in the constellation Canes Venatici, M51 is 37 million light-years away.

The Spitzer observations of M51 are part of a large 500-hour science project, known as the Spitzer Infrared Nearby Galaxy Survey, which will comprehensively study 75 nearby galaxies with infrared imaging and spectroscopy. From these data, astronomers will probe the physical processes connecting star formation to the properties of galaxies. This information will provide a vital foundation of data, diagnostic tools, and astrophysical inputs for understanding the distant universe, ultraluminous galaxies, and the formation and evolution of galaxies. (*Image courtesy of R. Kennicutt* (*Steward Observatory, Univ. of Arizona*).

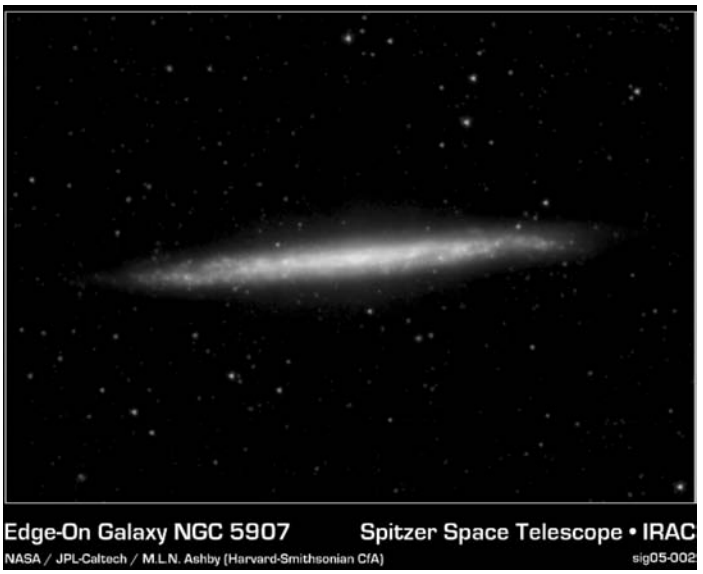

Fig. 32. The spiral galaxy NGC 5907, sometimes known as the "Splinter Galaxy" because of its unusual appearance, is located in the constellation Draco. It is fairly bright, and appears elongated because it has an edge-on alignment when viewed from Earth. It also has a strong set of dust lanes, visible in this image from NASA's Spitzer Space Telescope as red features. The central lane is so pronounced at visible light wavelengths, where it blocks our view of the starlight, that the galaxy was once mistaken for two objects and given two entries in the original *New General Catalogue*. The catalogue, published by J.L.E. Dreyer in 1888, was an attempt to collect a complete list of all nebulae and star clusters known at the time.

NGC 5907's special orientation and close proximity to Earth have made it a popular target for observation by both professional and amateur astronomers. Over the last decade, ever-improving infrared instrumentation have allowed scientists to detect light from the galaxy that was until now hidden by dust. Recent observations using Spitzer's InfraRed Array Camera at infrared wavelengths from 3-10 microns resulted in the discovery of a significant and potentially massive thick stellar disk. This is the first time that a thick disk has been detected and characterized in the infrared.

This image is composed of images obtained at four wavelengths: 3.6 microns (blue), 4.5 microns (green), 5.8 microns (orange) and 8 microns (red). The contribution from starlight has been subtracted from the 5.8 and 8 micron images to enhance the visibility of the dust features. (*Image courtesy of NASA/JPL-Caltech/M.L.N. Ashby* (*Harvard-Smithsonian CfA*).

of both large and small joints. The so-called sausage-shaped digit is considered typical. Although a connection between psoriasis and psoriatic arthropathy has been made, much remains to be learned. It is known, for example, that some forms of psoriatic arthropathy are distinguished only with difficulty from rheumatoid arthritis and that the latter can be present in a patient with psoriasis coincidentally and with no connection between the two diseases.

SPONGES. See **Porifera**.

SPORE. A special type of reproductive cell that develops directly into a new plant. Spores are of many kinds. In the Thallophytes they may be asexual cells or zygotes. Thick-walled spores formed after the union of isogametes are called zygospores. Oöspores are fertilized eggs. In the higher plants spores are always produced by diploid plants and develop into haploid gametophytes. In Selaginella and the seed plants small spores, microspores, produce male gametophytes; large spores, megaspores, produce female gametophytes. Pollen grains in the seed plants develop from microspores.

Some bacterial cells become thick-walled spores. This allows them to survive unfavorable conditions. Fungi also develop spores. See also **Fungus**.

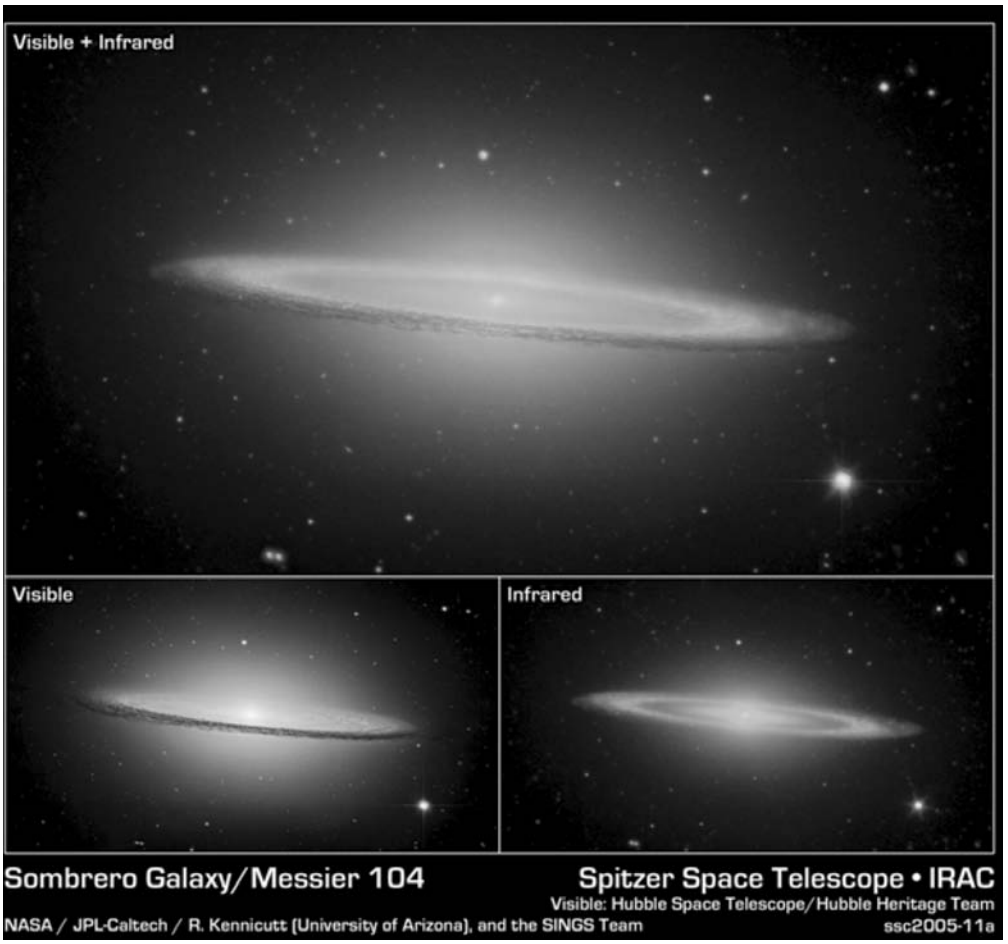

Fig. 33. NASA's Spitzer and Hubble Space Telescopes joined forces to create this striking composite image of one of the most popular sights in the universe. Messier 104 is commonly known as the Sombrero galaxy because in visible light, it resembles the broad-brimmed Mexican hat. However, in Spitzer's striking infrared view, the galaxy looks more like a "bull's eye."

In Hubble's visible light image (lower left panel), only the near rim of dust can be clearly seen in silhouette. Recent observations using Spitzer's infrared array camera (lower right panel) uncovered the bright, smooth ring of dust circling the galaxy, seen in red. Spitzer's infrared view of the starlight, piercing through the obscuring dust, is easily seen, along with the bulge of stars and an otherwise hidden disk of stars within the dust ring.

Spitzer's full view shows the disk is warped, which is often the result of a gravitational encounter with another galaxy, and clumpy areas spotted in the far edges of the ring indicate young star-forming regions.

The Sombrero galaxy is located some 28 million light-years away. Viewed from Earth, it is just six degrees south of its equatorial plane. Spitzer detected infrared emission not only from the ring, but from the center of the galaxy too, where there is a huge black hole, believed to be a billion times more massive than our Sun.

The Spitzer picture is composed of four images taken at 3.6 (blue), 4.5 (green), 5.8 (orange), and 8.0 (red) microns. The contribution from starlight (measured at 3.6 microns) has been subtracted from the 5.8 and 8-micron images to enhance the visibility of the dust features.

The Hubble Heritage Team took these observations in May-June 2003 with the space telescope's Advanced Camera for Surveys. Images were taken in three filters (red, green, and blue) to yield a natural-color image. The team took six pictures of the galaxy and then stitched them together to create the final composite image. This magnificent galaxy has a diameter that is nearly one-fifth the diameter of the full Moon. (*Image courtesy of NASA/JPL-Caltech/R. Kennicutt* (*University of Arizona*) *and the SINGS team*).

SPOROPHYLL. A spore-bearing leaf. It actually bears the sporangia that contain the spores. It may be greatly modified in structure and appearance.

SPOROTRICHOSIS. This disease of worldwide distribution is caused by the dimorphic fungus *Sporothrix schenckii*, a fungus that thrives well in a variety of soils and decaying vegetation. It habituates areas of temperate and tropical climates. Exceptionally rich sources of the fungus are found in sphagnum moss, barberry or rose thorns, some soils, and splinters from rotting wood. Infection usually results from subcutaneous inoculation of the infectious spores as the result of contacting a sharp object that contains the spores. The disease is only secondarily contracted by inhalation of spores. Incidence of the disease is higher among males than females. The disease usually is manifested by subcutaneous nodules with an overlying purplish or pinkish coloration. This is followed by involvement of the draining lymph nodes. The disease progresses slowly. The cutaneous-lymphatic form of sporotrichosis usually responds well to treatment with a saturated solution of potassium iodide administered 3 or 4 times daily. Iodide therapy may be required for approximately one month. There are some side effects and the treatment should be supervised by a physician. Where there is an intolerance to iodide therapy, amphotericin B, a microbial agent used in treating other fungus infections, may be administered. A small percentage of patients display pulmonary manifestations of the disease. The clinical signs are almost identical with those of tuberculosis.

R. C. V.

SPRAIN. A variety of injuries in or about a join, that occur when the movement of the joint is carried beyond its normal range, or carried forcibly in a direction where its range is limited. Sprains occur in the ankle, knee, wrist, elbow, and spine, in that order of frequency. An injury in which a sudden wrenching or twisting produces tearing of the ligaments or tendons is a common form of sprain. Displacement of cartilages between joints, tearing of muscles around the joint, and tearing of the synovial membrane are others. The symptoms of a sprain are those of inflammation with pain, swelling, and limitation of motion of the part.

Treatment consists of immobilization of the joint with an adhesive strapping or an elastic bandage, elevation of the extremity, and sometimes aspiration of the joint cavity if an effusion or outpouring of inflammatory fluid occurs.

SPRAY DRYING. A process used in the production of numerous chemical and food products. It is widely used in connection with the production of powdered milk and instant coffee preparations. The spray drying is unique among dryers in that it dries a finely divided droplet by direct contact with the drying medium (usually air) in an extremely short retention time (3 to 30 seconds). This short contact time results in minimum heat degradation of the dried product, a feature that led to the popularity of the spray dryer in the food and dairy industries during its early development. In the case of coffee extract, water in the feed will range from 50 to 70%.

Atomization. In as much as the spray dryer operates by drying a finely divided droplet, the feed to the dryer must be capable of being atomized sufficiently to ensure that the largest droplet produced will be dried within the retention time provided. There are different requirements on the degree of atomization needed to result in the desired product. These factors including minimizing the fine and/or coarse fractions, controlling particle dryness, and controlling bulk density. All commercial atomizers, whether of the centrifugal-wheel, pressure-nozzle, or other types, will produce a particle-size distribution that follows a probability curve. As the total energy input increases, the average particle size will decrease and the particle-size distribution will improve, i.e., the spread between the largest and smallest particles will be less.

Centrifugal-wheel Atomizers. The wheel consists of a disk, which is rotated at very high speed (1700–50,000 revolutions per minute). See Fig. 1. Feed generally is introduced to the center, with centrifugal force dispersing the feed and throwing out a thin film to the periphery. As the film leaves the disk, it breaks up into a thread, which in turn forms droplets. The disk is located in the hot-air stream so that even though droplets are thrown toward the wall of the dryer, the hot air travels cocurrently and dries the particle sufficiently to prevent wall build-up upon contact. A spray dryer with a wheel atomizer must be relatively large in diameter and shorter than a dryer with pressure nozzles.

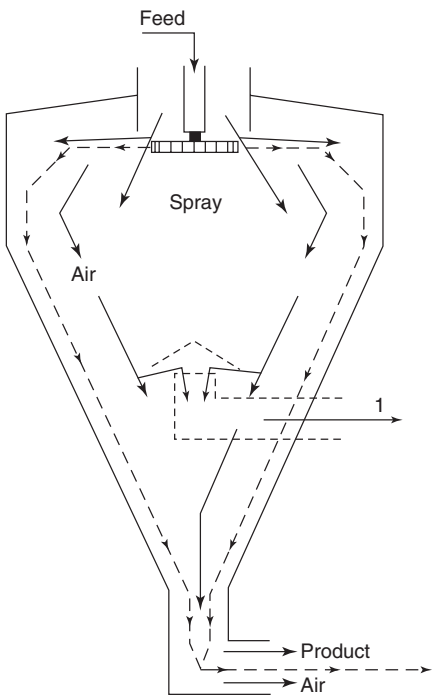

Fig. 1. Spray dryer with wheel atomizer: (1) Air outlet when drying chamber is used for initial separation.

Pressure-Nozzle Atomizers. This system consists of an orifice placed after a fixed mechanism, called a core, swirl chamber, or whizzer, depending upon the manufacturer. A high-pressure pump moves the feed to the nozzle body at a pressure of from 250 to 8000 pounds per square inch (17 to 544 atmospheres). The feed slurry is pumped through high-pressure piping to the whizzer, where a spin is imparted to the fluid before it enters the nozzle orifices. This results in a hollow-cone spray which throws droplets either cocurrent or countercurrent to the air flow.

The flow pattern is such that a cocurrent spray dryer must be relatively long and small in diameter (Fig. 2), whereas a countercurrent dryer is shorter and larger in diameter. A third type, sometimes referred to as a mixed-flow dryer (Fig. 3), uses an air pattern similar to a cyclone collector, i.e., the spray is introduced at the upcoming air stream (countercurrent) and the particles transfer to the air sweeping the wall (cocurrent).

A multistory, tall-form dryer chamber using nozzle atomization is shown in Fig. 4.

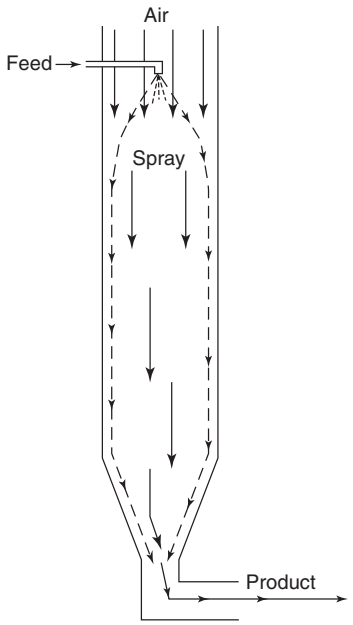

Fig. 2. Spray dryer featuring parallel flow.

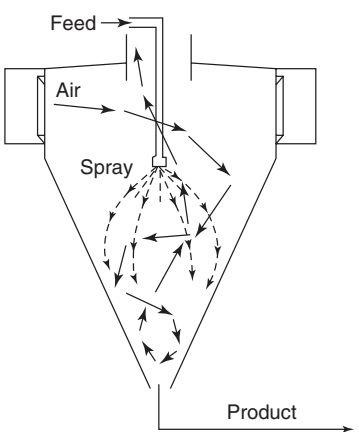

Fig. 3. Mixed-flow spray dryer.

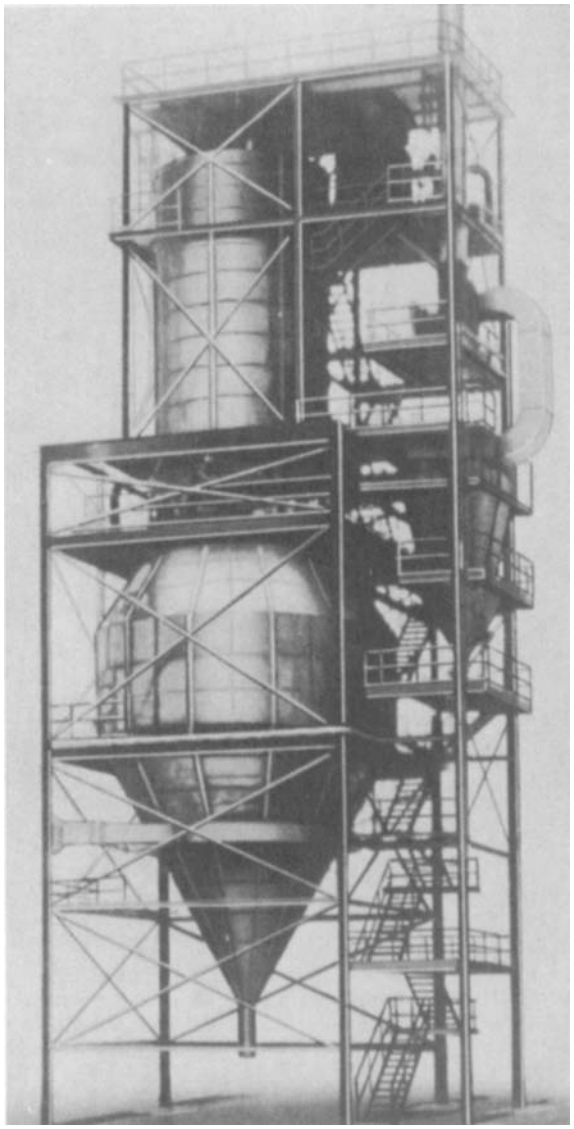

Fig. 4. Tall-form chamber employing nozzle atomization. System is particularly suited for dense particles requiring high-pressure atomization. (*Stork-Bowen*.)

SPRAYS. A spray comprises a cloud of liquid droplets randomly dispersed in a gas phase. Depending on the application, sprays may be produced in many different ways. The basic purposes of sprays are to (*1*) create droplet surface area for enhanced heat and mass transfer, (*2*) disperse a liquid over an area, (*3*) meter or control liquid throughput, and (*4*) generate droplet velocity and momentum. Depending upon the application need, many types of sprays can be produced. Hundreds of spray producing devices have been developed to achieve these purposes.

The mechanical devices designed to generate sprays are commonly called *spray nozzles* or *atomizers*. Liquid atomizers are widely used in modern industry to improve process performance. They are found in many industrial, agricultural, and propulsion systems. Processes that require atomizing systems include spray drying, scrubbing, micropowder formation of pharmaceuticals and catalysts, cooling, fuel combustion, spray painting and coating, application of herbicides and pesticides, food processing, molten-metal solidification, medical nebulizers, and aerosol sprays for consumer products.

Selection of the technology best suited for a specific application starts with the desired function. Table 1 shows a classification of functions with example applications and the desired benefit. This table is ordered with the most frequent usages first. The degree of sophistication required in the selection varies from matching pressure drop and desired liquid flow to the other extreme where detailed measurements of drop size and velocity distributions are utilized with computational fluid dynamics, CFD, to model the application.

Spray technology was improved as a result of environmental regulations in several areas. Reducing emissions of pollutants from combustion of liquid hydrocarbon fuel including carbon monoxide, unburned hydrocarbons, oxides of nitrogen, and smoke required more sophisticated atomizers. For example, aircraft jet engines and automotive engines utilize atomizers to inject hydrocarbon fuel. When paints and coating formulations were changed to reduce the solvent emission, the devices used to atomize the products had to be designed to accommodate increased liquid viscosity. Spray technology is also applied to abate emissions with scrubbers and gas quenching. Because of the potential problems associated with sprays, it has become increasingly important to understand the process of atomization. Liquid atomizers must be properly designed and selected to minimize unnecessary hazards.

In the past, the design of atomizers and spray processes was based on traditional fluid dynamic principles and empirical methods. Fuel atomizers

TABLE 1. SPRAY FUNCTION AND BENEFIT SUMMARY

Application Type	Functions Achieved	Examples	Benefit
Surface application or dispersion	Uniform distribution of liquid on surface	Tablet coating, spray painting, agricultural (herbicide and insecticide application), application of spray of a web of a paper, fire protection, distribution on packed tower, land irrigation, consumer products such as cleaners	Uniform coating minimizes the amount of material applied, reducing cost and adverse effects of too high an application rate; spray transported to the surface
Drop surface area	Enhanced mass and heat transfer — more rapid evaporation	spray quenching, spray drying, scrubbing, dust control, humidification	reduces equipment size and maximizes throughput; wide and stable region of operation; avoids defects caused by too little or too much heat or mass transport
Spray impact	Momentum transport to surface	Cleaning, descaling of steel strip, tank cleaning (clean-in-place), debarking (paper)	Uniform removal of material–no defects caused by lack of removal
Aerosol delivery and particle production	Sized to achieve aerodynamic particle characteristics–liquid and solid particles	Biopharmaceutical aerosol, delivery aerosol	Narrow size distribution achieves desired particle characteristic and uniform particle morphology

for gas jet engines (gas turbines) illustrate the development of technology. This application is demanding due to a factor of 10 in the range operating pressure of the combustion and the limited volume available for the combustion chamber. In the 1950 to 1960 period, atomizer design and selection to optimize performance used trial-and-error methods by building a device and testing in a combustion test stand. This slow and expensive method allowed for only a few designs to be evaluated as a new engine was being designed. In the 1970 to 1980 time frame, innovative methods with practical instruments measuring the drop size were developed which enabled quantitative evaluation of the spray, the drop size, and other parameters independent of combustion. Engine emissions were reduced and the length between service intervals increased. In the 1990s, spray technology advanced rapidly through the synergism of the next generation of reliable spray drop size and velocity measurements and mathematical modeling, including computational fluid dynamics (CFD). The science also developed better fundamental understanding of the mechanisms of liquid break-up and dispersion, and prediction of important spray parameters with improved accuracy. More confident prediction of process performance resulted in innovations and optimized designs, further enhancing systems.

Because high quality, low cost, and optimum performance are required of spray equipment, improved analytical and experimental tools are indispensable for increasing productivity in many industries. In most instances, it is no longer adequate to characterize a spray solely on the basis of flow rate and spray pattern. Information on droplet size, velocity, volume flux, and number density is often needed and can be determined using advanced laser diagnostic techniques. These improvements have benefited a wide spectrum of consumer and specialized industrial products.

Liquid Atomizers

The transformation of bulk liquid to sprays can be achieved in many different ways. Basic techniques include applying hydraulic pressure, electrical, acoustic, or mechanical energy to overcome the cohesive forces within the liquid. Work is required to overcome the liquid surface tension generating a smaller particle size and to accelerate the liquid that forms the collection drops in the spray.

Atomizers can be classified according to the energy source used to achieve liquid breakup. Figure 1 shows this classification diagram. Typical sources of energy include kinetic energy of the liquid and additional gas if added for this purpose. Mechanical energy is used in the form of a rotating or vibration (ultrasonic) surface. When an electric charge is the primary source of energy, it is called an electrostatic atomizer.

Pressure or hydraulic atomizers are the most commonly used due to simplicity and effectiveness in many applications. Two fluid nozzles are often used where a wide range of operating rates are required, because the atomizing gas provides an independent means of adjusting performance and the control in internal flows enables a smaller drop size to be produced. Flashing flow nozzle use has increased with the development of supercritical atomizers for both paint application and pharmaceutical micro powder production. Liquid atomizers classified by distinct design features and spray characteristics are summarized in Table 2.

Physics of Liquid Atomization

Liquid atomization involves a series of complicated physical processes. These processes can generally be divided into three different flow regimes: internal flow, breakup, and droplet dispersion. The internal flow regime extends from the atomizer inlets to the discharge orifice where liquid emerges. The liquid breakup regime starts at the atomizer exit plane and ends at a certain distance downstream where primary atomization is complete. The final process of atomization is the dispersion regime where spherical droplets gradually evolve into a particular spray pattern.

Spray Characteristics

Spray characteristics are those fluid dynamic parameters that can be observed or measured during liquid breakup and dispersal. They are used to identify and quantify the features of sprays for the purpose of evaluating atomizer and system performance, for establishing practical correlations, and for verifying computer model predictions. Spray characteristics provide information that is of value in understanding the fundamental physical laws that govern liquid atomization.

Spray Parameters. There are several common spray parameters.

Droplet Size Distribution. Most sprays comprise a wide range of droplet sizes. Some knowledge of the size distribution is usually required, particularly when evaluating the overall atomizer performance.

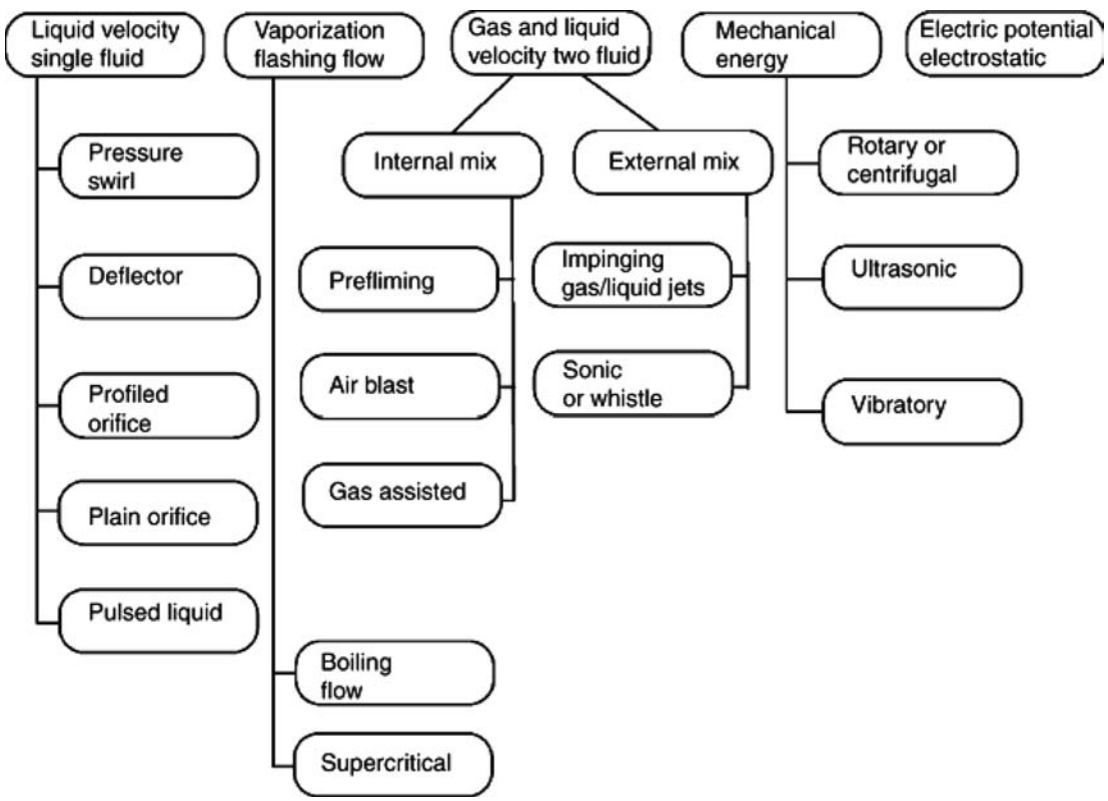

Fig. 1. Classification atomizers based on source of energy.

TABLE 2. SUMMARY OF ATOMIZERS TYPES AND DESIGN FEATURES

Atomizer	Description	Design and Spray Features
	Single Fluid	
Pressure swirl	Circular orifice outlet preceded by swirl chamber having $^{3}1$ tangential inlets;	Hollow conical pattern with spray angles between 30 and 120°; flow rate varies with square root of operating pressure; widely used in oil heating equipment spray;
Deflector	Liquid stream impinged on solid surface to create liquid sheet	Flat spray pattern or spiral form very common usage due to effectiveness in producing fine drop size and general solid cone pattern; impingement–spray angle achieved 10° to 180°; wide industrial usage; modified design allows for solid cone spray pattern; many types of designs of swirling devices
Profiled orifice (cross-cut)	Single orifice with inlet and outlet profile	Oval or flat spray pattern–simple design; frequently used if spray pattern is appropriate
Plain orifice	Cylindrical outlet orifice and inlet	designed to produce a solid stream of liquid achieving high impact; limited usage
Pulsed liquid	Pressure or acoustic pulse applied to liquid upstream of the nozzle	Similar to single fluid nozzle with narrow drop size width or relative span; limited usage
	Vaporization	
Boiling flow	Liquid flashes within or downstream of nozzle	Vapor from boiling liquid induces break-up of liquid; rare usage
Supercritical	Added atomizing agent and sufficient superheat to vaporize	Supercritical carbon dioxide used in some spray painting and pharmaceutical applications
	Two Fluid–Internal Mix	
Pneumatic (twin-fluid)	Movement of gas/vapor is primary source of energy utilized to produce spray	Gas stream directed through various configurations to impinge or lift a liquid stream; tangential slots and a chamber often used to enhance mixing and fluid interaction; large variety of commercial applications; all two fluid nozzles allow the gas to be varied independent of the liquid flow providing an operational and design degree of freedom
Air-assisted	Pneumatic atomizer in which pressurized air is utilized to enhance atomization produced by pressurized liquid	Requires external source of pressurized air; device tends to be energy inefficient, but can produce very fine droplets; commonly used in industrial furnaces or gas turbines
Airblast	Pneumatic atomizer that utilizes a relatively large volume of low pressure air	Liquid is spread into a thin conical sheet exposed to high velocity air on both sides of sheet; widely used in aircraft gas turbine engines
Piloted airblast	Airblast atomizer combined with a lower capacity pressure atomizer	Typically a small pressure atomizer tip surrounded by an annular orifice; atomizing air flows between and outside the two concentric sprays; used in gas turbine engines
	Two Fluid–External Mix	
Impinging gas-liquid jets	A central stream of liquid is impacted by a number of high velocity gas jets causing break-up	Requires more atomizing gas. Large internal passages for liquid- less tendency to plug if the liquid contains solids; robust design; used in waste incineration
Sonic	Pneumatic or vibratory atomizer in which energy is imparted to liquid (frequencies <20 KHz)	High speed gas jet directed to impinge on plate or resonant cavity to produce high frequency sound waves; produces droplets <50 μm, but acoustic noise may be problem
	Mechanical Energy	
Centrifugal	Rotating solid surface is the primary source of energy utilized to produce spray	Liquid is fed into center of spinning disk, cup, or wheel, and spreads out toward rim; produces a 360° spray pattern and relatively uniform drop size; used in spray drying and cooling applications; also used in spray painting, rotary bell, with air flow to shape spray. High rotational speeds common 5,000 to 25,000 RPM; drop size adjusted by rotation speed
Ultrasonic	Energy is imparted to the liquid with a ultrasonic transducer and discharge surface at ultrasonic frequency of 25 to 120 KHz	Drop size depends on the nozzle design and frequency of transducer; generally small scale 10 liters/hr; Sauter mean diameter 40 to 120 microns; widely used in medical inhalation therapy
Vibratory (piezoelectric)	oscillating solid surface is primary source of energy	Consists of hypodermic needle vibrating at controlled frequency; can produce uniform droplet sizes to 30 μm, determined by liquid flow rate, resonant frequency, and needle orifice size; used primarily in laboratory studies
	Electric Potential–Electrostatic	
Electrostatic	Electric charge is imparted on the liquid relative to ground to produce spray	Some devices use capillary tubes or conical disks directly charged at high voltage; others charge liquid film or jet by electrodes outside atomizer; produces very fine droplets, but cannot handle high flow rates; electrical properties of liquid are constrained; used in printing or painting processes

Mean Diameters. Several mean diameters are frequently used to represent the statistical properties of droplets produced by liquid automizers. These mean diameters include volume mean and Sauter mean diameters.

Median Diameter. The median droplet diameter is the diameter that divides the spray into two equal portions by number, length, surface area, or volume. Median diameters may be easily determined from cumulative distribution curves.

Number Density and Volume Flux. The determination of number density and volume flux requires accurate information on the sample volume cross-sectional area, droplet size and velocity, as well as the number of droplets passing through the sample volume at any given instant of time. Volume flux is the volume contained by the droplets passing through a unit cross-sectional area per unit interval of time.

Cone Angle. The spray cone angle is one of the most important parameters in the specification of atomizers. A common method of defining the spray cone angle is to draw two tangent lines originating at the orifice and extending to the outermost spray edges at a specified axial distance.

Patternation. The spray pattern provides important information for many spray applications. It is directly related to the atomizer performance. The pattern information must be able to reveal characteristics such as

skewness, degree of pattern hollowness, and the uniformity of liquid flux over the entire cross-sectional area.

Spray Dynamic Structure. Detailed measurements of spray dynamic parameters are necessary to understand the process of droplet dispersion. Improvements in phase Doppler particle analyzers (PDPA) permit *in situ* measurements of droplet size, velocity, number density, and liquid flux, as well as detailed turbulence characteristics for very small regions within the spray.

Spray Correlations. One of the most important aspects of spray characterization is the development of meaningful correlations between spray parameters and atomizer performance. The parameters can be presented as mathematical expressions that involve liquid properties, physical dimensions of the atomizer, as well as operating and ambient conditions that are likely to affect the nature of the dispersion. Empirical correlations provide useful information for designing and assessing the performance of atomizers. Dimensional analysis has been widely used to determine nondimensional parameters that are useful in describing sprays.

Spray Instrumentation

An ideal droplet measurement instrument should (*1*) not interfere with the spray pattern or breakup process, (*2*) provide for large representative samples, (*3*) permit rapid sampling or counting, (*4*) have adequate resolution and accuracy over a wide range of droplet sizes, and (*5*) accommodate variations in the liquid and ambient gas properties. Significant advances have been made in the development of laser diagnostic techniques for measuring sprays. Prior to selecting such an instrument, users should have a thorough understanding of its capabilities and limitations. Existing droplet measurement techniques may be classified into three broad categories: (*1*) optical nonimaging techniques; (*2*) imaging techniques; and (*3*) nonoptical methods.

Industrial Applications

Spray technology has thousands of industrial applications, with combustion of liquid hydrocarbon fuels being the most economically and environmentally significant. Traditional fuels is one of the most economically important spray applications due to the shear amount of fuel consumed and the environment impact of the resultant combustion gas. More stringent control of fuel combustion, for process heaters, gas turbines, and boilers has been achieved with better atomization technology and control. Combustion of non-traditional fuels (higher viscosity relative to Diesel fuel) including heavy fuel oil and process waste streams poses additional challenges due to the more constrained requirements and material properties. These requirements have prompted research and design engineers in many industries to improve the design, manufacture, quality control, and testing of atomizers.

Some concerns directly related to atomizer operation include inadequate mixing of liquid and gas, incomplete droplet evaporation, hydrodynamic instability, formation of nonuniform sprays, uneven deposition of liquid particles on solid surfaces, and drifting of small droplets. Other possible problems include difficulty in achieving ignition, poor combustion efficiency, and incorrect rates of evaporation, chemical reaction, solidification, or deposition. Atomizers must also provide the desired spray angle and pattern, penetration, concentration, and particle size distribution. In certain applications, they must handle high viscosity or non-Newtonian fluids, or provide extremely fine sprays for rapid cooling.

Commercially tens of thousands of nozzles are available from vendor catalogs. The process of selecting a nozzle that will achieve the desired result often links the knowledge of use requirements with the knowledge of the spray nozzle manufacturer. Several factors must be considered, the first is to match the spray pattern. Although atomizers are usually small components in many industrial spray applications, they play an important role in determining the performance and efficiency of the entire process. It has long been recognized that atomizers must be properly selected to achieve optimum performance.

Because of the complexity of designs and performance characteristics, it can be difficult to select the optimum atomizer for a given application. The best approach is to consult and work with atomizer manufacturers. Their technical staffs are familiar with diverse applications and can provide valuable assistance. They will require the following information: properties of the liquid to be atomized, i.e., density, viscosity, and surface tension; operating conditions and range of operation required, such as flow rate, pressure, and temperature range; required mean droplet size and size distribution; desired spray pattern; spray angle requirement; ambient environment; flow field velocity requirements; dimensional restrictions; flow rate tolerance; material to be used for atomizer construction; cost; and safety considerations.

Noncombustion Applications. The varied applications can be grouped into four broad groups as shown in the Table 3 with examples of each. The type of nozzles and criteria for selection of a specific family of nozzles and choice of a specific nozzle size differs for these applications. The process of design is iterative. A preliminary design cycle removes some designs from further consideration because of constraints such as range of operation that can achieve the required performance; hydraulic capacity; operational limitations; such as pressure drop; reliability requirements. This is followed by a selection cycle to select critical parameters, such a drop size and spray pattern. Tables 3 and 4 provide guidance in selection.

For example, spraying a liquid that contains solids will often preclude nozzles with extremely small internal passages to assure reliable operation. Similarly, a very small flow (0.1 L/h) may eliminate the possibility of using a single fluid nozzle because the small orifice is not feasible.

Surface Application. Complete coverage and uniformity of application are the key measures of performance for distribution usages. The requirements are process specific as the most appropriate quantitative measure. The portion of the spray not deposited on the intended surface is critical in many spray distribution system. This can be due to fines entrained by the surrounding gas or large drops with trajectories missing the desired surface. Often fixed nozzle designs include a number of nozzles with overlapping spray patterns to achieve the desired coverage. The spray pattern may be a flat fan or a full or hollow cone depending on the specific results desired. Distribution types tend to fall in two groups, one where very large drop size is advantageous to minimize adverse effects and the second type where the film quality of the deposition has specific requirements, spray painting for example.

In agricultural spraying, one of the biggest concerns is the drifting of small droplets. Drifting sprays not only lead to waste and environment problems, but also could endanger other nearby crops. Droplets smaller than 150 μm can be easily blown away from the intended target area by a cross wind in aircraft mounted spray delivery. A typical herbicide atomizer produces a spray with 15–20% of the liquid volume contained in droplets less than 150 μm. Atomizer improvements can be made so that the spray contains a narrow droplet size distribution with liquid volume less than 5% contributed by the smaller droplets. Correlations between droplet size and surrounding field conditions are also important.

TABLE 3. SUMMARY OF APPLICATION PERFORMANCE

Application type	Functions achieved	Typical values
Aerosol delivery and particle production	Size to achieve aerodynamic particle characteristics–liquid and solid particles	$D_{V0.50}$ 1 to 10 or 15 to 30 micron
Drop surface area	Enhanced mass and heat transfer — more rapid evaporation	$D_{V0.50}$ 50 to 300 micron; typical values of D_{32} for pressure swirl atomizers range from 50 to 100 μm for fuel combustion
Surface application or dispersion spray impact	Uniform distribution of liquid on surface momentum transport to surface	$D_{V0.5}$ 200 to 500 for many agricultural applications; up to 5000 micron- for flow distribution spatial uniformity of impact force

TABLE 4. SUMMARY OF ATOMIZER SPRAYS FOR SPECIFIC APPLICATIONS

Atomizer Spray	Special Application
Cone spray, hollow or solid	Aerating water, brine sprays, chemical processing, coil defrosting, dust control, evaporative condensers, evaporative coolers, industrial washers, roof cooling, spray ponds, spray coating, spray drying, gas scrubbing and washing, humidification, gas cooling, cooling towers, coal washing, degreasing, gravel washing, dish wash-in, foam control, suspensions and slurries for food and chemical products, pollution control, and oil heating
Flat spray	Asphalt or tar laying, bottle washing, coal and gravel washing, foam control, degreasing, metal cleaning–rinsing, spray coating, vehicle washing and water mist-in, descaling, roll cooling, quenching, and agricultural spraying
Plain jet spray	Rocket engines, diesel engines, mixing of liquids, metering and cutting
Air atomizing spray	Aerating water, dust control, evaporative condensers, evaporative coolers, industrial washers, spray coating, spray drying, gas scrubbing and washing, humidification, gas cooling, continuous casting, cooling casting and molds, curing concrete products, evaporative coolers, foam control, incineration, quenching, spray coating, spray painting, spray drying, flue gas desulfurization, pollution control, gas turbine engines, and medical spray

Spray Impact. Surface cleaning nozzle selection depends on the specific process requirements related to the performance parameters required. A number of specialized nozzles have been developed for tank cleaning to remove residual materials. The three types of nozzles are fixed, multi-orifice "spray ball" type nozzles, and self powered rotating. The cleaning fluid provides the rotational power for turning the nozzle and an external shaft provides a rotational power. The selection of nozzle depends on specific process requirements. Spray impact is often the critical criterion. Therefore a small drop size is of little relevance, perhaps even a disadvantage. Because these smaller drops will more rapidly loose momentum to the surrounding gas.

General surface cleaning nozzles are often of a specialized design to achieve maximum surface impact. The stand-off distance, the spacing between the solid surface and the nozzle is a critical optimization parameter. The web or moving sheet of material is treated as it moves through the spray plumes. Fixed cleaning and descaling systems often have a number of nozzles together in overlapping patterns.

Multiple Nozzles. Many spray applications use compound nozzles where there are multiple outlets on a single nozzle body. This approach is most commonly used with single fluid nozzles. This usage achieves a wider spray application area and a smaller drop size than a single nozzle due the smaller outlet orifice size. A similar function is achieved with an array of nozzles on one or more piping headers. The segmentation of the flow achieves dispersion of the spray across a larger cross-sectional area.

Spray Pattern Selection Criteria. Although spray requirements differ from one application to another, the spray pattern or shape is a reasonable criterion for selecting liquid atomizers for certain processes. Table 4 lists a variety of applications based on the pattern of the spray.

SPREADING COEFFICIENT. A thermodynamic expression for the work done in the spreading of one liquid on another. It is the difference between the work of adhesion between the two liquids and the work of cohesion of the liquid spreading, which may be expressed by the equation

$$F_s = \gamma_B - \gamma_A - \gamma_{AB}$$

where F_s is the spreading coefficient, γ_B is the surface tension of the stationary liquid, γ_A is the surface tension of the spreading liquid, and γ_{AB} is the interfacial tension between the liquids.

SPRING. Devices used to absorb energy or shock as in automobile springs; to serve as a source of power as in clocks or watches; and to provide a force to maintain pressure between contacting surfaces as in friction clutches. Springs with ground ends are generally more satisfactory than those with plain ends; compression springs are more desirable for heavy loads than extension springs, because of the possibility of stress concentration in the loop of the extension spring. Compression springs can, however, be employed for tensile loading. Conical coil springs, if properly designed, may be compressed flat under load. Disk springs represent a recent development that is being extensively employed for heavy loads. Laminated or leaf springs are used in vehicles of various types, although coil springs are now being used in automotive applications. Coil springs may be made of square, rectangular, or round wire. See Fig. 1.

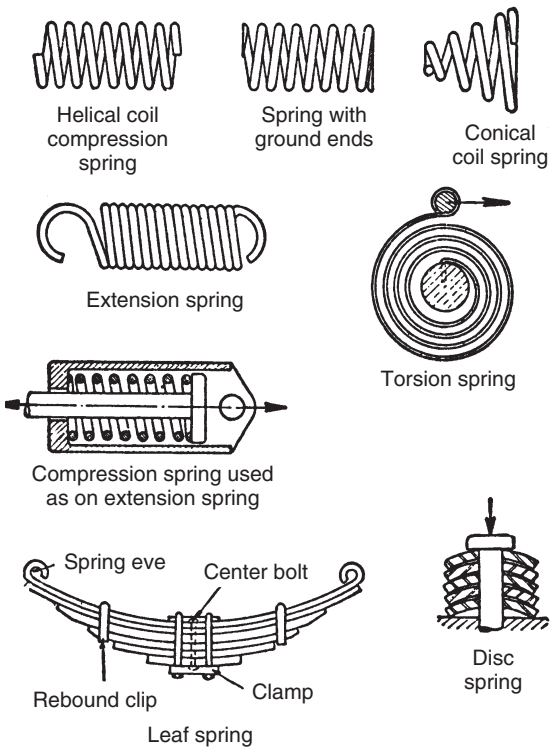

Fig. 1. Types of springs.

SPRING CLOCK. A clock that uses a mainspring to power its balance wheel. Until the fifteenth century, all European clocks were weight-driven. Early spring clocks, developed before the seventeenth century invention of the balance wheel and hairspring by Huygens, had no effective control over the mainspring's progressive loss of power as it unwound. Consequently, first the *fusee* and later the *stackfreed* were developed for equalizing the spring's declining force.

The term fusee is derived from the Latin *fusata* — a cone-shaped device spirally wound with a thread, attached to the spring, designed to compensate through leverage for the declining power of the unwinding clock spring. The term stackfreed is probably derived from the German — a device for compensating through leverage for the declining force of an unwinding clock or watch spring, employing a pinion fixed to the arbor around which the spring is coiled and a second spring with an eccentric cam.

Although not accurate, the resulting clocks were useful because, unlike weight-driven clocks, the spring clocks worked continuously while and after being moved; that is, they were portable. Huygens used the hairspring to control the periodic oscillation of the balance wheel which, in turn, determined the periodic freeing of the pallet from the escape wheel. The latter rotated to work the clock's wheel train which operated the hands on the dial.

The eighteenth-century English horologist John Harrison designed and built the first accurate spring clock for use as a ship's chronometer. Harrison used a mainspring-powered balance wheel movement (incorporating a fusee) set in a watch-like case about 5 inches (12.5 centimeters) in diameter. In 1770, Thomas Mudge of England invented the detached lever escapement that freed the balance wheel from direct contact with the escape wheel, thus completing the basic mechanical clock movement. This basic movement (without a fusee), versions of which still are used in clocks, was miniaturized in the twentieth century for use in small jeweled-lever travel clocks and wristwatches. The mainspring-powered balance wheel normally oscillates two and one-half times a second, causing the jeweled lever escapement to tick five times a second.

Spring-operated timing devices cover a range of intervals, which may vary from a fractional second to a week, or a month or more. The typical lever-type escape movement used today is dependent for its accuracy on precision of manufacture, temperature compensation, and the effect of external loads. Spring movements are limited to driving light loads because of low torque and lack of constant torque. Accuracy may be within 0.2 seconds absolute in a good stopwatch and 5 seconds per day in a good clock movement.

SPRING INDEX AND SPRING RATE. The spring index is the ratio between the mean diameter of the coil of a helical compression spring and the diameter or radial thickness of the spring wire or strip. The spring index is used as a modifier in computing the safe load a spring may carry. For the majority of spring types, the deflection of the spring is proportional to the load on it. The ratio of load to deflection, which may have the units of pounds per inch or inch-pounds per radian, is known as the spring rate, spring constant, or spring scale.

SPRING WATER. See **Hot Spring**.

SPRITE. See **Lightning**.

SPRUCE TREES. Members of the family *Pinaceae* (pine family), these trees are of several species. Spruces are of the genus *Picea*. In terms of tree population and regional areas covered, the spruces exceed the fir trees. See also **Fir Trees**. Some of the species of spruce are extensively used for pulp wood in paper production. The fiber length of the Sitka spruce is a little over 3 millimeters ($\frac{1}{8}$ inch) in length, putting it just behind the Douglas fir and the longleaf pine in this respect; and considerably ahead of the jack pine and lodgepole pine, all used as pulp woods.

Important species of spruce trees not listed on accompanying Tables include:

Chinese spruce	*P. asperata*
Colorado spruce	See Blue spruce
Dragon spruce	See Chinese spruce
Eastern Himalayan weeping spruce	*P. Spinulosa*
Himalayan weeping spruce	*P. smithiana*
Japanese tiger-tail spruce	*P. polita*
Likiang spruce	*P. likiangensis*
Oriental spruce	*P. orientalis*
Sargent spruce	*P. brachytyla*
Schrenk's spruce	*P. schrenkiana*
Serbian spruce	*P. omorika*
Weeping spruce	See Brewer's spruce
Yezo spruce	*P. jezoensis*

Spruce trees are considered very hardy. They are evergreen trees, often conical. The record spruce trees in the United States are detailed in Table 1. See also **Conifers**.

TABLE 1. RECORD SPRUCE TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Black spruce (1989) (*Picea mariana*)	62	157	78	23.8	21	6.4	Wisconsin
Black Hills spruce (1996) (*Picea glauca* var. *densata*)	104	264	122	37.2	25	7.6	South Dakota
Blue spruce (1980) (*Picea pungens*)	186	472	122	37.2	36	11	Utah
Brewer spruce (1999) (*Picea brewerana*)	272	691	137	41.8	44	13.4	California
Engelmann spruce (1995) (*Picea engelmannii*)	283	719	179	54.6	27	8.2	Washington
Norway spruce (1994) (*Picea abies*)	180	457	120	36.6	66	20.1	New York
Red spruce (1986) (*Picea rubens*)	169	429	123	37.5	39	11.9	North Carolina
Red spruce (1987) (*Picea rubens*)	144	366	146	44.5	34	10.4	North Carolina
Sitka spruce (1987) (*Picea sitchensis*)	673	1709	206	62.8	93	28.3	Oregon
Sitka spruce (1987) (*Picea sitchensis*)	707	1796	191	58.2	96	29.3	Washington
White spruce (typ.) (1995) (*Picea glauca* var. *glauca*)	125	318	130	39.6	28	8.5	Minnesota

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).

The white spruce (sometimes called cat spruce or skunk spruce) is a tall tree, usually attaining a height of 70 to 100 feet (21 to 30 meters) in favorable circumstances, somewhat resembles the balsam fir in color and contour. The numerous branches tend to be pendulous. When the needles are bruised, they exude a pungent and unpleasant odor. In addition to pulp wood for paper production, the light, soft, straight-grained and pale yellow wood is used for interiors, flooring, and general construction. The tree ranges from Labrador, Newfoundland, and Nova Scotia all the way west across Canada to British Columbia and is found in the northern parts of the northeastern United States, extending westward at that latitude as far as the Rocky Mountains. It is also found in the mountainous regions of Massachusetts and Connecticut.

The timber of the red spruce is quite strong. The tree sometimes attains a height of about 100 feet (30 meters). Near the center of the tree, the branches are essentially spread horizontally, but the upper branches ascend at an angle of about 45°. This tree ranges from New foundland westward through Pennsylvania and on to Minnesota. It is found in the White Mountains of New England as high as 5000 feet (1500 meters) and in the Adirondacks and Allegheny Mountains to about 4000 feet (1220 meters). The tree ranges along the Allegheny Mountains as far south as Georgia. Some of the better timber from this tree is used for piano sounding boards, but the majority is used for pulp wood, for sheathing and flooring in building construction. Early in this century, the red spruce was threatened by over-harvesting, averted by the passage of the Weeks Act in 1911 for the purchase of national forest at the headwaters of navigable streams. This provided government supervision and control over about one-hundred thousand acres in the White Mountain region.

Closely related, but smaller than the red spruce, the black spruce (or bog spruce) is a smaller tree found in the mountains of the southern states. This tree ranges widely from Labrador, Newfoundland, and Nova Scotia westward past Hudson Bay and on across Canada into southern Alaska. Occurrence in the south is essentially dictated by the presence of swampy regions where it thrives. Black spruce is also a pulp wood and is also used for heavy construction, such as piles, posts, and ship construction.

The Sitka spruce is a western tree, ranging from northern California into Alaska and at elevations ranging from sea level to about 3000 feet (900 meters). Normally, under favorable conditions, the tree may reach a height of some 150 to 180 feet (45 to 54 meters). A Sitka spruce is illustrated in Fig. 1. Parts of fallen Sitka spruces have been found, indicating the trees once approached 300 feet (90 meters) in height. The rugged characteristics of this tree have made it a favorite for planting forests in northern Europe.

The Englemann spruce is also a western tree and is found at high elevations from northwestern Canada (Alberta and British Columbia) southward in a wide swath through Montana, Idaho, Washington, and Oregon to Arizona and New Mexico. The timber from the tree finds general construction use, but is not as strong as most timbers. The blue spruce (sometimes called Colorado blue spruce or silver spruce) is of light coloration, with a distinctive light bluish-gray color, appearing silverish in some light. The tree is a favorite for gardens and landscaping. Normally, the tree does not attain a height much in excess of 40 feet (12 meters) under favorable conditions, but there are exceptions as will be noted from Table 1. The natural region of the tree includes the Colorado and eastern Utah Rocky Mountains and northward into Wyoming. However, the tree has been planted widely throughout the United States. The color tends to vary with location, sometimes becoming more of a bluish-green or light green.

Brewer's or the weeping spruce is also a western tree, found from northwestern California northward into Oregon. Some trees also are found in the Coastal range on the northern slopes. The tree normally attains a height of less than 75 feet (22.5 meters), but can well exceed this figure as shown in Table 1. The tree branches downward to the ground, giving it the weeping appearance. The tree prefers altitudes between 4000 and 8000 feet (1200 and 2440 meters).

The tallest native tree of Europe is the Norway spruce, attaining a height of about 200 feet (60 meters) under favorable conditions. It is the common Christmas Tree of Europe. After the Ice Ages had eliminated the tree from Britain, it was absent until about the year 1500 when it was reintroduced to the British Isles. The tree ranges from Norway southward and eastward, reaching the Italian Alps. The tree was introduced into North America many years ago and can be found in parks and private grounds of northern cities. Another rugged European spruce is the Serbian spruce, which is mainly found in the mountainous regions of eastern Yugoslavia. It is a very fast growing tree. The oriental spruce actually is not from the orient, but is native to the Caucasus Mountains. It is a popular garden species in Europe.

Fig. 1. Sitka spruce located at Seaside, Oregon. (*W. Gucterian, Portland, Oregon*.)

Asian spruces include the Sargent spruce, which is found in western China. Some authorities compare it favorably with the Norway spruce. Because of its attractive flowers, the Likiang spruce, found in China's southwest Yunnan province, is planted mainly for reasons of decor. The Himalayan weeping spruce is often compared with the North American weeping spruce (Brewer's spruce). Schrenk's spruce is found in central Asia.

TABLE 2. ENGINEERING DATA ON SPRUCE TREES

Common Name for Species	Green Condition			Air Dried (12% Moisture)		Maximum Crushing Strength (Parallel to Grain)		Maximum Tensile Strength (Perpendicular to Grain)	
	Moisture Content (Percent)	Weight/ Cu. Foot (Pounds)	Weight/ Cu. Meter (Kilograms)	Weight/ Cu. Foot (Pounds)	Weight/ Cu. Meter (Kilograms)	(Psi)	(MPa)	(Psi)	(MPa)
Eastern spruce	45	34	545	28	449	2600	17.9	200	1.4
Englemann spruce	80	39	625	23	368	2190	15.1	240	1.7
Sitka spruce	42	33	529	28	449	2670	18.4	250	1.7

The engineering characteristics of some spruce timber are given in Table 2.

Spruce Budworm For many years, the spruce budworm (*Choristoneura fumiferana*) has been recognized as one of nature's most destructive forest insects. The first documented epidemic occurred in 1704, and since then, there have been a number of epidemics, each lasting from 5 to 11 years. Authorities believe that the insect has been infecting the spruce-fir forest at intervals of 50 to 100 years as far back as the Ice Age. A major epidemic occurred over the years 1910 to 1920 that spread through Quebec, New Brunswick, Maine, and northern Minnesota, with an estimated destruction of 225 million cords of pulpwood. In some areas, 90% of the fir trees were reported killed during that epidemic. During relatively recent decades, widespread aerial spraying of chemical insecticides was the remedial measure of choice. But, despite extremely large expenditures for materials and personnel for undertaking such massive spray projects, chemical pesticides proved only partially successful in suppressing the budworm. In the early 1980s, forest managers turned to integrated pest management, by which all available necessary control techniques are consolidated into a concerted program to manage insect populations in ways that avoid or reduce economic damage and minimize adverse environmental side effects. An important part of integrated pest management is a study of the dynamics of the spruce budworm itself. What is its role and how does it interact in the forest ecosystem?

As pointed out by M.J. Jones (*American Forests*, 18–23, June 1980), "The budworm itself is part of an integrated system, a natural cycle that assures the continual regeneration of the spruce-fir forest. Balsam fir and red spruce enjoy a shared role in the coniferous stands north of the pine belt and south of the fir belt in the east. These two species differ in character, yet cooperate in returning land to a coniferous state after a major disturbance, such as windthrow, logging and insect attack. Balsam fir begins to produce seed early (at 15 years) and often (every 2 years). Fir seedlings usually are abundant and grow rapidly when competing trees are removed. Red spruce begins to produce seed later (at 25 years) and less frequently (every 3 to 8 years), and does not grow up as rapidly. Thus, a disturbance in a spruce-fir stand tends initially to shift the composition balance toward fir. And balsam fir is the preferred food of the spruce budworm, despite its name. To a lesser extent, the budworm also attacks red, white, and black spruce, and occasionally tamarack and hemlock. In the very act of eating, the budworm prepares for future meals. In stands where it reaches epidemic levels, the bug destroys the host species in such a way that ensures the development of a new stand of that same species — for future infestation. The factors that contribute to an outbreak are not completely understood, but it is believed that for budworm populations to explode, mature and overmature fir must be combined with a series of warm, dry summers. Where these conditions coincide, budworms thrive and multiply tenfold each year. At the same time, the fir produces prolific seed and establishes a new stand."

In addition to other biological approaches used in recent years, pheromones (sex attractants) have been synthesized for use as bait in trapping amorous males. Pheromones and other biological controls are discussed in entry on **Insecticide and Pesticide Technology**.

SPRUE (Tropical). A disease that mainly occurs in India, Puerto Rico, and Vietnam. The disease features a malabsorption of two or more substances — fats, proteins, carbohydrates, minerals, vitamins, and even water. These losses occur in the feces in an acute diarrhea with pale bulky stools. Steatorrhea is present in 95% of cases. There is abdominal distention with colic, weakness and wasting, megaloblastic anemia and edema.

The disease is now considered to be caused by colonization of the upper intestinal tract by coliform bacilli. This, in turn, produces lesions based on the villi of the jejunum and ileum, which broaden and fuse.

Normally self-limiting, sprue has caused mortality up to 35% in some villages in India. Treatment involves antibiotics — tetracycline and ampicillin — together with folic acid and Vitamin B_{12} therapy.

R. C. V.

SPUR-FOWL. See **Partridge**.

SPUR GEARING. This form of toothed gearing is used for transmitting power between shafts whose axes are parallel. The velocity ratio of a spur gear set is the ratio of the number of revolutions of one gear to the number of revolutions of the other. The pitch circles of a pair of spur gears are those imaginary circles that are equivalent to the peripheries of a pair of friction wheels that would operate without slipping at the same velocity ratio and center distance as the gears themselves. The point of tangency P of the pitch circles on the line of centers is the pitch point of the gearing. The smaller of the two gears is usually referred to as the pinion.

SPURIOUS CORRELATION. Correlation that is misleading. Take two variables x and y, which are independent. Consider a third variable z, which is correlated with x and with y. Form $v = f(x, z)$ and $w = f(z, y)$, then frequently v and w will show considerable dependence which may be traced to the correlation of x with z and y with z. In general, then, spurious correlations may be defined as correlation which is introduced by other variables rather than the ones under study.

The real question at issue in correlation is actually this: Are the variables in which we are interested x and y or v and w? If the variables are x and y then the correlation of y with w is spurious. If the casual variables, however, are v and w and not x and y, then the correlation of v and w is valid and not spurious. The term "spurious" is perhaps itself misleading. It does not imply that the correlation does not exist; only that it may be due to a rather circuitous train of casual influences.

SIR MAURICE KENDALL, International Statistical Institute, London

SPURIOUS RADIATION. Any radiation from a transmitter other than that produced by the carrier and its normal sidebands. A radiated harmonic of the carrier is one example of a spurious radiation.

SPUTNIK (The First Artificial Earth Satellite). Humanity's leap into space was one of the greatest scientific achievements of the twentieth century. However, one of the ironies of history is that this great scientific and engineering achievement was largely facilitated by the Cold War between the two superpowers, the United States and the Soviet Union.

In the late 1950s, the United States held a significant advantage over the Soviet Union in number of nuclear warheads and capability to eliminate the most important strategic facilities on its enemy's territory. Although

the Soviet Union already had nuclear weapons, it did not have second-strike capability because it did not have any delivery vehicles capable of delivering warheads to U.S. territory. The senior political leadership of the Soviet Union assigned its missile science and industry a task of "special governmental importance"–development of a ballistic missile that could render the United States vulnerable.

The early experimental intercontinental ballistic missiles developed by Soviet scientists and engineers were used to place the first artificial Earth satellites into orbit. Thus, the history behind the development and launching of the first satellite into orbit is primarily the story of a missile that became a launch vehicle for a satellite rather than a missile carrying a weapon of mass destruction.

As long ago as February 1953, a government decree assigned NII-88, the lead institute for missile technology, the task of performing "theoretical and experimental research related to developing a two-stage ballistic missile and studying the future applications for a missile with a range of 7,000–8,000 km (4,350–4,971 miles)." This task was led by Sergei Korolev, who at that time was the Chief Designer of OKB-1 (at that time part of NII-88). Korolev, for his part, was head of the Chief Designer's Council, which included the following Chief Designers: Valentin Glushko for rocket motors, Nikolai Pilyugin for trajectory control systems, Vladimir Barmin for ground launch systems, Mikhail Ryazanskii for radio systems, and Viktor Kuznetsov for gyro control devices. The preliminary design for the missile called for developing a 170-metric-ton, two-stage missile with a 3,000-kg (6,614 lbs) detachable nose cone. The nose cone was designed to hold a nuclear warhead weighing up to 1,000 kg (2,205 lbs) and having an 80-kiloton maximum yield.

However, in 1953, the Soviet Union successfully tested a thermonuclear warhead — the "hydrogen bomb," with a yield a few dozen times that of a nuclear warhead. In late 1953, Korolev was ordered to change the design and increase the throw weight to 3,000 kg (6,614 lbs). This required an increase in the total payload mass to 5,500 kg (12,125 lbs). Major revisions in the missile design were required to maintain the desired range specifications.

The basic changes implied by the increased throw weight requirement were as follows:

1. change launch configuration that used the upper load-bearing members of the side-mounted engines as supporting points for the four launch trusses and removed as the missile begins to climb;
2. switch to a high-thrust, four-chamber propulsion system;
3. use movable steering engines in place of exhaust vanes;
4. increase fuel capacity;
5. increase of 38 metric tons in the thrust of each propulsion system;
6. addition of backup gyro control devices;
7. addition of systems to monitor drainage of tanks and synchronization of fuel consumption by the side-mounted engines
8. development of a fundamentally new launch system that reduced the load on the missile structure, thereby substantially reducing the weight of the missile.

The Government decree ordering development of the R-7 two-stage ballistic missile was approved on 20 May 1954. A subsequent decree provided a schedule and list of deliverables. Flight testing was scheduled for February 1957. Development and fabrication of all systems and the first few missiles took place during 1955–1956.

The missile design represented a fundamental improvement in structure, frame configuration, dimensions and mass, propulsion-system thrust, control actuators, a new dynamic launch system configuration, and new inertial and radio navigation techniques. The missile itself consisted of four side-mounted, first-stage engine assemblies mounted around the central engine assembly of the second stage. The internal design of the side-mounted engine assemblies and central engine assembly were similar to the single-stage designs then in use. The engines used kerosene and liquid oxygen as propellants. All five engine assemblies operated from the ground up and were started almost simultaneously. The side-mounted engines were turned off upon stage separation, and the second stage remained active.

Each engine assembly was based on a standard four-chamber engine with sea-level thrust greater than or equal to 80 metric tons. This package arrangement required a synchronized tank drainage system and an engine-thrust control system. This missile marked the first use of special steering chambers that moved by electrohydraulic actuators in response to commands issued by the control system.

The development process for this missile included extensive experimental testing of individual systems, in addition to experimental testing of the overall design. Final testing of the control system was performed on special M5RD test missiles based on the R-5 missile. Flight testing of 10 M5RD missiles using the new control-system equipment enabled verification of the apparent-speed-control system, the tank drainage system, and a new telemetry system, including the sensor instrumentation (in particular, a vibrational sensor system).

The R-5 R test missiles were used for flight testing telemetry-based missile velocity measurements, using a centimeter-wavelength pulsed radio system, radio-wave attenuation in engine jets, and correctness of the underlying design principles for the radio direction finder. Flight testing three R-5 R missiles provided a large amount of experimental material that enabled substantial modifications to the instrumentation fabricated for initial flight/design testing of the R-7 missile.

Almost all of the sensor equipment for the onboard instrument system was developed from scratch. In all, seven sets of recording sensors were installed on board the missile. In addition, special ground-based recording equipment was used to monitor the missile launch and the behavior of launch systems. More than 600 in-flight parameters were measured using a total of 2800 kg of onboard instrumentation. Unlike all previously developed single-stage missiles, the R-7 missile and launch fixtures formed a single dynamic system. The launch ground system included more than 30 individual systems and assemblies.

The interfaces between ground systems and missile and the interfaces between individual ground systems were tested using special missile mockups interfaced to the ground systems at the launch facility. However, before this, appropriate system testing of the launch system and missile was performed at the Leningrad Machinery Plant. The missile-lift procedure was simulated using high-capacity lifting cranes and a missile filled with water in place of fuel. It was essential to ensure that the gantries retracted simultaneously and that the missile frame would mechanically mate with the launch system. The complete ground system at the launch site was tested using a simulated R-7 missile, which was repeatedly placed on the launch stand and repeatedly fueled.

The Scientific Research Institute for Firing Tests (NII-229) built several high-capacity rocket test stands for testing the propulsion systems in combination with the missile frame. From August 1956 to March 1957, NII-229 performed five firing tests of the side-mounted engine units, three tests of the central engine unit, and two tests of the complete package of five engine units. The first R-7 missile for flight testing arrived at the Tyuratam support facility (Scientific Test Site NIP-5, the future Baikonur) in March 1957. The horizontal testing performed at the NIP-5 support facility included electrical and pneumatic testing of each engine unit, postshipment verification of engine-unit alignment, assembly of the engine units into a single package, and integration testing of all electrical and pneumatic systems ("horizontal system testing").

The first meeting of the State Flight Test Committee occurred on 10 April 1957. The Committee was chaired by M.V. Ryabikov, Chairman of the Military Industrial Complex, and had the following members: Chief Marshal of Artillery M.N. Nedelin (Deputy Chairman); Chief Designer S.P. Korolev (Engineering Manager); Chief Designers V.P. Glushko, N.A. Pilyugin, V.P. Barmin, M.S. Ryazanskii, V.I. Kuznetsov, S.M. Vladimirskii (Deputy Chairman, State Committee for Radio Electronics), A.I. Nesterenko (Manager, Scientific Test Site 5), G.N. Pashkov (State Planning Committee [Gosplan]), I.T. Peresypkin (USSR Ministry of Communications), and G.R. Udarov (Deputy Chairman, State Committee for Military Equipment).

The missile was first launched on 15 May 1957. The flight appeared to proceed normally for the first 60 seconds, at which time a fire broke out in the tail compartment. Reduction of the telemetry data revealed that one of the side-mounted engines fell off 98 seconds into the flight, when the missile became unstable. The root cause of the accident turned out to be a leak in a fuel line. Nevertheless, this launch did confirm that the control-system parameters for the first-stage segment were correct and gave us confidence in the launch dynamics.

The second scheduled launch attempt on 11 June 1957 was unsuccessful because the disc on the main oxygen valve for side-mounted unit C froze

and an error had been made during installation of the nitrogen blowdown valve on the oxidant line for the central engine unit. The missile was returned to the Support Facility.

The third launch was on 12 July 1957. Thirty-three seconds into the flight, the missile became unstable. The root cause of the accident turned out to be a short circuit between the control-signal circuits and the housing in the angular-velocity integrator for the roll channel. The fourth launch on 21 August 1957 was successful, and the missile, for the first time, hit a target on Kamchatka Peninsula. A TASS statement announcing the launch of a long-range, multistage intercontinental ballistic missile was carried by the USSR mass media on 27 August.

The fifth launch of the R-7 missile on 7 September 1957 confirmed the results of the previous launch. However, although the missile components and systems operated normally during the active portion of the flight, the warhead reentry vehicle (RV) broke up upon reentry into the lower atmosphere. A significant amount of time was required for research and development work related to, and fabrication of, new warhead RVs capable of withstanding the high temperatures and large gas-dynamic loads that occurred during the reentry portion of the flight. With the consent of the Government and the State Commission, it was decided to use two of the original twelve R-7 missiles built for development testing as launch vehicles for the first artificial Earth satellites. These launches provided a practical opportunity to accumulate additional experimental data on all missile systems except for the forward compartment containing the nuclear warhead. Thus, these early satellite launches were an integral part and outgrowth of development testing for early intercontinental ballistic missiles.

A fortunate convergence of historical fates in the early 1950s led to the renewal of creative contacts between Sergei Korolev and Mikhail Tikhonravov, his former colleague in development of early perwar unguided missiles during the 1930s. In the late 1940s, Tikhonravov led a group of enthusiasts from the highly classified Scientific Research Institute 4 [NII-4] who were studying designs for space launch vehicles, as well as a variety of issues related to subsequent manned spaceflight. Tikhonravov and his group were the first professional people in the Ministry of Defense system who dared to say that the R-7 intercontinental ballistic missile developed under Korolev's direction could, with slight modifications, be used as a satellite launch vehicle.

With slight changes to the flight plan, the missile could place a satellite weighing up to 1,500 kg (3,307 lbs) into orbit instead of delivering a 5.5-metric-ton nuclear warhead at a range of 8,000 km (4,971 miles). The Ministry of Defense generals did not support Tikhonravov's initiative, but Korolev quickly grasped the possibilities for practical implementation of his long-held dream of human spaceflight, and was able to arrange for Tikhonravov's transfer from NII-4 to OKB-1 (Korolev's design bureau). In May 1954, Korolev had presented a proposal to the Minister of Armaments (Dmitrii Ustinov), the Council of Ministers, and the USSR Academy of Sciences to develop the world's first artificial Earth satellite and launch it with the R-7 missile for research purposes. The basic idea contained in Korolev and Tikhonravov's report was that "the artificial Earth satellite is an inevitable phase in the development of space hardware, following which interplanetary missions will become possible."

In August 1954, the USSR Council of Ministers approved a proposal to study the scientific and engineering issues involved in a spaceflight. Korolev had support from the following senior government officials, as well as the Academy of Sciences: Deputy Chairman of the Council of Ministers V.M. Malyshev, D.F. Ustinov, and Ministers B.L. Vannikov, M.V. Khrunichev, and K.N. Rudnev. Despite the military's fears that development of a spacecraft would be a distraction from the primary tasks involved in developing the R-7 missile, on 30 January 1956, the Council of Ministers approved the development of an unstabilized spacecraft ("Object D") weighing 1,100–1,400 kg (2,425–3,086 lbs) and carrying 200–300 kg (441–661 lbs) of scientific research instrumentation. The Government gave the USSR Academy of Sciences responsibility for developing the scientific research equipment. The required task orders were issued as directives to the Ministry of Defense Technology (the lead ministry) and all other ministries and organizations involved in missile development and production.

OKB-1 and its subcontractor organizations completed their design work in 1956 and then moved on to fabricate Object D, which was to become the first artificial Earth satellite. Object D was to be used for scientific research in the following areas: density and ionic composition of the high-altitude atmosphere, solar particles, magnetic fields, cosmic rays, temperature conditions within the spacecraft itself, braking of the spacecraft in the upper atmosphere, and the accuracy of spacecraft position and orbit determination. The scientific instrumentation and spacecraft onboard systems were to have been powered by solar panels and storage batteries, and the spacecraft would have had an automatic temperature control system. This spacecraft was also to have been the first recipient of an onboard control system with a special programmable timer. In-flight control of the scientific research program was to have been performed via a radio command link from the ground. A special radio telemetry system was to have transmitted the research results to the ground. An extensive network of ground stations, forming a unified command and telemetry system controlled from a single center at NII-4, was to have been constructed.

By late 1956, it was clear that the schedules for fabricating the scientific instrumentation had slipped, and it became uncertain whether the spacecraft could even be launched during the U.N.-sponsored International Geophysical Year. Because press reports indicated that the United States was also preparing to launch a spacecraft early in the International Geophysical Year, Korolev proposed postponing the launch of Object D and launching a very simple spacecraft, the PS, carrying no scientific instrumentation instead.

On 15 February 1957, the Government accepted the proposal by Korolev and the Academy of Sciences to launch an extremely simple unstabilized Earth satellite (Object PS) to verify that the PS could be observed in orbit and that signals transmitted by the PS could be received, as well as to ensure worldwide priority in the space race. The Government would permit the spacecraft launch to occur only after one or two successful launches of the R-7 missile. The extremely simple satellite (the PS) was designed, fabricated, and prepared for launch using the missile in only 8 months. The launch was scheduled for 6 October. However, intelligence reports from overseas indicated that the Americans were preparing their own satellite for launch in early October, so Korolev sped up the preparations, and the PS was launched on 4 October. The first artificial Earth satellite was launched into space on the fifth launch of the first intercontinental missile. Two of the preceding four launches had been unsuccessful because the problems encountered by the developers of the first intercontinental missile were new.

The goal of this launch was to place an extremely simple satellite into orbit and also to obtain additional experimental data on the dynamics of the missile launch and propulsion systems, the control and guidance systems, the stage separation system, the onboard sensors, the operation of equipment on the ground, and the command and telemetry system on the ground. During the round-the-clock effort to prepare the rocket for launch, several problems were identified and eliminated right on the launch pad. In response to one problem report during rocket fueling, one of the fuel tanks for the side-mounted engines was drained and refilled to test the "tank full" alarm system.

The guidance system was adjusted to place the missile into an orbit with the following parameters:

perigee: 223 km (139 miles);
apogee: 1,450 km (901 miles);
period: 101.5 min.

These orbital parameters could be achieved using half of the guaranteed fuel supply, provided that the guidance systems and all engine systems operated properly. Trajectory measurements indicated that the rocket performed normally during the active portion of the flight. However, the second-stage engine ran out of fuel before it was scheduled to be turned off by the guidance system.

Launch of Sputnik 1

The world's first artificial Earth satellite was launched into space on 4 October 1957 at 22:28 Moscow time. It ended up in an orbit with the following parameters: perigee; 228 Km (142 miles): apogee; 947 Km (588 miles): inclination; 65.1°: and period: 96.17 min. Reduction of the telemetry data enabled collecting a large amount of experimental data

concerning operation of the missile, various individual missile systems, and the ground launch systems. The spacecraft weighed 83.6 kg (184 lbs); the body of the spacecraft consisted of a sphere 580 mm (23 inches) in diameter with four collapsible-whip antennas (2.4 m and 2.9 m (7.9 ft and 9.5 ft) long). See Figs. 1 and 2. The body of the first artificial Earth satellite consisted of two aluminum alloy hemispheres filled with dry nitrogen (pressure 0.13 MPa); the joint between the two hemispheres was sealed using a rectangular-cross-section, vacuum-grade O-ring. The pressurized enclosure held an electrochemical power source and two radio transmitters that continuously transmitted on 20.005 and 40.002 MHz (wavelength 17 and 7.5 m, respectively). The transmitter signals consisted of alternating telegraph "marks" and "spaces," each 0.3 s long. The "mark" on each frequency was transmitted simultaneously with the "space" on the other frequency. The radio transmitter system had a total mass of 3.5 kg (7.7 lbs), and each transmitter had an output of about 1 W. The telemetry data (temperature and interior pressure) were transmitted to the ground by modulating the frequency of the "mark" and "space" signals. Each transmitter had two collapsible-whip antennas (approximately 70° apart). Each pair of antennas had a nearly spherical antenna pattern.

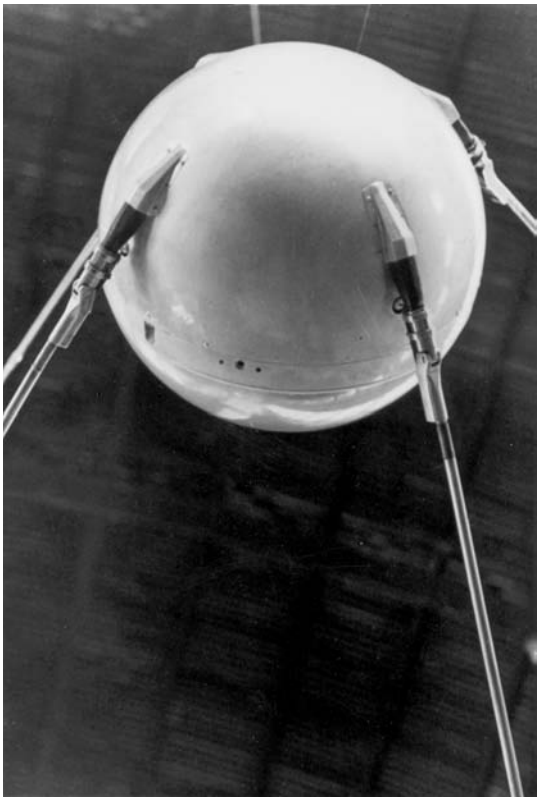

Fig. 1. Sputnik 1. (NASA).

The temperature control system had a radiator with a fan-driven, sealed-loop, forced-gas heat exchange system designed to maintain a stable interior temperature in the face of variable external thermal fluxes. The temperature control system used a bimetallic thermal relay as the sensor element. Whenever the temperature increased above 36 °C (96.8 °F), the fan came on, and nitrogen circulated through the system to transfer heat away from the hemisphere that was acting as a radiating surface (emission coefficient 0.35–0.4, solar absorption coefficient 0.23–0.4). The fan was turned off whenever the temperature fell below 20 °C (68 °F).

The intended purpose of the automated onboard electrical system was to turn on the electrical power to the instruments, once the spacecraft reached orbit (i.e., upon separation from the launch vehicle). During the launch phase, the spacecraft was placed under a nose cone for protection against aerodynamic and thermal effects; the nose cone was jettisoned when the second-stage engine shut down. The spacecraft carried three silver-zinc batteries weighing 51 kg (112 lbs). The batteries could support

Fig. 2. Sputnik 1, exploded view. (*NASA*).

operation of the instruments for 3 weeks. The first satellite lasted 92 days, and completed ~1400 orbits around Earth. On 4 January 1958, it reentered Earth's atmosphere and burned up.

The orbital parameters of the first Soviet artificial Earth satellite were such that it was visible from all continents across a wide range of latitudes. Observations of the spacecraft's motion, reduction of the observations, and prediction of the future motion of the spacecraft based on these results served as an early practical exercise in using ground-based spacecraft control systems and equipment for measuring spacecraft parameters. The first satellite was observed using radio equipment, as well as optical instruments at astronomical observatories. The news that the first artificial Earth satellite had been launched aroused extremely broad interest among radio amateurs and amateur astronomers around the world. In the Soviet Union, 66 optical observing stations and 26 clubs with extensive collections of radio observing gear regularly observed the spacecraft. In addition, thousands of radio amateurs attempted radio observations of the spacecraft. State scientific radio monitoring stations also observed with radar and radio range finder systems. This was the first rich set of statistical data concerning the transmission of meter-wavelength radio waves through the ionosphere and also represented the first opportunity to receive radio signals at two different frequencies from regions of the ionosphere that had heretofore been inaccessible, that is, above the ionization peak or even above the entire ionosphere.

Extremely valuable data were also obtained on radio-wave absorption in previously unstudied layers of the ionosphere, as well as new data on the structure of these regions and the ion concentration at various altitudes and times of day. These systematic measurements showed that the altitude of the main peak in the ionosphere and the peak electron concentration vary from day to night, north to south, and east to west. Radio propagation measurements at the frequencies emitted by the spacecraft at various altitudes provided a new avenue for ionospheric research. These observations led to the discovery that the decrease in electron concentration in the upper ionosphere (above the main peak) with altitude is five to six times slower than the increase with altitude below the peak. For example, when the observations were made (in October), the electron concentration increased by approximately a factor of 10 from 100–300 km (62–186 miles) altitude, whereas it decreased only by a factor of 2 from 300–500 km (186–311 miles) in altitude. The initial indications

that micrometeoroids were not hazardous to spacecraft was an extremely important result.

The radio methods used included radio ranging and Doppler observations of the radio signal from the spacecraft. These early experiments indicated that the Doppler effect could be used successfully to determine spacecraft orbital parameters. It became obvious that the accuracy of orbit determination could be quite high if the transmitter frequency were increased and if automated frequency measurement equipment were used. Early, high-sensitivity photographic techniques were developed for observing this spacecraft. Image-converter tubes turned out to be especially promising in this regard.

The news that the Soviet Union had launched the world's first artificial Earth satellite turned out to be quite an unexpected sensation for the entire human community. The flight of the first satellite around Earth caused a stunning resonance around the world. Virtually the entire world press carried front-page banner headlines reporting the news, thereby underlining that Soviet science had taken the lead. The American government was shocked, along with American scientists confident of their superiority. The senior leadership of the Soviet Union was surprised by this enthusiastic reaction from their people and people around the world. Therefore, to consolidate the political success that had been so unexpectedly achieved in the Cold War, the General Secretary of the CPSU Central Committee, Nikita Khrushchev, proposed that Korolev launch a new satellite in honor of the 43rd anniversary of the October Revolution. The first, extremely simple satellite was still operating in orbit, and there was no sense in launching another, similar satellite.

A second spacecraft was readied in less than a month and launched on 3 November 1957. The dog Laika, who later became famous, was the first experimental animal to orbit Earth. The second spacecraft did not separate from the second stage of the rocket, and, for the first time, data on the behavior of a dog in space was transmitted to the ground via a multichannel telemetry link.

Object D, which was to have been the first spacecraft, was not launched until 15 May 1958. It was the third Soviet spacecraft and the first that could truly be called a space laboratory based on the amount of scientific instrumentation on board.

The successful launch of the first artificial Earth satellite marked the beginning of humanity's journey into space. Many extremely urgent scientific problems required direct experiments at altitudes of hundreds or thousands of kilometers above Earth's surface. Although the significance of artificial Earth satellites had long been understood, launching them had remained an insoluble problem. The main difficulty had been developing a rocket that could give a spacecraft a velocity of the order of 8000 m/s. Only after the Soviet Union had developed an intercontinental ballistic missile did it become possible for the first time in history to launch an artificial Earth satellite. The superior design of this missile enabled placing a spacecraft with the required weight of scientific instrumentation into orbit. Further improvements of the R-7 missile — in particular, the addition of a third and then a fourth stage led to manned space programs, communications satellites, and the first automated interplanetary spacecraft for studying the Moon, Venus, and Mars. Modernized versions of the R-7 missile are currently used for manned and cargo spacecraft to support the International Space Station.

SPUTTERING. 1. In a gas discharge, material is removed, as though by evaporation, from the electrodes, even though they remain cold. This phenomenon is known as sputtering. 2. The term is also used for the corresponding phenomenon when the discharge is through a liquid. In the first case, sputtering is a nuisance that limits the life of a device; in the second case, it is put to work to make colloidal solutions of metals. 3. A result of the disintegration of the metal cathode in a vacuum tube due to bombardment by positive ions. Atoms of the metal are ejected in various directions, leaving the cathode surface in an abraded and roughened condition. The ejected atoms alight upon and cling firmly to the tube walls and other adjacent surfaces, forming a blackish or lustrous metallic film. This effect is often utilized to form very fine-grained coatings of metal upon surfaces of glass, quartz, etc., purposely exposed to the sputtering. Films of different metals can be obtained by using cathodes made of these metals. Glass plates may be thus silvered, or suspension fibers of spun quartz rendered conducting for use in electrometers, etc.

SQUALL. See **Fronts and Storms**.

SQUARE AND SQUARE ROOT. The square of a number or quantity is the product of that number or quantity when multiplied by itself. Hence, 4×4 yields 16, the latter being the square of 4. Similarly, the number 4 is termed the square root of the number 16. The process of raising any number to any integral *power*, as in squaring (a power of 2) or in cubing (a power of 3) is known as *involution*. The process of extracting roots, that is, of finding that 4 is the square root of 16, or of finding that 3 is the cube root of 27, is known as *evolution*. See also **Exponent**; **Number Theory**; **Radical (Mathematics)**; and **Root (Mathematics)**.

SQUARE LAW MODULATOR. A device whose output is proportional to the square of its input. The carrier and modulating signal are added in the input to produce a modulated carrier in the output.

SQUARE WAVE. A square wave, as the name indicates, has the wave form shown in Fig. 1.

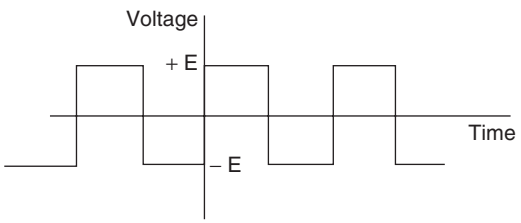

Fig. 1. Square wave.

Any periodic wave, regardless of its shape, may be analyzed into a series of sine and cosine components whose frequencies are harmonically related. The number of these components will be determined by the shape of the wave, but in general the sharper the corners of the original wave the more component terms. Thus a square wave will require a wide range of frequencies to express it. These components are not mere mathematical fictions but are true electrical components in the case of an electric wave. They may be separated and examined by means of proper filter circuits. Since a square wave will contain a long series of frequencies, it may be used for rapidly determining the frequency response of a piece of equipment by applying the wave to the input and noting the distortion of the output wave. The distortion is due to certain frequencies of the original wave being attenuated or amplified out of proportion in passing through the circuit. Thus the necessity of making a laborious series of tests at various frequencies using sine waves is avoided. When an operator is properly trained in interpreting the results of such testing it offers a rapid means of checking amplifiers, networks, etc. These square waves may be generated by a variety of electronic circuits.

SQUASH. Of the family *Cucurbitaceae* (gourd family), squash plants are of three major species and one minor species of the genus *Cucurbita*. These several species, plus the designations of summer and winter squash, tend to complicate a classification of these plants. There is not a direct relationship between species or growth pattern and whether a plant is a summer or a winter variety. Although a majority of squash plants assume an indeterminate growth pattern as vine-like, tendril-bearing herbs, some take the more determinate form of bushes or semibushes. In terms of food value, the winter squash is rated very high among all vegetables. Winter squash usually is baked or used in pies. Varieties of winter squash more closely resemble the pumpkin, and canning and freezing processes are

very similar. Many, but not all varieties of winter squashes are members of the species *Cucurbita maxima*. Some also are members of *C. moschata* and *C. mixta*. Varieties of *C. maxima* and *C. moschata* can be crossed artificially, but such crossing does not occur naturally in the field.

Specific Varieties. The genus *Cucurbita* is indigenous to the Americas. The largest concentration of wild species is in Mexico, in a vast area from just south of Mexico to the border between Mexico and Guatemala. The cultivated species *C. pepo*, *C. mixta*, and *C. moschata* are North American, whereas *C. maxima* is from South America. Because of the uncharted movement of pre-Columbian peoples and their crops in the Americas, it is difficult to pinpoint the exact area of origin of the cultivated species. One authority suggests that *C. pepo* is native to the southwestern United States and northern Mexico. *C. moschata* and *C. mixta* are lowland species ranging from Vera Cruz, Mexico, southward through Central America. In this area, cultivars of *C. mixta* are much used for their tasty, edible seeds.

Through years of cultivation, research, and experimentation, numerous varieties of squash have been developed. See Fig. 1.

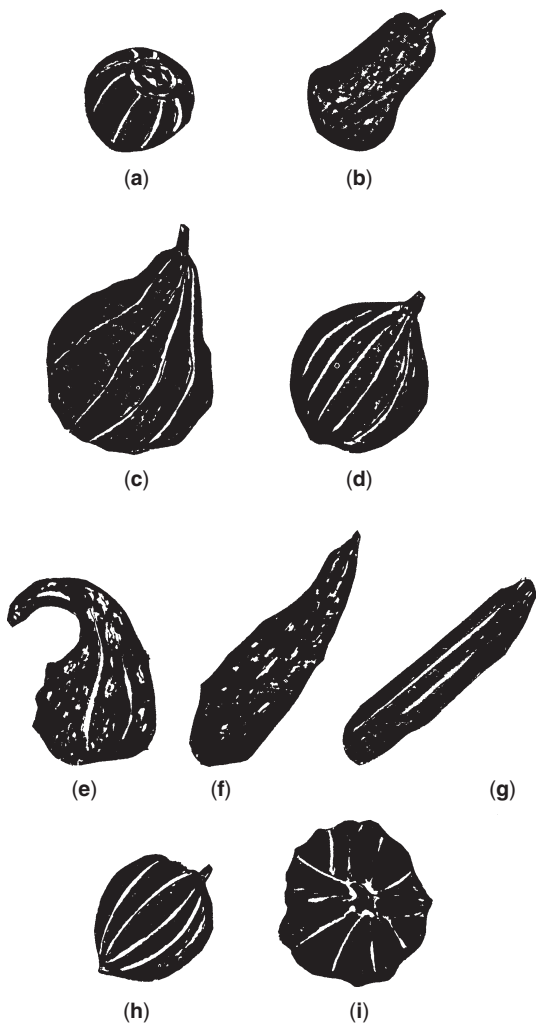

Fig. 1. Various types of squash. Winter squash: (**a**) Buttercup; (**b**) Butternut; (**c**) Hubbard; (**d**) Gold Nugget. Summer squash: (**e**) Crookneck; (**f**) Straightneck; (**g**) Zucchini; (**h**) Acorn; (**i**) Scallop.

Pollination. Squash plants have unisexual flowers. In order to produce fruit, squashes require cross-pollination — that is, the transfer of pollen from the anthers of the male flower to the stigma of the female flower. Inadequate pollination results in reduced yield and misshapen fruit. Bees provide the primary means of pollen transfer, and often beehives are used. Experienced growers will have one hive for every 3 to 5 acres (1.2 to 2 hectares) of squash plants. Beehives are placed in the center of the field so that bees do not have to travel more than a few hundred feet to feed. Obviously, there should be no insecticide applications during the flowering period.

Nutritional Aspects. Winter squash is high in vitamin A. Summer squash is a good source of vitamin C. Squash has fair amounts of iron. It is low in sodium and protein. Squashes, particularly the summer varieties, are considered low-calorie foods.

Prepared squash is one of the more popular baby foods.

SQUASH BORER *(Insecta, Lepidoptera)*. The larva of a moth, *Melittia satyriniformis*, which bores in the root and stem of squash vines, often killing the plant. The moth is a beautiful species with olive fore wings, transparent hind wings, and legs tufted with orange and black.

The larva thrusts waste material out of holes in the stem. When detected by this means it can be cut out of the plant and killed. In large fields where hand control is impossible, deep plowing when the vines are dead kills many of the insects. Other methods depend on an accurate knowledge of the time of deposition of the eggs. Spraying is effective during that period.

SQUASH BUG *(Insecta, Hemiptera)*. A true bug, *Anasa tristis*, about $\frac{5}{8}$ inch (16 millimeters) long, gray-brown above and mottled with yellow below, showing red in flight from areas beneath the wings. It sucks the juices of pumpkins, squash, and related vines and spreads a bacterial wilt.

The adults hibernate beneath debris on the ground and may be trapped under pieces of board and destroyed.

SQUID. See **Mollusks**.

SQUIRRELFISHES *(Osteichthyes)*. Of the order *Berycomorphi*, family *Holocentridae*, squirrelfishes, also known as soldierfishes, are usually of some shade of bright red and prefer tropical reefs. There are about 70 species, well distributed throughout world tropical waters. The largest (*Holocentrus spinifer*) attains a length of about 2 feet (0.6 meter) and is found in the eastern Pacific. *Ostichthys japonicus* (deep-water squirrelfish) differs from other fishes of the family by preferring deeper water. The fish is marketed commercially in Hawaii under the name *menpachi* and is considered a premium food fish. It has been reported that squirrel-fishes can produce sounds.

SQUIRRELS AND OTHER SCIUROMORPHS *(Mammalia, Rodentia)*. This large family of rodents also includes the chipmunks, gophers, spermophiles, prairie dogs, woodchucks, marmots, and whistlers, among others.

The squirrel is an arboreal or terrestrial rodent with a long bushy tail. Representatives of the true squirrels are found on all continents but Australia. North America has ten species of true squirrels, some widely distributed and extremely variable, and two species of flying squirrels. The little red squirrel, *Sciurus hudsonicus*, is the most widely known, with the gray, *S. carolinensis*, and fox, *S. niger*, also well known and widely distributed. The latter two animals are valued as small game, many people considering the flesh to be excellent. These squirrels may gather as much as 20 pounds (9 kilograms) of nuts per season for storage to be used during the winter months. Some species also accumulate thick layers of fat in preparation for winter.

Flying squirrels belong to the genus *Sciuropterus* and are distinguished from true squirrels and related forms by the presence of folds of skin stretching from the front to the hind legs along the sides of the body. These folds, held extended by the legs, support the animal in the air during long gliding leaps. See Fig. 1. The African flying squirrels belong to a different family, the *Anomaluridae*. The sciuroptera are found from Scandinavia eastward to Japan and from northern Canada southward to Honduras. Large numbers are found in India and the Malayan regions. Size ranges widely, but some species approach 3 feet (.9 meter) in length. General coloration is a fox-like red, or red spotted with white or black. In the larger species, the fold of the gliding membrane connects the hind limbs with the tail. The smaller species have the membrane along the side from front to back feet. All species are omnivorous and have large, dark eyes. It has been reported that glides of up to 200 feet (60 meters) from high to low tree branches occur.

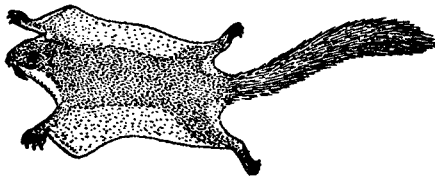

Fig. 1. Flying squirrel.

Chipmunks are small burrowing rodents of squirrel-like appearance, but with the tail shorter and not bushy. They are brown or grayish with longitudinal stripes on the back or sides. They are omnivorous and, while not usually troublesome, sometimes do destroy flowering bulbs during the winter. Chipmunks belong to several genera and numerous species and subspecies. Some of the western species are called golden chipmunks or rock squirrels and others antelope chipmunks or ground squirrels. They are related to the ground squirrels and gophers. While predominantly North American, some species are found in Siberia.

Pocket gophers are stout-bodied burrowing animals of several species, found throughout the United States. They have fur-lined cheek pouches opening at the sides of the mouth. So-called ground squirrels are slender burrowing species of the gopher and are found in the central and western states. Gophers are injurious to crops. The pocket gophers eat roots, and the ground squirrels are more injurious to grain. The term *gopher* is from the French, meaning "to tunnel." Gophers live in tunnels. The entrance to a tunnel is hidden, but the presence of a large mound of dirt nearby indicates the proximity of a tunnel. The tunnels have numerous entries and ports of escape and can be long and complex. Gophers are particularly destructive in dry seasons, when they gnaw roots for their moisture content. In size, the gopher is comparable to a large rat, but with larger proportioned claws. Because of the grinding sound made when cutting roots, the animal sometimes can be heard while working.

The spermophile is a small slender animal with short legs, small external ears, a short hairy tail, and large cheek pouches. They are also called ground squirrels or gophers. Most of the several species of spermophiles are confined to limited areas in the arid lands of the western United States. The striped species, commonly called gopher, ranges from central Ohio to the Rocky Mountains and from Canada to Texas. This species is brown with alternating clay-yellow stripes and rows of spots on the back and sides. The animal is destructive to crops and known for damaging lawns.

The woodchuck is a large heavy-bodied animal of the Northern Hemisphere. See Fig. 2. Woodchucks have short stout legs and are powerful burrowing animals, penetrating many feet into the ground. They also climb readily, although somewhat clumsily. They eat vegetation of many kinds and sometimes become troublesome in fields and gardens. North America has three species of woodchucks, the common woodchuck, *Marmota monax*, the yellow-bellied woodchuck, *M. flaviventris*, and the whistler, *M. caligata*. The first occurs from Kansas to Georgia, northward to Alaska and Hudson Bay. The second ranges from the Rocky Mountains to the Pacific, and the third is also western, ranging from Montana and Washington to Alaska. The names *marmot* and *groundhog* are also generally applied to them. The Old World species are widely distributed in Europe and Asia, where they are more commonly called marmots. Some of these include the bobac, *M. bobac*, and the alpine marmot, *M. marmota*. The fur is sparse and rather coarse, but it is used to a limited extent. The flesh of woodchucks is eaten, but it is inferior to that of other common rodents. While its flavor has been described as good, the flesh is coarse in texture, as compared with that of squirrels and rabbits.

Fig. 2. Eastern woodchuck. (*W. Goodpaster*.)

The prairie dog is a burrowing animal found chiefly west of the Mississippi River but has been introduced into a few eastern states. The animal is small and stout-bodied, with shallow cheek pouches. The prairie dog is a plant feeder and in settled regions can damage crops severely. The animal is also called the prairie marmot. The prairie dog ranges from 10 to 12 inches (25 to 30 centimeters) in length, plus a tail of 2 to 4 inches (5 to 10 centimeters) in length. Because of their damaging ways, the population is small due to extensive extermination.

STABILITY. In general, the tendency to remain in a given state or condition, without spontaneous change; and thus that attribute of a system which enables it to develop restoring forces between its elements, equal to or greater than the disturbing forces, so as to restore a state of equilibrium between the elements. Thus, a body of air is in a stable state if, when displaced somewhat from its original position, it tends to return thereto. A chemical compound is said to be stable if it is not readily decomposed.

In meteorology, *static stability* (also called *hydrostatic stability*, *vertical stability*, *convectional stability*) is the stability of an atmosphere in hydrostatic equilibrium with respect to vertical displacements, usually considered by the parcel method. The criterion for stability is that the displaced parcel be subjected to a buoyant force opposite to its displacement, e.g., that a parcel displaced upward be colder than its new environment. This is the case if $\gamma < \Gamma$, where γ is the environmental lapse rate and Γ the process lapse rate, dry-adiabatic for unsaturated air and saturation-adiabatic for saturated air.

Neutral stability (also called *indifferent stability*, *indifferent equilibrium*) is the state of an unsaturated or saturated column of air in the atmosphere when its environmental lapse rate is equal to the dry-adiabatic lapse rate or the saturation-adiabatic lapse rate, respectively. Under such conditions, a parcel of air displaced vertically will experience no buoyant acceleration.

Conditional stability is a condition of a negative feedback system which causes it to be stable (nonoscillating) for certain values of gain, and unstable for other values.

STABILITY (Mechanical). Mechanical stability is that property of a body that causes it to develop forces opposing any position or motion disturbing influence. The subject may be divided into *static stability* and *dynamic stability*. The former is concerned with the production of the restoring forces, the latter with the oscillations that are set up in the system as a result of the restoring forces.

Another classification is: (1) *positive stability*, when the displaced object returns to an initial state of equilibrium after a temporary disturbance; (2) *neutral stability*, when the object tends to remain in a definite position but when disturbed may come to rest in a new position; and (3) *negative stability* (i.e., instability), when the object assumes an entirely new position when disturbed from its initial state. A simple damped pendulum illustrates the first; a sphere on a horizontal plane, the second; while a slender cylinder standing vertically on end is a case of negative stability.

Let it be assumed that an object at rest or in a state of uniform motion receives a disturbing force. Depending on the kind of stability possessed, it might react with one of the motions shown in Fig. 1. If it is dynamically stable as well as statically stable, its motion-time history may be one of diminishing oscillation or of simple subsidence, depending on the magnitude of damping, and inertial effects. Dynamic instability may occur with either static stability or static instability. These lead to divergent oscillation, or to complete divergence.

STABILITY (System). For control and feedback system analysis, a system is stable only if all roots of its characteristics equation lie to the left of the imaginary axis of the s-plane. Thus, if the roots of the characteristic

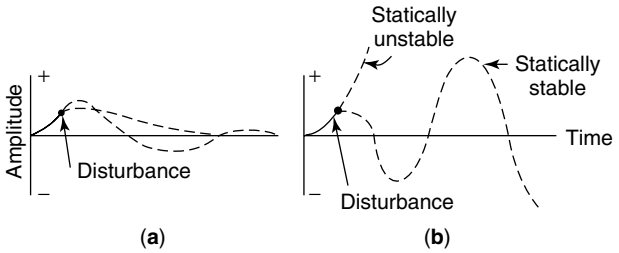

Fig. 1. (**a**) Positive stability (both statically and dynamically stable); (**b**) negative stability (both dynamically unstable).

equation can be determined, the question of stability is answered. If, however, the characteristic equation is of high order, the determination of roots may involve a great deal of work. In cases such as this the existence of roots in the right half of the s-plane may be determined using either the Routh or Hurwitz criterion. The methods are as follows:

Routh Criterion. If, as is the case with all lumped parameter systems, the characteristic equation can be written in polynomial form

$$a_0 + a_1 s + a_2 s^2 + \cdots + a_n s^n = 0$$

the array

$$\begin{array}{cccc} a_0 & a_2 & a_4 & \cdots \\ a_1 & a_3 & a_5 & \cdots \\ A_1 & A_2 & A_3 & \cdots \\ B_1 & B_2 & \cdots & \cdots \\ C_1 & \cdots & \cdots & \cdots \end{array}$$

is set up, in which $A_1 = (a_1 a_2 - a_0 a_3)/a_1$, $A_2 = (a_1 a_4 - a_0 a_5)/a_1$, $A_3 = (a_1 a_6 - a_0 a_7)/a_1$, etc., and succeeding rows are obtained from the preceding two rows in the same manner as the third is obtained from the first two. The rows will be found to get shorter by one element every two rows and to be $(n + 1)$ in number.

The system is stable if and only if all the elements of the first column have the same sign. (In fact, the number of changes of sign on going down the first column is the number of roots of the characteristic equation in the right half-plane.)

If a zero is formed in the first column before the array is complete (which prohibits the calculation of further rows), it may indicate either instability or critical stability. If the zero is preceded by two rows consisting of the same number of elements, such that the ratio of corresponding elements in the two rows is constant, roots on the imaginary axis are indicated. Moreover, in this case, the elements of either of these rows, read from right to left, successively multiplied by s^0, s, s^2, etc., added and equated to zero will give the equation whose roots are the roots of the characteristic equation lying (in conjugate pairs) on the imaginary axis. If, on the other hand, the zero is not preceded by two rows with proportional elements, then there is at least one root in the right half-plane and the system is unstable.

A necessary but, except when $n = 1$ or 2, an insufficient condition for stability is that all the polynomial coefficients shall be nonzero and all have the same sign. This condition is always implicitly contained in the Routh criterion.

Hurwitz Criterion. Using the same polynomial form of the characteristic equation as before, the array

$$\begin{array}{ccccccc} a_1 & a_0 & 0 & 0 & 0 & \cdots & \cdots \\ a_3 & a_2 & a_1 & a_0 & 0 & 0 & \cdots \\ a_5 & a_4 & a_3 & a_2 & a_1 & a_0 & \cdots \\ a_7 & a_6 & \cdots & \cdots & \cdots & \cdots & \cdots \end{array}$$

is drawn up, extending for $(n - 1)$ rows and columns, absent coefficients being replaced by zeros.

The system is stable if and only if:

1. All the coefficients of the polynomial are of the same sign, which must be assumed positive; and
2. The values of the determinants of order 2 to $(n - 1)$ and having the top left array element as their top left element are also positive.

The application of either the Routh or Hurwitz criteria is a valuable tool in the analysis of system stability. However, there are limitations that must be recognized. To use either of these techniques the system equation must be known. In many cases, and this is especially true in process control applications, the system equation is not available. In applying these techniques little information can be obtained concerning the relative stability of the system. Furthermore, it is difficult to determine the effect on stability of individual parameters for design considerations. Due to these limitations, the stability of a system is normally determined from frequency response curves using the Nyquist stability criterion. The frequency response curves may be obtained from the system equations or determined experimentally. A general description of the Nyquist method is as follows.

Nyquist Criterion; 1 (for a control system). It is assumed that if $G(s)$ is the output to error transfer function, then as $s \to \infty$, $G(s) \to 0$. This is normally the case in any practical system.

If the system is stable on closed loop, the vector locus of $G(i\omega)$ drawn from $\omega \to -\infty$ to $\omega \to +\infty$ in the sense of increasing ω (i.e., the vector locus of $G(s)$ corresponding to following the imaginary axis in the s-plane) encircles the point $(-1, 0)$ P times counterclockwise, where P is the number of poles of $G(s)$ to the right of the imaginary axis, multiple poles counting according to their order.

The following points should be noted:

1. If $P \neq 0$ the system is unstable on open loop, i.e., with the (-1) feedback from output to error broken.
2. The value of P may be found, in lumped parameter systems, by writing $G(s) = N(s)/D(s)$, where N and D are polynomials; P is then the number of zeros of $D(s)$ to the right of the imaginary axis, which may be found most simply by the Routh criterion.
3. If $G(s)$ has poles *on* the imaginary axis, these must be circumvented in the s-plane by infinitesimal semicircles in the right half-plane having these poles as centers. These indentations will correspond in the plane of $G(s)$ to a clockwise rotation through 180° at indefinitely large radius for every simple pole so encountered, multiple poles again counting according to their order. These infinite semicircles must be taken into account in assessing the number of encirclements of the point $(-1, 0)$.
4. Since $G(-i\omega)$ is the complex conjugate of $G(i\omega)$, the locus of $G(s)$ for negative real frequencies is the mirror image, in the real axis of the $G(s)$ plane, of the locus for corresponding positive real frequencies.
5. If and only if $P = 0$, an adequate simpler criterion is that the locus of $G(i\omega)$ drawn in the sense of increasing ω, shall leave the point $(-1, 0)$ to its left. See also **Feedback**. This same concept may be applied in using the Bode plot. In this context the system gain must be less than 1.0 when the phase angle is equal to minus 180°. It is easily seen that this corresponds to the point $(-1, 0)$ on the Nyquist plot.

Nyquist Criterion; 2 (for a general feedback system). It is, of course, always possible to reduce the basic equations of the system

$$a_{1j}(s)Q_1(s) + a_{2j}(s)Q_2(s) + \cdots + a_{nj}(s)Q_n(s) = f_j(s),\ j = 1, 2, \ldots n$$

by eliminating all but two of the Q's, to a pair of equations relating these two quantities only, which can be put in the form

$$Q_1(s) - \beta s)Q_2(s) = F_1(s)$$

$$Q_2(s) - \mu(s)Q_1(s) = F_2(s)$$

This, in effect, reduces the system to a single-loop system of loop transfer function $\mu(s)\beta s)$. Since the characteristic equation is

$$\Delta(s) = 1 - \mu(s)\beta s) = 0$$

the above formulation of the Nyquist criterion may be applied, replacing $G(s)$ in the preceding section by $-\mu(s)\beta s)$. Thus the system will be stable provided that:

1. The locus of $-\mu(i\omega)\beta i\omega)$ encircles the point $(-1, 0)$ P times counterclockwise, or

2. The locus of $+\mu(i\omega)\beta i\omega)$ encircles the point $(+1, 0)$ P times counterclockwise, or
3. The locus of $1 - \mu(i\omega)\beta i\omega)$ encircles the origin P times counterclockwise, P being in each case the number of simple poles of $\mu(s)\beta s)$ lying in the right-hand half-plane, any poles on the imaginary axis being circumvented as explained above.

In a multiloop system, however, μ or β or both may comprise subsidiary, possibly unstable loops, so that in general $P \neq 0$. To avoid the reduction of the equations to the above form and the subsequent finding of the value of P by the Routh criterion, the Nyquist method may be extended as follows.

We start from the premise that a passive system is necessarily stable. In other words, if, in the given system, the active elements are made inactive, we have a stable system. We then imagine each of the active elements to be activized one at a time until the system is back to its normal state, investigating at each stage the behavior of the return difference for the reactivized element. (The order in which the elements are reactivized is entirely a matter of convenience.)

Rendering an element inactive has the effect, in the set of general system equations, of making some parameter of that element zero. In the case of an electron tube, the amplification factor or the mutual conductance vanish; in the case of a rotary machine amplifier, the armature voltage per ampere-turn vanishes, and analogously for other types of active elements. Further, it can be shown that the return difference for any parameter is the ratio of the values assumed by the system determinant when the parameter has its normal value, to when this value is made zero, provided only that the determinant is a linear function of the parameter.

We suppose then that there are m active elements and, having placed these in some arbitrary order, we denote by Δ_r the value of the system determinant when the first r of these elements are activized, the remainder being inactive. Starting from the completely inactive system, the return difference for the first element is Δ_1/Δ_0. The return difference for the second element (the first one remaining active) is Δ_2/Δ_1. The return difference for the third (the first two remaining active) is Δ_3/Δ_2 and so on, until finally the return difference for the mth element (all other remaining active) is Δ_m/Δ_{m-1} in which, furthermore, $\Delta_m \equiv \Delta$, the normal system determinant. Now the number of counterclockwise encirclement of the origin made by the Nyquist locus of the return difference of the rth element Δ_r/Δ_{r-1} is $(z_{r-1} - z_r)$, where z_r denotes the number of zeros of Δ_r in the right half-plane. Hence the sum of such encirclements made by all the successive return difference loci is $(z_0 - z_1) + (z_1 - z_2) + \cdots + (z_{m-1} - z_m) = z_0 - z_m$. But z_0 is zero since the system is then passive. For stability, moreover, z_m must be zero. Hence, *for stability of the normal system, the sum of the encirclements of the origin made by the various return difference Nyquist loci must be zero*.

STABILIZATION (Ship). In addition to the obvious method of suitable design of the hull, a number of specific devices have been developed for damping the motions of a ship among the waves, especially the rolling motion. Ships have been built carrying large gyroscopes, but in general this method proved too costly in money and added weight for the effect obtained. A more widely used method is that of *anti-rolling tanks*, also called *water chambers*, which are usually placed in stabilizing bulges on each side of the hull. By controlling the flow of water from the tanks on one side to those on the other, so that the period of the contained water is proportionate (ideally about 70%) to the ship's period of roll, the maximum stabilization can be obtained. (Its amount is much less than that of a gyroscope, but far less costly.) Control of the water flow may be effected by a valve-controlled air line connecting the upper parts of the U-tubes connecting the tanks. This control can also be used to shut off the system in wave systems of very irregular pattern, which cause erratic behavior of the ship when the water is shifted among the anti-rolling tanks.

STABILIZER. Any substance that tends to keep a compound, mixture, or solution from changing its form or chemical nature. Stabilizers may retard a reaction rate, preserve a chemical equilibrium, act as antioxidants, keep pigments and other components in emulsion form, or prevent the particles in a colloidal suspension from precipitating.

See also **Inhibitor**.

STABLE FLY *(Insecta, Diptera)*. Similar to the house fly in appearance, the small stable fly, *Stomoxys calcitrans* (Linne), is a severe pest against horses and mules, usually biting the legs of the animals. It also attacks cattle, hogs, goats, sheep, rabbits, dogs, rats, and humans. The insect is widely distributed throughout the United States. In the northern states, the insect winters over as larvae and pupae, usually in wet areas near straw and manure. In the southern states, the fly can be found in all stages all year. Where stable flies are abundant, animals can lose a substantial amount of blood during the course of a day because each stable fly will require from 1 to 2 drops of blood each time it bites. The bites are painful and irritating and generally contribute to deterioration of the health of the animals attacked. Dairy cows yield less milk; cattle lose weight; horses can become unmanageable. The fly is also suspected of carrying a number of diseases, such as anthrax, leprosy, surra, and swamp fever (infectious anemia of horses), although no solid proof of this has been available.

Prevention through cleanliness of animal quarters cannot be overstressed as an effective measure. Highly valued animals can be protected with blankets and coverings. Fly traps, mechanical or electrical, are suggested for dairy barns and other areas frequented by the flies. Numerous commercial repellent formulations are available — for use in disinfecting animal quarters as well as for spraying on affected parts of the animals once or twice per week.

STACK. In geology, a rock pillar or monument that occurs relatively close to marine cliffs which have usually been developed in hard, horizontally bedded, but jointed, sedimentary rocks. In some cases, a stack is the remaining pillar of an arch. Both sea arches and stacks are well developed on the coast lines of the Gaspé Peninsula and the North East Highlands of Scotland.

STADIMETER. An instrument for determining the distance to an object of know dimension by measuring the angle subtended at the observer by the object.

STAGE. 1. A self-propelled separable element of a rocket vehicle. 2. A step or process through which a fluid passes, especially in compression or expansion. 3. A set of stator blades and a set of rotor blades in an axial-flow compressor or a turbine (see also **Turbine (Steam)**); an impeller wheel in a radial-flow compressor.

STAINS. With few exceptions, stains used in wood finishing are formulated to improve the appearance of the substrate. Unlike paints, sealers, and topcoats, stains are utilized either to accentuate the natural beauty of the wood or to hide inherent defects found in most species of wood. The application of stains to substrates includes spray, flow, dip, roll-coat, or hand application, ie, brush or rag methods. The type of application method used depends on the function of the stain itself as well the type of product being manufactured.

There are various types of wood stains and criteria used to choose the right type for a job. Although there are several distinct groups or types of stains, it is safe to categorize wood stains into two groups: dye stains and pigmented stains.

Dye Stain or Soluble Colors

A defining characteristic of dyes is the ability to dissolve in a given medium. Dissolution leaves no particles to refract or scatter light and thus

a dye solution is transparent. A distinct advantage of a soluble-type stain is this transparency and brightness afforded by use of various dye types. Solubility is increased by agitation or heat, or a combination of the two.

Solvent Dyes. As the name implies, these dyes are popular because of their solubility in a variety of industrial solvents. Color strength, brilliance, lightfastness, and the ability to formulate with solvents other than alcohol and water have helped to increase their use and popularity. Because these dyes are soluble in solvents other than alcohol or water, the finisher may lessen the effect to the substrate itself. The moisture content of alcohols and the tendency of alcohol to draw moisture from the air during the drying process result in grain raising of the wood. Using solvents other than alcohols lessens this effect to some degree. These "smoothcoat" stains are used on certain species of wood to lessen the amount of grain rupture associated with moisture. Based on cell structure or quality, certain species of wood are prime candidates for solvent stains.

Acid Dyes. These dyes are sodium salts of color acids and are the most widely used dyes for nongrain-raising wood stains. Generally speaking, acid dyes have excellent brightness, strength, and lightfastness. They are partially soluble in alcohol, but perform best when initially incorporated in ethylene glycol or propylene glycol and later reduced in methanol. They exhibit excellent transparency.

Theory and Practice of Wood Staining

Color Mixing. The various types of dye powders used to make dye stains are blended to achieve the desired color. Most finishers purchase wood stains premixed to specified colors. In the wood-finishing industry, various shades of brown are the most common. These colors are usually blended from primary colors. Color-matching skills can be acquired only by practice, but the basic theory of color matching is relatively simple and easily understood.

In a color circle, the three primary colors consisting of red, yellow, and blue are spaced equally, 120° apart. Between them are the secondary colors: orange, green, and purple. The secondary colors are made by combining the adjacent primary colors. Thus, a mixture of red and yellow produces orange, a mixture of yellow and blue produces green, and blue and red gives purple. Colors that are directly opposite one another on this circle are complementary colors that when mixed become varying shades of brown, the most commonly used color in wood stains. By slightly altering the levels in which each of these colors is present, literally thousands of variations of brown can be achieved. In most wood stains, black or a blue-black is used in place of a pure blue.

Types of Wood Stains. The term wood stain in this article applies only to those stains that are applied directly to the wood or over another wood stain. The types of stains used are dependent on the application, finished product, and regional terminology. Multiple wood stains are frequently used in the residential furniture industry to achieve a desired look. They include equalizers to match up varying shades and nongrain-raising (NGR) stains spraged overall 1.

Pigmented Stains

Pigment colors are finely divided color particles that do not dissolve in any available solvent; they can only be dispersed by grinding them in a liquid. The wood stains discussed thus far, with the exception of equalizers that incorporate white or pearl essence, generally are more transparent and brighter than pigmented stains. There are, however, certain wood stains that can be formulated with pigments and still give the finish a desirable look. These pigmented wood stains are used in a variety of applications, and in many instances such use shortens the number of steps needed to achieve a desired appearance. Pigmented wood stains are used commonly in the finishing of kitchen cabinets, where shorter finishing systems are desirable. Also, pigmented wood stains are popular with "do-it-yourselfers."

There are a large number of pigments to choose from when formulating a stain. Three basic groups of pigments used in the industry are: (*1*) natural or earth colors consisting of umbers, siennas, yellow oxide, and red oxide. Vandyke brown is also a natural pigment, but it is of organic rather than mineral origin.

(*2*) Organic pigments are carbon compounds which are usually derived from coal-tar bases or petroleum. Organic pigments include carbon and lampblack, which are derived from natural gas by incomplete combustion. Other examples of organic pigments include lithols, toluidines, and phthalocyanines. See also **Pigments (Organic)**.

(*3*) Chemical pigments or synthetics may be metal compounds. A good example is white titanium dioxide. Other chemical pigments include cadmium sulfide colors, iron blue, and several synthetic versions of iron oxides.

Penetrating Stains. Penetrating or no-wipe stains are used in a variety of applications. The most common use of these direct-to-wood stains is on small-pore species of wood. Maple, cherry, and coniferous species such as pine are good candidates for penetrating stains.

As the name implies, these stains are sprayed on and require little if any wiping. The solvent itself penetrates into the pore and allows the pigment and a small amount of binder to remain on the surface. These stains usually are composed of an oil-type vehicle and a combination of earth pigments reduced in a combination of aliphatic and aromatic hydrocarbons such as naphtha and toluene. The solvent system itself plays a big role in the appearance of the stain owing to the varying degrees to which solvents penetrate. Restrictions on the use of certain aromatic hydrocarbons have affected the manner in which these stains work.

The transparency and brightness of dyes cannot usually be duplicated through the use of pigments. However, optimum clarity and look can be achieved when using pigmented stains by consideration of such factors as the amount of pigment contained in the stain and the type. Application also plays a significant role in the strength and transparency of a stain. Usually the finisher wants to avoid a painted look when using penetrating stains.

Advantages of penetrating stains are numerous. The stains are commonly applied by spraying or dipping, the latter being the most economical method of staining. Additionally, pigments used in penetrating stains are generally less expensive than dyes. Because of the uniform appearance provided by penetrating stains, many finishing applications utilize penetrating stains as the only color step.

Toners and Tinted Sealers. These materials are usually pigments dispersed in nonpenetrating lacquers. In some instances, solvent or spirit dyes can be used to improve clarity. The solids of the vehicle can be adjusted to control the depth of penetration into the substrate.

Toners can be used in a variety of applications, depending on the substrate and the effect desired. They can be sprayed either directly onto the wood or over other wood stains. The solids of toners are usually low (5–15 wt%) and generally require the use of a washcoat or sealer prior to topcoating.

Although the difference between toners and tinted sealers may not be clearly defined, it is usually the role of the tinted sealer to provide both color and sealing properties. Therefore the tinted sealer usually is higher in solids and provides the majority of color to the finish. There has been a resurgence of popularity of tinted sealers, owing to the appeal of blonde or natural finishes. The fact that tinted sealers are becoming more popular may be the result in part of their ability to fill the roles of both stain and film builder within a finishing system.

Both toners and tinted sealers provide uniform pigment distribution without penetration. The use of more transparent pigments can also provide acceptable clarity, but with limited depth and contrast.

Overtone Stains

Although washcoats are not classified as stains, the role they play in the staining procedures makes it important to examine the properties they bring and the contribution they make to the finishing process. Washcoats for wood finishing can be defined as thin coats of sealer applied to control the amount of penetration and subsequent staining from overtone stains and fillers. Naturally, the solids content of a washcoat determines the amount of penetration of an overtone stain. Washcoats are usually sanded prior to application of a glaze, wiping stain, or filler. Therefore the extent of the sanding also plays a role in the penetration and staining action.

Washcoats perform the following roles in the finishing process: (*1*) they form a thin film to protect the wood stain(s) from the effects of handling, or the solvent from subsequent finishing steps; (*2*) they raise and stiffen wood fibers to enable the surface to be sanded prior to application of wiping stains and fillers, and this sanded, smooth, hard surface facilitates

the wiping and clean-up of fillers and other wiping steps; (*3*) they seal the surface of the wood and wood pores to prevent pinholes and blistering when fillers are used on large-pore substrates; and (*4*) by controlling the solids of a washcoat, the amount of penetration of overtone stains can be controlled.

The solids content of a washcoat is usually 5–12 wt%. It is important that washcoats leave a very thin film of material to allow the proper amount of sealing and to prevent bridging the pore, which would result in blistering of subsequent build coats.

Fillers. Wood fillers are applied directly over the washcoat in a multistep operation. Fillers that are not properly dried will eventually shrink, and full fill is not achieved.

Fillers perform two significant functions: they fill pores and give color to the pores.

Glazes and Wiping Stains. Some applications such as kitchen cabinet finishing utilize wiping stains direct-to-the-wood. In most fine furniture applications, wiping stains and glazes are applied over the washcoat or sealer step.

These overtone stains are normally composed of pigments, oils, solvents, and driers. The important quality of glazes and wiping stains is the ability to apply a color coat which can be wiped on and then highlighted to add depth and contrast to the overall appearance of the finish.

These wiping coats are usually sprayed on and then wiped with rags to varying degrees, depending on how much color and effect the finisher desires from the wiping coat.

The wiping and blending properties of a wiping stain are important considerations when formulating these types of products. A good glaze must not be sticky or bite into the sealer and must stay open long enough to be wiped, brushed, and worked to the desired level by the finisher. Long working times are important, yet these stains must be recoatable within a reasonable period of time. Unless the stains are formulated correctly, the glaze or wiping stain may cause poor intercoat adhesion or discoloration when lacquer topcoats are applied.

Shade Stains. These stains are usually applied after the sealer or first topcoat and are typically sprayed on specific areas to compensate for uneven color distribution during the initial finishing process.

Another common use of the shade stain is to enhance the contrast or depth of the finish. This is usually the role of the glaze, but when additional contrast is needed, the finisher may elect to shade certain areas. Care must be taken not to apply too much shade, which can result in a painted or artificial appearance.

Pad Stains. More progressive or higher end furniture finishers add color or pad stains to enhance grain patterns, produce shadows, and create hues found only in exceptionally fine veneers and woods. These pads are applied at varying levels to create the illusion of the third dimension.

Pad stains are divided into two groups: spray pads and hand pads. The difference between them, not surprisingly, can only be defined by the means of application. Like the shade stains, they are usually applied over the sealer or first topcoat and subsequently are topcoated themselves.

The primary purpose of the pad stains is to accent figures.

Distressing Stains. Interest and charm can be added to furniture by the deliberate infliction of imperfections. These imperfections may be caused by physical distress such as hammers, files, nails, chains, or rocks or caused by finish distress such as "fly specking" or staining to simulate past abuse, such as waterstains caused by the careless placement of a drinking glass.

Physical distressing is usually a part of the initial finishing procedure and is done in the white wood stage. Finish distressing is normally part of the latter phases of the finishing operation. Like the pad and shade stains, distressing stains are usually applied over the sealer or between coats of topcoat.

Health and Safety Factors

Most of the stains discussed are solvent-borne and therefore possess inherent properties such as flammability, toxicity, and reactivity. Those properties make it necessary to observe safe handling practices when using or storing wood stains. Adequate ventilation and avoidance of any source of possible ignition are key in the use and storage of these materials. Personal protection when using stains should include safety glasses or goggles, respirators, aprons, and rubber gloves. Overexposure to certain solvent vapors may cause respiratory damage or impaired judgment, whereas prolonged skin contact may result in skin irritations or even neurological effects.

Provisions of the Clean Air Act have resulted in the regulation of certain wood finishing applications. Residential and Institutional Furniture and Kitchen Cabinet Industries are under regulations which specify the amount and types of solvent emissions allowed. The size and location of a finishing facility determine the extent of the effect stemming from the regulations.

These regulations are based in part on the amount of solvents in relation to the amount of solids. Most wood stains are low solids materials which rely on their transparency and their ability to penetrate and dry fast. Those characteristics themselves put great emphasis on the type of solvents that are used to formulate stains. The low solids content of wood stains limits the scope of solvent substitution or reformulation.

RON W. TUCKER, Lilly Industries, Inc.

STALACTITE AND STALAGMITE. A *stalactite* is a deposit of a mineralized solution, commonly calcium carbonate, which hangs like an icicle from the roof or wall of a limestone cavern. See Fig. 1. The formation of the stalactite usually is quite a slow process. Corresponding columnar structures built upward from the floors of caves beneath the stalactites are called *stalagmites*. Stalactite is derived from the Greek, meaning to fall in drops. Stalagmite, also derived from the Greek, means that which drops. When a stalactite from the top of a cave and a stalagmite from the floor of the cave join, the resulting singular structure is called a *column*.

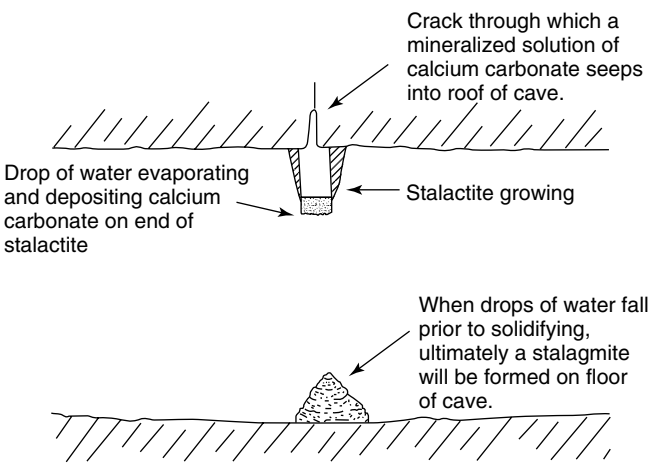

Fig. 1. Formation of stalactite and stalagmite.

STALAGMOMETER. An apparatus for the measurement of surface tension by the drop-weight method.

STALING (Bakery and Food Products). Most authorities agree that staling of bakery products commences immediately after the product leaves the oven and that it is a reasonably progressive process, not involving a delayed start or of a cyclic nature. Post-processing conditions obviously can favor or be unfavorable to the process of staling. In bread, the moisture content of the crumb averages about 45% (weight) when the loaf leaves the oven. The crust, on the other hand, has a moisture content of 5–7%. Under these conditions (lack of equilibrium), the crust loses moisture on the outside to the atmosphere, while it picks up moisture from the crumb on the inside of the loaf. The result is a toughening of the crust, accompanied and aided by formation of a soggy undersurface. The crumb, of course, becomes drier and drier with time. As moisture is expelled to the atmosphere, along with other volatiles, flavor decreases. Flavor loss also is the result of essential deactivation of certain flavoring components when they are absorbed by the inner solids. It is also likely that unexplained chemical reactions occur (oxidation, etc.) that alter the chemical structure and hence aroma and flavor of the flavoring components. With some

products, the staling processes are not necessarily fully irreversible. Some breads, such as Italian breads, can be moistened and placed in an oven and returned to a reasonable degree of organoleptic acceptability. Some bakers purposely underbake their product to slow up the staling process.

Many authorities believe that starch is in some way the key to most of the staling phenomena. A tie-in with starch is evident in a practical way by observing that bread put in the refrigerator tends to become stale sooner than when left at a reasonable room temperature; but if the bread is placed in a freezer, it may be retained for long periods, but with some evidence of staleness once the bread is thawed. It is known that starch retrogrades at a faster rate as the temperature is lowered, but beyond a certain point the starch degradation is greatly slowed at very low temperatures and hence the staling rate is slowed. Various additives have alleviated the staling process to some degree.

STALL. A term in common use to describe the condition of an aerodynamic burble upon a wing. An airplane that has "stalled" has had the streamline flow over the upper wing surface partly destroyed. The lift is partially lost so weight and lift are out of equilibrium. Hence, a stall is followed by a nosing down motion accompanied by rapid loss of altitude. The term "stall" here applies to an aerodynamic phenomenon. The term is also used when an aircraft engine ceases to operate, when it is said to stall.

See also **Aerodynamics and Aerostatics**; and **Airplane**.

STAMENS. Stamens are the male reproductive organs of flowers. Their role is to produce pollen. Genes that control the developmental identity and cellular differentiation of stamens are now being identified. Stamens evolved from microsporangia-bearing organs of early seed plants.

Structure, Anatomy, and Ontogeny

Typically, stamens are made up of two parts, an anther in which pollen is formed, and a supporting sterile filament (Fig. 1). The anther itself is usually an elongated structure that contains four linear pollen sacs (microsporangia) arranged in two pairs. These pairs of pollen sacs, or thecae, lie on each side of a central undifferentiated region of the anther called the *connective*. A single vascular thread runs the length of the stamen, through the filament and the anther connective. The filament may be attached to the base of the anther (basifixed), or closer to its center, either on the outward-facing surface (dorsifixed) or the inner surface (ventrifixed). In some flowers, the base of the filament is continuous with the petals, especially if the corolla is tubular (as in many asterids). Stamens are sometimes fused to each other, involving either the filaments (as in many peas, Fabaceae), or the anthers (as in many daisies, Asteraceae). Collectively, all the stamens in one flower are called the *androecium*, and the number varies between species, from one to thousands.

Stamen development begins when small domes of cells arise within the flower primordium, between the outer perianth and the inner gynoecium. In a developing stamen primordium, subepidermal cells in four locations are defined early as archesporial initials. These divide periclinally to produce sporogenous cells (internally) and parietal cells (immediately beneath the epidermis). In most species, the sporogenous cell lineage is limited to producing the microsporocytes (pollen mother cells) that occur in a linear file or as a layer. On the other hand, the parietal lineage produces three cell types. One is the tapetum, cells that surround the microsporocytes and later the developing pollen. (Cells internal to the sporogenous cells also develop into tapetum). Tapetal cells provide the developing microsporocytes and microspores with nutritive chemicals, and later with components required for development of the pollen coat. There are two classes of tapetum, secretory and amoeboid. In the latter, tapetal cell walls break down and the contents pass between the sporogenous cells. In addition to the tapetum, the parietal cell lineage produces two further external layers, a middle layer (later crushed), and an endothecium that underlies the epidermis and that is later involved in anther dehiscence (see below).

Microsporogenesis

Sporogenic cells within each pollen sac undergo meiosis in synchrony. This may be facilitated by channels that interconnect adjoining pollen mother cells so that they constitute a syncytium. As meiosis concludes, the four haploid cell products (microspores) remain together in a tetrad, each cell initially enclosed in impenetrable wall of callose, a $(1 \rightarrow 3)\beta$-d-glucan. In most species (especially the eudicots), the cells are arranged as a tetrahedron, with the callose forming simultaneously after the two cell divisions have occurred. In others (especially basal dicots and monocots), the four cells are arranged less compactly, with the callose forming sequentially, first between the two cells that result from the first meiotic division and later between the products of the second division [Furness, et al.: 2002]. In either case, the callose soon breaks down and the four microspores separate. These continue to differentiate into pollen grains, with their nucleus undergoing a mitotic division to generate a vegetative nucleus and a sperm nucleus. The latter occurs within its own cell, and later it will divide again. Pores or slits develop in the wall of the pollen grain, one in the case of basal dicots and monocots, but three in eudicots (the difference tosome extent associated with the form of the earlier tetrad. The outer wall of the pollen grain is laid down partly using material generated by the tapetum, including the lipid-rich pollenkitt (pollen cement) that makes the grains sticky. The tapetum then degenerates, its role complete, and the residue (tryphine) may also be attached to the mature pollen grains. Genetic specificity is conferred on pollen grains that demonstrate sporophytic self-incompatibility, such as in *Brassica*, by a pollen coat protein (SCR) that is secreted into the pollen sac by developing microspores [Schopfer, et al.: 1999].

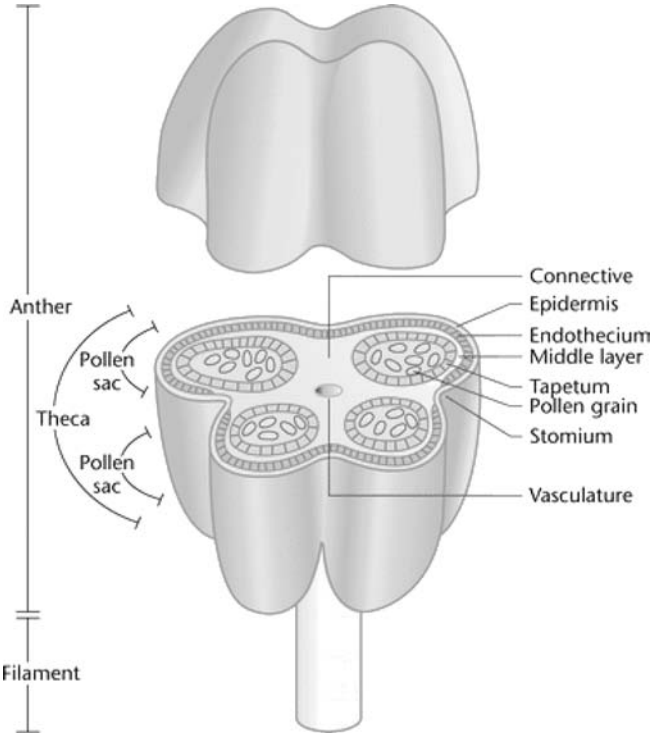

Fig. 1. Diagram of a typical stamen (e.g. the true lily, *Lilium* (Liliaceae)) at a stage when the pollen is maturing (after meiosis and before dehiscence). The stamen is made up of an anther (pale green) and a filament (white). The internal structure of the anther is shown in a transverse section. There are two thecae, each with two pollen sacs, separated by a connective (white). A vascular strand is present within the connective. Tissues within each pollen sac are, from outside in, the epidermis (pale yellow), a late-forming endothecium with lignified thickening (orange), a middle layer (white), the nutritive tapetum (pink) and developing pollen grains (dark yellow). When pollen is mature, the two pollen sacs will join and each theca will dehisce along the stomium.

Dehiscence

As the pollen matures [Keijzer, 1987], cells lying between the two adjacent pollen sacs within a theca degenerate. Also, in most anthers the subepidermal cells, especially those that surround the thecae, generate bands of lignin, becoming thickened and rigid. These cells constitute the endothecium. Such thickening does not occur, however, in the stomium, cells that usually occur in a groove between the two pollen sacs of

each theca. Stomia may face inwards (introrse) or outwards (extrorse) within the flower, depending on their location within each anther. In some species, oxalate crystals accumulate in stomial and underlying cells, perhaps to provide an alternative reward for pollen-eating pollinators. Anther dehiscence occurs when each theca is forced open along the stomium, apparently by mechanical forces generated by the endothecium. The pollen grains then escape.

Dehiscence in some species is different in that the endothecium is reduced or absent, and pollen is simply released from pores that arise in the anther wall.

Genes and Stamen Development

The first stamen development genes known so far confer a stamen identity on the appropriate floral organ primordia. Their action is position dependent, usually limited to the third whorl. Stamen identity genes each encode transcription factors of the MADS family. In the model species *Arabidopsis thaliana*, the three *SEPALLATA* genes redundantly function to ensure that organs adopt a floral fate. They combine with the B function genes *APETALA3* and *PISTILLATA* and the C function gene *AGAMOUS* to specify stamen identity within the third whorl. The combined roles of these MADS genes have been demonstrated by expressing SEP, B and C function genes together in leaf primordia. This results in stamen-like organs appearing in place of leaves [Honma and Goto, 2001]. Similar genes have been identified in other species including *Antirrhinum majus*, *Petunia hybrida*, tomato, rice and maize, although the direct targets of these regulatory genes remain difficult to identify.

Genes active later in stamen cell differentiation have also been identified (Table 1), especially from mutant screens designed to identify male sterile plants. Such mutants are useful for breeding or growing crop species such a hybrid maize where sterility is a desirable trait. It seems that the full process of pollen production is sensitive to disruption by the loss of gene activity across a wide range of functions. See also **Plant Breeding**.

Interactions with Pollinators

Many mechanisms have arisen that promote the transfer of pollen to carpels of other flowers of the same species, but that reduce transfer to carpels within the same flower, or to flowers of the same individual. This helps avoid self-fertilization, thus maintaining genetic diversity within a population. Mechanisms that promote out-crossing include dioecy and monoecy, heterostyly, genetic self-incompatibility, and differences in timing of the release of pollen and of the receptivity of carpels, as well as various mechanical adaptations (see below).

A wide diversity of pollinating agents is involved in pollen transfer. Many plants rely on the wind to spread pollen to receptive carpels, including most grasses and some temperate forest trees such as beeches, birches, poplars and casuarinas. The stamens of such species are often exposed, and produce copious amounts of pollen that is small and smooth (not sticky).

The majority of plants, however, are pollinated by animals. Of these, the largest group are the insects, including bees, wasps and ants (Hymenoptera), butterflies and moths (Lepidoptera), beetles (Coleoptera), and thrips (Thysanoptera). Among other animals, birds represent a major class of pollinators, as well as some bats and other small mammals. In most cases the animals are attracted to flowers by a food reward, either nectar or pollen. Usually the pollen is transferred indirectly to other flowers by its attachment to the body of the pollinating animal. If pollen is being consumed by the pollinator, clearly sufficient must remain for pollination to occur. Many animal pollinated flowers are showy, with ultraviolet, blue and yellow pigments that are visible to insects, or with red pigmentation that is often associated with bird pollination. These pigments are usually displayed in petals, although in some species the stamens are abundant and/or colored to act as attractors, as in *Acacia* and other Mimosaceae, and in *Eucalyptus* and some other Myrtaceae (Figure 2). Scents may also be produced to attract pollinators, especially those active at night (in which case the flowers are often white). See also **Pollination**.

Fig. 2. Flowers of *Eucalyptus* (*Corymbia*) *ficifolia* (Myrtaceae), each with many pigmented stamens that act to attract pollinators. Pigment is localized to the long filaments, each of which is capped by a tiny anther. The perianth (petals and sepals) occurs as a cap that falls off as buds open.

Mechanical adaptations in the structure of stamens and pollen are many and diverse. For example, the pollen grains of animal-pollinated species are often heavy and sticky, and sometimes held together by threads. Anthers of many bird or mammal pollinated flowers swing freely on their filament (i.e. they are versatile), and their stomia are long, allowing pollen to be transferred by contact with the passing animal. Some flowers such as the tomato are buzz-pollinated, with bees or other insects vibrating the pollen out of the anthers through small pores so that it coats their

body. In orchids, there is usually only a single stamen that is physically joined with the gynoecium. All the pollen from one theca is released in a package, a pollinium, which attaches to an insect pollinator as it negotiates a specialized pathway through the flower. This is then deposited on the stigma of the next flower visited. Orchid flowers have many ovules, and the clumped pollen helps ensure that most are pollinated. In a range of families, pollen is transferred from the anther to a secondary site before being collected by the pollinator. These include some members of the Asteraceae in which pollen is extruded from the conjoined anthers by a piston-like extension of the sterile style, and the Proteaceae and Goodeniaceae in which pollen is transferred to a pollen presenter on the non-receptive style. In some flowers, one or more of the stamens may lose the ability to make pollen (becoming a staminode), and act to attract pollinators, or as a mechanical device to guide pollinators appropriately within the flower.

Evolution

Stamens occur in angiosperms, plants in which the ovules are enclosed in carpels. Recently the phylogenetic relationships within the angiosperms have been firmly established. Endress [2001] deduced the likely stamen characteristics of ancestral angiosperms based on properties shared by the nine basal angiosperm families that are still extant. These properties include a moderate to low number of stamens per flower, perhaps spirally arranged. The stamens probably had short filaments, the anthers had a connective tip, there were two thecae each with two sporangia, and dehiscence occurred through slit-like stomia. The oldest known fossil angiosperm, *Archaefructus*, grew in early Cretaceous times (at least 125 million years ago) [Sun, et al.: 2002], and their stamens were closely similar to this. On the other hand, their "flowers" were quite different (stamens occurred in pairs on branched "stems," they were inserted on the axis below the scattered carpels, and there was no visible sign of perianth organs).

It has been more difficult to trace the origin of stamens because the ancestry of angiosperms has not been firmly established. Recent molecular data have suggested they diverged early from an ancestor that gave rise to all the extant gymnosperms (cycads, *Gingko*, conifers and gnetophytes). As in angiosperms, the male reproductive organs of gymnosperms generate pollen within microsporangia. However, this usually occurs in unisexual cones (strobili) of leaf-like organs (microsporophylls). Importantly, in gymnosperms the spore-bearing tissues are not regularly arranged in two thecae, each containing two microsporangia. Also, the pollen gametophyte undergoes more than two mitoses, and the sperm cells are motile, at least in cycads and *Gingko*. Despite these differences, it seems likely that gymnosperm microsporophylls gain their identity by the action of MADS genes related to the B and C function stamen identity genes of angiosperms [e.g. Sunström and Egström, 2002]. Moving back in time, it is not yet clear how the angiosperm ancestor is related to other extinct seed plants including seed ferns, Bennettitales and *Caytonia*. It is to be hoped that new fossil material will eventually help resolve this question.

STANDARD ATMOSPHERE. See **Meteorology**.

STANDARD CONDITIONS. Many physical and chemical phenomena and substances are defined in terms of *standard* conditions. In some instances, a temperature commonly prevailing in a chemical laboratory may be selected. Thus, when comparing a number of substances, such as their index of refraction, one may find lists in handbooks that give these values as measured by a given temperature and pressure. The Smithsonian Tables, for example, include such data for scores of substances. The researcher then can seek formulas for converting such values to other temperatures/pressures. Interpolations in some instances can be linear over a wide range of values, or the relationships may be nonlinear.

In the case of gases, properties may be tabulated in terms of their existence at 0 °C (32 °F) and 760 mm pressure. To determine the volume of a gas at some different temperature and pressure, corrections derived from known relationships (Charles', Amonton's, Gay-Lussac's, and other laws) must be applied as appropriate. In the case of pH values given at some measured value (standard for comparison), the same situation applies. Commonly, lists of pH values are based upon measurements taken at 25 °C (77 °F). The pH of pure water at 22 °C (72 °F) is 7.00; at 25 °C (77 °F), 6.998; and at 100 °C (212 °F), 6.13. Modern pH instruments compensate for temperature differences through application of the Nernst equation.

Standard conditions are not necessarily consistent with standards definitions. The careful researcher will always take note of the conditions stated for determining values in a tabulated list.

STANDARD DEVIATION. The standard deviation of a probability distribution is the square root of its variance. It is the most useful measure of dispersion.

STANDARD ERROR. A name often given to the standard deviation of a sampling distribution.

STANDARD FREE ENERGY INCREASE. Often referred to as standard free energy. The increase in Gibbs free energy (see also **Free Energy**) when the reactants in a chemical change, all in their standard states (e.g., unit concentration, or at 1 atmosphere pressure) are converted into the products in their standard states. Given by

$$\Delta G^{\circ} = -RT \ln K$$

where R is the gas constant, T, the absolute temperature, K, the equilibrium constant. See also **Free Energy Change**.

STANDARD PRECIPATION INDEX. See **Meteorology**.

STANDARD PRECIPITATION INDEX (SPI). See **Drought Indices**.

STANDARD STATE. The stable form of a substance at unit activity. The stable state for each substance of a gaseous system is the ideal gas at 1 atmosphere pressure; for a solution it is taken at unit mole fraction; and for a solid or liquid element it is taken at 1 atmosphere pressure and ordinary temperature.

STANDARD UNIT (Statistics). A variate may be changed to standard units by the transformation

$$t = \frac{x - \overline{x}}{\sigma_x}$$

where t is in standard units, x is the variate, $\overline{x}$ is the mean, and σ_x is the standard deviation of the distribution. In such cases t has a mean of zero and a standard deviation of 1 and is said to be in standard measure.

STANDING CLOUD. See **Clouds and Cloud Formation**.

STANDING-WAVE RATIO. Any transmission line such as a waveguide or an acoustic transmission system, unless terminated by its characteristic impedance, will exhibit a superposition of standing and progressive waves. The standing-wave ratio is a measure of the relative amplitudes of the two types of wave. It is defined as the ratio of the maximum amplitude of pressure (or voltage) to the minimum amplitude of pressure (or voltage) measured along the path of the waves. Thus, at a given frequency in a uniform waveguide, the standing-wave ratio is the ratio of the maximum to the minimum amplitudes of corresponding components of the field (or the voltage or current) along the waveguide in the direction of propagation. Alternatively, the standing-wave ratio may be expressed as the reciprocal of the ratio defined above.

STANLEY, WENDELL MEREDITH (1904–1971). Stanley was born at Ridgeville, Indiana on 16 August 1904, the son of a local newspaper proprietor. He studied chemistry at Earlham College, Richmond, Indiana, graduating in 1926. Postgraduate chemical studies were spent at the University of Illinois where he obtained his doctorate in 1929. Following further research at Munich with Heinrich Wieland in 1930–1931, he joined the Princeton plant pathology laboratory of the Rockefeller Institute for Medicine. In 1937 he moved to Princeton University, New Jersey. In 1948 he became Professor of Biochemistry and Director of the Virus Laboratory at the University of California, Berkeley, where he ended his career as Professor of Virology. As a young man he was a great athlete, and thought seriously of becoming a professional footballer. He was elected to the National Academy of Sciences in 1941. He was married with a son and three daughters. He died in Salamanca, Spain, on 15 June 1971 while attending a conference. His papers are deposited in the Bancroft Library at Berkeley.

Stanley began to study the *Tobacco mosaic virus* in 1932 and using the techniques that John Northrop had devised to crystallize enzymes, he isolated crystals of what he thought was a viral protein (in fact, a nucleoprotein) in 1934. He believed that this proved that viruses were chemical species and not submicroscopic living organisms, as had been hitherto believed. Subsequent studies by others showed TMV to have a huge molecular weight. In 1940 Stanley published the first electron microscope photograph of TMV. In 1946 he shared the Nobel Prize in Chemistry with James Sumner and Northrop for showing that viruses are crystallizable proteins. He later accepted that TMV also contains RNA. See also **Northrop, John Howard (1891–1987)**; and **Sumner, James Batcheller (1887–1955)**; and **Virology (The History)**.

STANNITE (Mineral). This mineral is a sulfo-stannate of copper and iron, sometimes with some zinc, corresponding to the formula, Cu_2FeSnS_4. It is tetragonal; brittle with uneven fracture; hardness, 4; specific gravity, 4.3–4.5; metallic luster; color, gray to black, sometimes tarnished by chalcopyrite; streak, black; opaque. The mineral occurs associated with cassiterite, chalcopyrite, tetrahedrite, and pyrite, probably the result of deposition by hot alkaline solution. Stannite occurs in Bohemia; Cornwall, England; Tasmania; Bolivia; and in the United States in South Dakota. It derives its name from the Latin word for "tin," *stannum*.

STAR. There is probably no one class of physical objects that has attracted more popular and scientific attention throughout the ages than have the stars. A small portion of the mass of mythological material that is associated with these bodies will be found in the various articles dealing with the individual constellations and a few of the brighter stars.

A star, as distinguished from a *planet*, is a self-gravitating object capable of generating its own energy by nuclear processes, or the remnant (white dwarf or neutron star) of such an object. The *protostellar phase* would be seen as the formative part of the life of a star. The contraction of the gas cloud leads to core temperatures high enough to ignite the central engine. A lower mass limit of 0.08 solar masses appears to be required in order to initiate the simplest nuclear reactions, while the upper stable mass may be as great as several hundred solar masses.

The most important things to know about stars are that they are massive and they have no walls. The first means that they must reach very high internal temperatures in order to generate sufficient pressures to guarantee their stability against collapse. The second means that they have outer boundaries that communicate to space all of the excess energy that they are able to generate. Since the Universe is so large and empty and cold, the absence of insulation requires all internal heat to flow outward. Thus, any star ultimately cools and no star can last in a hot stage forever. In addition, though enormous, only a finite amount of energy is available. The gravitational potential energy can be tapped only at the expense of disequilibrating the body, either slowly as in contraction or catastrophically fast as in collapse. Alternatively, you could image that the rest energy could some how be used, but this requires nuclear processes to occur and still only a fixed amount of energy can be obtained through nucleosynthesis. No matter how much energy you try to release, it leaves the star, never to be recovered. So stars must die. This, in a nutshell, is the driving condition of stellar evolution.

Star Formation and Evolution

Star formation occurs in molecular clouds, large regions of high density in the interstellar medium (though still less dense than the inside of an earthly vacuum chamber). Star formation begins with gravitational instability inside those clouds, often triggered by shockwaves from supernovae or collision of two galaxies (as in a starburst galaxy). High mass stars powerfully illuminate the clouds from which they formed. One example of such a nebula is the Orion Nebula. See also **Nebula**.

Stars spend about 90% of their lifetime fusing hydrogen to produce helium in high-temperature and high-pressure reactions near the core. Such stars are said to be on the main sequence.

Small stars (called red dwarfs) burn their fuel very slowly and last tens to hundreds of billions of years. At the end of their lives, they simply become dimmer and dimmer, fading into black dwarfs. However, since the lifespan of such stars is greater than the current age of the universe (13.7 billion years), no black dwarfs exist yet. See also **Giant and Dwarf Stars**.

As most stars exhaust their supply of hydrogen, their outer layers expand and cool to form a red giant. In about 5 billion years, when the Sun is a red giant, it will be so large that it will consume both Mercury and Venus. Eventually the core is compressed enough to start helium fusion, and the star heats up and contracts. Larger stars will also fuse heavier elements, all the way to iron, which is the end point of the process. Since iron nuclei are more tightly bound than any heavier nuclei, they cannot be fused to release energy. Likewise, since they are more tightly bound than all lighter nuclei, energy cannot be released by fission. In old, very massive stars, a large core of inert iron will accumulate in the center of the star.

An average-size star will then shed its outer layers as a planetary nebula. The core that remains will be a tiny ball of degenerate matter not massive

enough for further fusion to take place, supported only by degeneracy pressure, called a white dwarf. These too will fade into black dwarfs over very long stretches of time.

In larger stars, fusion continues until an iron core accumulates that is too large to be supported by electron degeneracy pressure. This core will suddenly collapse as its electrons are driven into its protons, forming neutrons and neutrinos in a burst of inverse beta decay. The shockwave formed by this sudden collapse causes the rest of the star to explode in a supernova. Supernovae are so bright that they may briefly outshine the star's entire home galaxy. When they occur within the Milky Way, supernovae have historically been observed by naked-eye observers as "new stars" where none existed before. Eventually, most of the matter in a star is blown away by the explosion (forming nebulae such as the Crab Nebula) (Fig. 1) and what remains will be a neutron star (sometimes a pulsar or X-ray burster) or, in the case of the largest stars, a black hole. See also **Black Hole**; and **Supernova 1987A and 1993 J**.

Fig. 1. The Crab Nebula, remnants of a supernova which occurred around 1100 AD. (*Image courtesy of FORS Team, 8.2-meter VLT, European Southern Observatory*) (*ESO*).

The blown-off outer layers of dying stars include heavy elements which may be recycled during new star formation. These heavy elements allow the formation of rocky planets. The outflow from supernovae and the stellar wind of large stars play an important part in shaping the interstellar medium.

Appearance and Distribution of Stars

Look into the sky on a clear night, out of the glare of streetlights, and you will see a few thousand individual stars with your naked eyes. With even a modest amateur telescope, millions more will come into view.

So how many stars are there in the Universe? It is easy to ask this question, but difficult for scientists to give a fair answer!

Stars are not scattered randomly through space, they are gathered together into vast groups known as galaxies. The Sun belongs to a galaxy called the Milky Way. Astronomers estimate there are about 100 thousand million stars in the Milky Way alone. Outside that, there are millions upon millions of other galaxies also! See Fig. 2.

It has been said that counting the stars in the Universe is like trying to count the number of sand grains on a beach on Earth. We might do that by measuring the surface area of the beach, and determining the average depth of the sand layer.

Fig. 2. The nearby dwarf galaxy NGC 1569 is a 'hotbed' of vigorous star birth activity which blows huge bubbles and super-bubbles that riddle the main body of the galaxy. The galaxy's vigorous 'star factories' are also manufacturing brilliant blue star clusters. This galaxy had a sudden and relatively recent onset of star birth 25 million years ago, which subsided about the time the very earliest human ancestors appeared on Earth.

In this new image, taken with the NASA/ESA Hubble Space Telescope, the bubble structure is sculpted by the galactic super-winds and outflows caused by a colossal input of energy from collective supernova explosions that are linked with a massive episode of star birth.

The bubble-like structures seen in this image are made of hydrogen gas that glows when hit by the fierce winds and radiation from hot young stars and is racked by supernovae shocks. The first supernovae blew up when the most massive stars reached the end of their lifetimes roughly 20-25 million years ago. The environment in NGC 1569 is still turbulent and the supernovae may not only deliver the gaseous raw material needed for the formation of further stars and star clusters, but also actually trigger their birth in the tortured swirls of gas. (*Image courtesy of ESA, NASA and Peter Anders* (*Göttingen University Galaxy Evolution Group, Germany*).

If we count the number of grains in a small representative volume of sand, by multiplication we can estimate the number of grains on the whole beach.

For the Universe, the galaxies are our small representative volumes, and there are something like 10^{11} to 10^{12} stars in our galaxy, and there are perhaps something like 10^{11} or 10^{12} galaxies. See also **Galaxy**.

With this simple calculation you get something like 10^{22} to 10^{24} stars in the Universe. This is only a rough number, as obviously not all galaxies are the same, just like on a beach the depth of sand will not be the same in different places.

No one would try to count stars individually; instead we measure integrated quantities like the number and luminosity of galaxies. ESA's infrared space observatory Herschel, to be launched in 2007, will make an important contribution by 'counting' galaxies in the infrared, and measuring their luminosity in this range — something never before attempted. See Fig. 3.

In 1995, an image from the Hubble Space Telescope (HST) suggested that star formation had reached a peak at roughly seven thousand million years ago. Recently, however, astronomers have thought again. See Fig. 4.

The Hubble Deep Field image was taken at optical wavelengths and there is now some evidence that a lot of early star formation was hidden by thick dust clouds. Dust clouds block the stars from view and convert their light into infrared radiation, making them invisible to the HST. See also **Hubble Space Telescope (HST)**.

Herschel is designed to view exactly the time in the evolution of the Universe, at the right wavelengths where it is thought the majority of the obscured star formation can be seen.

So with Herschel, astronomers will see many more stars than before. We will be one step closer to provide a more reliable estimate to that question asked so often in the past — "How many stars are there?"

The nearest star to the Earth, apart from the Sun, is Proxima Centauri, which is 39.9 trillion kilometers, or 4.2 light years away (light from

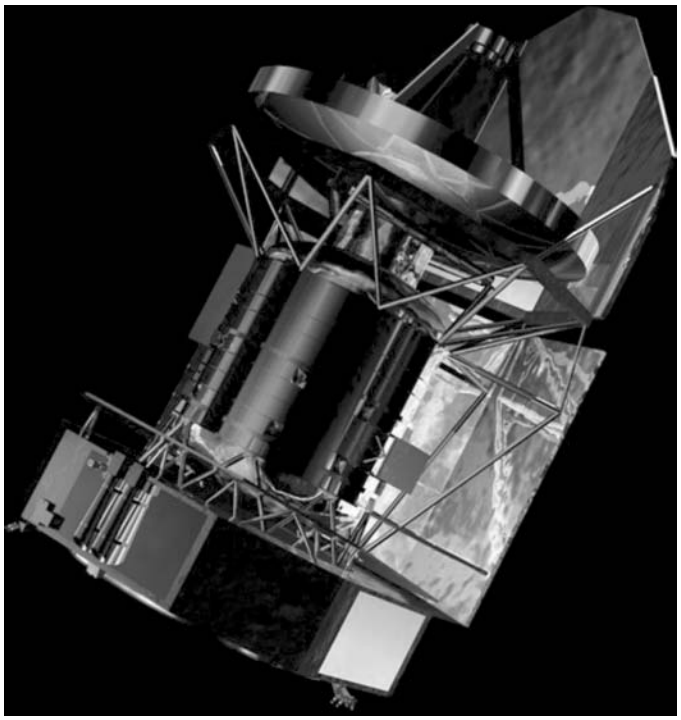

Fig. 3. The Herschel's telescope will collect infrared radiation from distant stars. Image shows telescope, vessel containing liquid helium cryostat (narrow, middle part), and service module at the bottom. (*Image courtesy of ESA 2002/Medialab).*

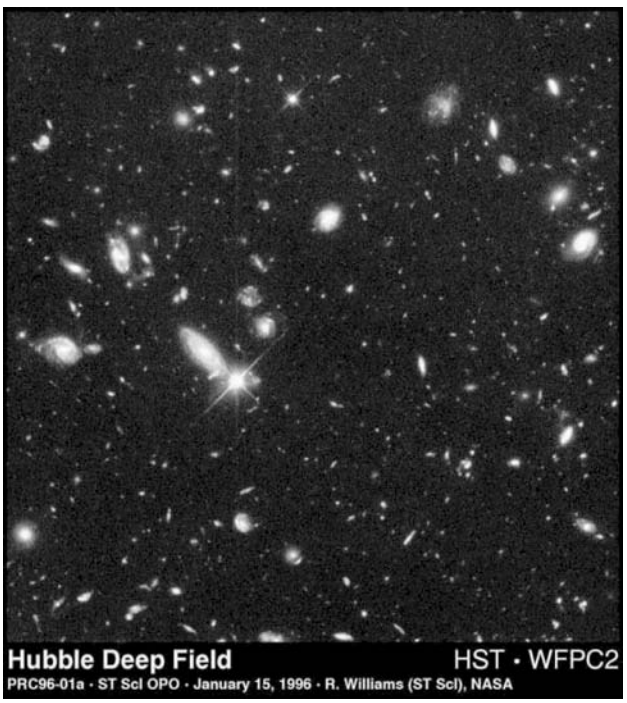

Fig. 4. The famous 1995 image of the Hubble Deep Field. By analyzing the galaxies revealed here, astronomers made their first estimates of the history of star formation in the Universe. However, there are many stars that cannot be seen on this image because dust clouds hide them from view. ESA's Herschel mission will see them, providing a more accurate determination of the amounts of stars that have formed in the Universe. (*Image courtesy of R. Williams (STScI), the Hubble Deep Field Team /NASA/ESA*).

Proxima Centauri takes 4.2 years to reach Earth). Travelling at the orbit speed of the Space Shuttle (5 miles per second — almost 30,000 kilometers per hour), it would take about 150,000 years to get there. Distances like this are typical inside galactic discs, where the Sun and Earth are located. Stars can be much closer to each other in the centres of galaxies and globular clusters, or much further apart in galactic halos.

Age and Size of Stars

Many stars are between 1 billion and 10 billion years old. Some stars may even be close to 13.7 billion years old, which is the observed age of the universe. See also **Cosmology**; **Red Shift**; and **Stellar Evolution**. They range in size from the tiny neutron stars (which are actually dead stars) no bigger than a city, to supergiants like the North Star (Polaris) and Betelgeuse, in the Orion constellation, which have a diameter about 1,000 times larger than the Sun — about 1.6 billion kilometers. However, these have a much lower density than the Sun. See also **Orion (The Hunter)**; **Polaris**; **Sun (The)**; and **Universe (The)**.

One of the most massive stars known is Eta Carinae, with 100–150 times as much mass as the Sun. Recent work by Donald Figer, an astronomer at the Space Telescope Science Institute in Baltimore, Maryland, http://www.stsci.edu/resources/, suggests that 150 solar masses is the upper limit of stars in the current era of the universe. He used the Hubble Space Telescope to observe about a thousand stars in the Arches cluster, a massive young star cluster near the core of the Milky Way, and found no stars over that limit despite a statistical expectation that there should be several. The reason for this limit is not precisely known, but the Eddington limit is part of the answer. The very first stars to form after the Big Bang may have been larger, up to 300 solar masses or more, due to the complete absence of elements heavier than lithium in their composition. This generation of supermassive stars is long extinct, however, and currently only theoretical.

With a mass only 93 times that of Jupiter, AB Doradus C, a companion to AB Doradus A, is the smallest known star undergoing nuclear fusion in its core. Smaller bodies are brown dwarfs, which occupy a poorly-defined grey area between stars and gas giants. The minimum mass a star can have is estimated to be in the vicinity of 75 Jupiters.

Other methods for determining the physical characteristics of the stars will be found under such titles as: absolute magnitude, apparent magnitude, stellar parallax, stellar magnitude, spectral class, binary stars, variable stars, cepheids, giant and dwarf stars, etc. The characteristics of a typical main-sequence G-type star will be found in the articles dealing with the sun and various solar characteristics. The source of the energy radiated by the stars is discussed in the article on the sun, and under carbon cycle and proton-proton chain. See Tables 1–6.

Numerous classes and specific stars are described in various entries throughout this encyclopedia. Consult alphabetical index.

Stellar Classification and Types of Stars

The still-common nomenclature that distinguishes hot and cool stars preserves an historical artifact. It is consequently worth a moment's reflection on the origin of the classification scheme used now for stellar spectra as a case study. In the first rush of ideas about stellar evolution, Lockyer and later Russell suggested that stars evolve along the main sequence from the hotter to cooler end. The meteoritic hypothesis (Lockyer) posited that the increased spectral complexity toward cooler temperatures was caused by continued accretion of metal-rich material over time, while the contraction hypothesis (Russell) attributed the distribution of colors and luminosities in the HR (Hertzsprung-Russell) diagram to a cooling sequence. Although different in detail, these ideas have the same basic trend of evolution — toward cooler, more compact stars with progressively more complex spectra. As a result, hot stars were initially called "early types" and those cooler than the Sun were called "late type." The names stuck, so now stars hotter than roughly class F are referred to as early-type and the cooler ones are still called late-type stars.[1]

The basis of the Morgan-Keenan or *MK* types is the relative visibility of specific absorption lines in spectra and their ordering. It is independent

[1] The basis of the distinction in now known to be wrong, the main sequence is a mass ordered sequence of hydrostatic stars undergoing core hydrogen processing, and the complexity of the spectra is an ionization effect.

TABLE 1. PHYSICAL CHARACTERISTICS OF SOME TYPICAL STARS

Star	Spectral Class	Density in Terms	Temperature in °K of Water	Referred to as Sun Unity

[a]These stars are estimated to be within 32.6 light years of the Sun.
NOTE: The distance measurements are based on the Hipparcos Catalogue and other astrometric data. In the event of a spectroscopic binary, the combined spectral type and absolute magnitude are listed in *italics*.

[a]These stars are estimated to be more than 48.9 light years distant from the Sun.
NOTE: The distance measurements are based on the Hipparcos Catalogue and other astrometric data. In the event of a spectroscopic binary, the combined spectral type and absolute magnitude are listed in *italics*.

TABLE 7. STELLAR CLASSIFICATION

Class	Temperature	Star Color	Mass	Radius Sun = 1	Luminosity
O	30,000–60,000 K 53,540–107,540 °F	Ultraviolet-violet	60	15	1,400,000
B	10,000–30,000 K 17,540–53,540 °F	Blue	18	15	20,000
A	7,500–10,000 K 13,040–17,540 °F	White-green	3.2	2.5	80
F	6,000–7,500 K 10,340–13,040 °F	Yellow-white	1.7	1.3	6
G	5,000–6,000 K 8,540–10,340 °F	Yellow	1.1	1.1	1.2
K	3,500–5,000 K 5,840–8,540 °F	Yellow-orange	0.8	0.9	0.4
M	2,000–3,500 K 3,140–5,840 °F	Orange-red	0.3	0.4	0.04

*It should be noted that while these descriptions of stellar colors are traditional in astronomy, they really describe the light after it has been scattered by the atmosphere. The Sun is not in fact a yellow star, but has essentially the color temperature of a black body of 5780 K; this is a white with no trace of yellow which is sometimes used as a definition for standard white.

of theory, as emphasized many time by its chief practitioners.[2] The system was, however, originally motivated by some early concepts of spectrum formation. The Harvard system, which was initially based on the complexity of the spectra and drew much of its inspiration from the ideas of Lockyer (those, in particular, that connected age and metallicity with temperature) and the relative strengths of lines of specific ionization. This one-dimensional system was an ordering in temperature only, although there were indications that some stars had different linewidths (Maury used *c* to indicate such narrow lines — contrasted with broader *a* and *b* types — which was later adopted in the Mount Wilson notation for giant, where *d* dimension of "luminosity" to the original one dimensional Harvard temperature classification system, was based on two fundamental ideas. One was ionization equilibrium as was the original HD system. The other was, however, based on pressure broadening of hydrogen lines due to the Stark effect. See also **Stark Effect**.

Line ratios reflect several things about the star — its temperature and gravity through the ionization balance and particular line strengths and broadening, and composition. The majority of bright stars you see in the night sky with the naked eye have been formed comparatively recently, so composition may not play too much role. But when one looks at fainter stars, sampling a wider range of the Galaxy in space and tie because they are statistically farther away and also possibly intrinsically fainter, then the requirement of a homogeneous population breaks down. Actually, it is not clear what spectral types thus really mean, although they certainly provide some handle on the properties of the stars, because the internal dispersion of physical characteristics defining spectral morphology depends on the class. See also **Stellar Magnitude**.

The Classification Scheme

The main classifications can be easily remembered using the mnemonic "**O**h, **B**e **A** **F**ine **G**irl, **K**iss **M**e" (variant: change "girl" to "guy"), (still taught to astronomy students today), invented by Annie Jump Cannon a US astronomer whose cataloguing work was instrumental in the development of contemporary stellar classification. Working from 1915 until 1924 on what would be published as the Henry Draper Catalogue, Cannon catalogued 225,300 stars and ordered them into stellar spectra of types O, B, A, F, G, K, M. Several other variations on the mnemonic also are in use. http://www.answers.com/topic/list-of-mnemonics-for-star-classification. The common classes are normally listed from hottest to coldest. See Table 7.

The reason for the odd arrangement of letters is historical. When people first started taking spectra of stars, they noticed that stars had very different hydrogen spectral lines strengths, and so they classified stars based on the strength of the hydrogen balmer series lines from A (strongest) to Q (weakest). Other lines of neutral and ionized species then came into play (H&K lines of calcium, sodium D lines etc). Later it was found that some of the classes were actually duplicates and those classes were removed. It was only much later that it was discovered that the strength of the hydrogen line was connected with the surface temperature of the star. The basic work was done by the "girls" of Harvard College Observatory, primarily Cannon and Antonia Maury, based on the work of Williamina Fleming. These classes are further subdivided by arabic numbers (0-9). A0 denotes the hottest stars in the A class and A9 denotes the coolest ones. The sun is classified as G2.

Spectral Types

O Stars. Class O stars are very hot and very luminous, being strongly violet in color; in fact, most of their output is in the ultraviolet range. These are the rarest of all main sequence stars, constituting as little as 1/32,000th of the total. O-stars shine with a power over a million times our Sun's output. These stars have prominent ionized and neutral helium lines and only weak hydrogen lines.

Examples include: Zeta Puppis, (ζ Pup / ζ Puppis) is a star in the constellation of Puppis. It also has traditional names "Naos" (*nay'-os*, from the Greek ναύσ "ship"), as well as "Suhail Hadar," which literally means "bright star of the ground" in Arabic, and Epsilon Orionis (ε Ori / ε Orionis) is a large blue star in the constellation of Orion. It also has the traditional name "Alnilam." It is the 30th brightest star in the sky, the 4th brightest in Orion, and a blue-white supergiant.

B Stars. Class B stars are extremely luminous and blue. Their spectra have neutral helium and moderate hydrogen lines. As O and B stars are so powerful, they live for a very short time. They do not stray far from the area in which they were formed as they don't have the time. They

[2] For instance, a B2 V star will always have that classification, even though its effective temperature and surface gravity may be assigned differently by different analyses, a comment due to Nolan Walborn, whose work on the extension of the MK system to the ultraviolet is referenced.

therefore tend to cluster together in what we call OB1 associations, which are associated with giant molecular clouds. The Orion OB1 association is an entire spiral arm of our Galaxy (brighter stars make the spiral arms look brighter, there are not more stars there) and contains the entire constellation of Orion. They constituting about 0.13% of main sequence stars — rare, but much more common than those of class O.

Examples include: Rigel (pronounced /'raɪ.dl/) (β Orionis) is the brightest star in the constellation Orion and the seventh brightest star in the sky, and Spica (α Vir / α Virginis / Alpha Virginis) is the brightest star in the constellation Virgo, and one of the brightest stars in the nighttime sky.

A Stars. Class A stars are amongst the more common naked eye stars. As with all class A stars, they are white or green. Many white dwarfs are also A. They have strong hydrogen lines and also ionized metals. They comprise perhaps 0.63% of all main sequence stars.

Examples include: Vega (α Lyr / α Lyrae / Alpha Lyrae) is the brightest star in the constellation Lyra, and the fourth brightest star in the sky. It is the second brightest star in the Northern night sky, after Arcturus, and can often be seen near the zenith in the mid-northern latitudes during the Northern Hemisphere summer, and Sirius (α CMa / α Canis Majoris / Alpha Canis Majoris) is the brightest star in the nighttime sky, with a visual apparent magnitude of -1.46. It is located in the constellation Canis Major.

F Stars. Class F stars are still quite powerful but they tend to be main sequence stars. Their spectra is characterized by the weaker hydrogen lines and ionized metals, their color is white with a slight tinge of yellow. These represent 3.1% of all main sequence stars.

Examples include: Canopus (α Car / α Carinae / Alpha Carinae) is the brightest star in the southern constellation of Carina, and the second brightest star in the sky, (Table 3.) with a visual magnitude of -0.62, second only to Sirius, and Procyon (α CMi / α Canis Minoris / Alpha Canis Minoris) is the brightest star in the constellation Canis Minor and the eighth brightest star in the nighttime sky.

G Stars. Class G stars are probably the most well known if only for the reason that our Sun is of this class. They have even weaker hydrogen lines than F but along with the ionized metals, they have neutral metals. G is host to the "Yellow Evolutionary Void". Supergiant stars often swing between O or B (blue) and K or M (red). While they do this, they do not stay for long in the G classification as this is an extremely unstable place for a supergiant to be. These are about 8% of all main sequence stars.

Examples include: The Sun, and Capella (α Aur / α Aurigae / Alpha Aurigae) is the brightest star in the constellation Auriga and sixth brightest star in the sky.

K Stars. Class K are orangish stars which are slightly cooler than our Sun. Some K stars are giants and supergiants, such as Arcturus while others like Alpha Centauri B are main sequence stars. They have extremely weak hydrogen lines, if they are present at all, and mostly neutral metals. These make up some 13% of main sequence stars.

Examples include: Arcturus (α Boo / α Boötis / Alpha Boötis) is the brightest star in the constellation Boötes, and the third brightest star in the night sky, with a visual magnitude of -0.05, after Sirius and Canopus, and Aldebaran, (α Tau / α Tauri / Alpha Tauri), is the brightest star in the constellation Taurus and one of the brightest stars in the nighttime sky. Because of its location in the head of Taurus, it has historically been called the Bull's Eye.

M Stars. Class M is by far the most common class if we go by the number of stars. All our red dwarfs go in here and they are plentiful; over 78% of stars are red dwarfs, such as Proxima Centauri. M is also host to most giants and some supergiants such as Antares and Betelgeuse, as well as Mira variables. The spectrum of an M star shows lines belonging to molecules and neutral metals but hydrogen is usually absent. Titanium oxide can be strong in M stars. The red color is deceptive; it is because of the dimness of the star. When an equally hot object, a halogen lamp (3,000 K) which is white hot is put at a few kilometers distance, it appears like a red star.

Examples include: Betelgeuse (Alpha (α) Orionis) is a semiregular variable star located 427 light-years away. It is the second brightest star in the constellation Orion, and the tenth brightest star in the night sky. Although it has the Bayer designation "alpha", it is not as bright as Rigel (Beta Orionis). It is a vertex of the Winter Triangle asterism; Barnard's star is a star in the constellation Ophiuchus which is notable for having the largest proper motion ($10.3''$ per year) of any star relative to the Sun. This large proper motion was discovered by the astronomer E. E. Barnard in 1916.

Spectral Types for Rare Stars

A number of new spectral types have been taken into use for rare types of stars, as they have been discovered:

- W: Up to 70,000°K (125,540 °F) — Wolf-Rayet stars.
- L: $1,500 - 2,000$°K (2,240–3,140 °F) — Stars with masses insufficient to run the regular hydrogen fusion process (brown dwarfs). Class L stars contain lithium which is rapidly destroyed in hotter stars.
- T: 1,000°K (1,340 °F) — Cooler brown dwarfs with methane in the spectrum.
- C: Carbon stars.
  - R: Formerly a class on its own representing the carbon star equivalent of Class K stars, e.g. *S Camelopardalis*.
  - N: Formerly a class on its own representing the carbon star equivalent of Class M stars, e.g. *R Leporis*.
- S: Similar to Class M stars, but with zirconium oxide replacing the regular titanium oxide.
- D: White dwarfs, e.g. *Sirius B*.

Class W represents the superluminous Wolf-Rayet stars, being notably different since they have mostly helium instead of hydrogen. They are thought to be dying supergiants with their hydrogen layer blown away by hot stellar winds caused by their high temperatures, thereby directly exposing their hot helium shell. Class W is subdivided into subclasses WN and WC according to the dominance of nitrogen or carbon in their spectra (and outer layers).

Class L stars get their designation from the lithium present in their core. Any lithium would be destroyed in ongoing nuclear reactions in regular stars, which indicates that these objects have no ongoing fusion processes. They are a very dark red in color and brightest in infrared. Their gas is cool enough to allow metal hydrides and alkali metals to be prominent in the spectrum.

Class T stars are very young and low density stars often found in the interstellar clouds they were born in. These are stars barely big enough to be stars and others that are substellar, being of the brown dwarf variety. They are black, emitting little or no visible light but being strongest in infrared. Their surface temperature is a stark contrast to the fifty thousand kelvins or more for Class O stars, being merely up to 1,000°K (1,340 °F). Complex molecules can form, evidenced by the strong methane lines in their spectra.

Class T and L could be more common than all the other classes combined, if recent research is accurate. From studying the number of proplyds (protoplanetary discs, clumps of gas in nebulae from which stars and solar systems are formed) then the number of stars in the galaxy should be several orders of magnitude higher than what we know about. It is theorized that these proplyds are in a race with each other. The first one to form will become a proto-star, which are very violent objects and will disrupt other propylids in the vicinity, stripping them of their gas. The victim propylids will then probably go on to become main sequence stars or brown dwarf stars of the L and T classes, but quite invisible to us. Since they live so long (no star below 0.8 solar masses has ever died in the history of the galaxy) then these smaller stars will accumulate over time.

Class R and N stars are carbon stars (red giants thought to reach the end of their life) which run parallel to the normal classification system from roughly mid G to late M. These have more recently been remapped into a unified carbon classifier C, with N0 starting at roughly C_6.

Class S stars have ZrO lines rather than TiO, and are in between the Class M stars and the carbon stars. Class S stars have their carbon and oxygen abundances almost exactly equal, and both elements are locked up almost entirely in CO molecules. For stars cool enough for CO to form that molecule tends to "eat up" all of whichever element is less abundant, resulting in "leftover oxygen" on the normal main sequence, "leftover carbon" on the C sequence, and "leftover nothing" on the S sequence.

In reality the relation between these stars and the traditional main sequence suggest a rather large continuum of carbon abundance and if

fully explored would add another dimension to the stellar classification system.

Finally, the classes P and Q are occasionally used for certain non-stellar objects. Type P objects are planetary nebulae and type Q objects are novae.

White Dwarf Classifications

The class D is sometimes used for white dwarfs, the state most stars end their life in. Class D is further divided into classes DA, DB, DC, DO, DZ, and DQ. Note the letters are not related to the letters used in the classification of true stars, but instead indicate the composition of the white dwarf's outer layer or "atmosphere".

The white dwarf classes are as follows:

- DA: a hydrogen-rich "atmosphere" or outer layer, indicated by strong Balmer hydrogen spectral lines.
- DB: a helium-rich "atmosphere" or outer layer, indicated by neutral helium spectral lines.
- DQ: a carbon-rich "atmosphere" or outer layer, indicated by atomic or molecular carbon lines.
- DZ: a 'metal'-rich "atmosphere" or outer layer, indicated by calcium II lines.
- DC: no strong spectral lines indicating one of the above categories.
- DX: spectral lines are insufficiently clear to classify into one of the above categories.

All class D stars use the same sequence from 1 to 9, with 1 indicating a temperature above 37,500 K (67,040 °F) and 9 indicating a temperature below 5,500 K (9,440 °F).

Yerkes Spectral Classification

The "Yerkes spectral classification," also called the "MKK" system from the authors' initials, is a system of stellar spectral classification introduced in 1943 by William Wilson Morgan, Phillip C. Keenan, and Edith Kellman of Yerkes Observatory.

This classification is based on spectral lines sensitive to stellar surface gravity which is related to luminosity, as opposed to the Harvard classification which is based on surface temperature.

Since the radius of a giant star is much larger than a dwarf star while their masses are roughly comparable, the gravity and thus the gas density and pressure on the surface of a giant star are much lower than for a dwarf.

These differences manifest themselves in the form of *luminosity effects* which affect both the width and the intensity of spectral lines which can then be measured. Denser stars with higher surface gravity will exhibit greater *pressure broadening* of spectral lines.

A number of different luminosity classes are distinguished:

- 0 hypergiants (later addition);
- Ia most luminous supergiants;
- Ib less luminous supergiants;
- II bright giants;
- III normal giants;
- IV subgiants;
- V main sequence stars (dwarfs);
- VI subdwarfs (rarely used);
- VII white dwarfs (rarely used)

Marginal cases are allowed; for instance a star classified as Ia-0 would be a very luminous supergiant, verging on hypergiant.

UBV System

The UBV system, also called the Johnson system, is a photometric system for classifying stars according to their magnitude. The letters U, B, and V stand for ultraviolet, blue, and visual magnitudes, which are measured for a star in order to classify it in the UBV system. The choice of colors on the blue end of the spectrum is because of the bias that photographic film has for those colors. It was introduced in the 1950s by American astronomers Harold Lester Johnson and William Wilson Morgan.

Naming of Stars

A number of stars has been assigned proper names historically from various cultures, especially the brighter stars. Many of these names are still used today.

As individual naming is not exactly practical for a large number of stars, a more schematical nomenclature is needed. Several of these schemes have been introduced, and a number of them is still in use today.

The earliest naming system which is still popular was introduced by Johann Bayer in his *Uranometria* star catalog of 1603. As many predecessors and successors, he used constellations to identify stars within them. To distinguish the stars in each constellation, he labelled them with Greek letters, and approximately in the order of their (apparent) brightness, so that the brightest star was labelled Alpha, the second brightest Beta, an so on. For example, the brightest star in Cygnus the Swan is Alpha Cygni (note the use of the genitive of the Latin constellation name) which is also called Deneb, or the brightest star in Leo the Lion is Alpha Leonis, also called Regulus. Misestimates and other irregularities are the reasons why this is only an approximate scheme: For example, the brightest star in Gemini the Twins is Beta Geminorum (Pollux) while Alpha Geminorum (Castor) is only the second brightest star of the constellation. Unfortunately, the Greek alphabet has only 24 letters, and many constellations contain many more stars, even if the naming is restricted to those visible to the naked eye; Bayer employed low case letters a .. z and then upper case letters A .. Z for the stars number 25 to 50 and 51 to 76 in each constellation, respectively.

Another popular naming scheme is the use of the so-called Flamsteed numbers, which were introduced in the catalog *Historia Coelestis Britannica* which had been compiled by John Flamsteed (1646-1719), and was published unauthorized in 1712 after editing by Edmond Halley (1656-1742); Flamsteed's own corrected publication of this work did not contain the numbers, btw. In this scheme, stars of each constellation are numbered in the order of their Right Ascension (for example: 61 Cygni). Because the numbers were taken from the preliminary, error-rich version of the catalog, there are many deviations from the desired order in the numbers.

The only body which has been recognized by the scientific community as having competence to name stars or other celestial bodies is the International Astronomical Union (IAU) www.iau.org/. See also IAU Recommendations for Nomenclature; http://cdsweb.u-strasbg.fr/iau-spec.html. Many of the star names in use today were inherited from the time before the IAU existed. Special names are assigned for new novae and supernovae. Novae are named according to their constellation together with the year of their occurrence (e.g., "Nova Cygni 1975"), and later given a variable star designation ("Nova Cygni 1975" is also "V 1500 Cygni"). Supernovae are named for their year of occurrence and an uppercase letter, e.g., "SN 1987A". If the alphabet is exhausted, double lower case naming is used: [Year] aa .. az, ba .. bz, etc; e.g., "SN 1997bs". Most stars, however, have no name and are referred to, if at all, by means of catalogue numbers.

Proper Names. Many of the brighter, or otherwise interesting, stars have proper names. Most of these derive from Arabic, but there are also a few Latin ones, such as Polaris (Polaris: The brightest star in Ursa Minor; at the end of the handle of the little dipper; the northern axis of the earth points toward it), and even a few English ones, such as Barnard's Star. See Table 8.

There are a number of problems with these names however:

- Spellings are often not standardized (Almach or Almaach or Almak or Alamak)
- Many stars have more than one name of roughly equal popularity (Mirfak or Algenib or Alcheb; Regor or Suhail al Muhlif; Alkaid or Benetnasch; Gemma or Alphecca; Alpheratz and Sirrah)
- Because of imprecision in old star catalogs, it may not be clear exactly which star within a constellation a particular name corresponds to (eg, Alniyat, Chara).
- Some stars in entirely different constellations may have the same name: Algenib in Perseus and Algenib in Pegasus; Gienah in Cygnus and Gienah in Corvus, Alnair in Grus and Alnair in Centaurus.

In practice, the traditional names are only universally used for the very brightest stars (Sirius, Arcturus, Vega, etc) and for a small number of

TABLE 8. TRADITIONAL STAR NAMES

Proper Name	Designation
Acamar	Theta Eridani
Achernar	Alpha Eridani
Achird	Eta Cassiopeiae
Acrab	Beta Scorpii
Acrux	Alpha Crucis
Acubens	Alpha Cancri
Adhafera	Zeta Leonis
Adhara	Epsilon Canis Majoris
Ain	Epsilon Tauri
Al Kalb al Rai	Rho2 Cephei
Al Minliar al Asad	Kappa Leonis
Al Giedi	Alpha Capricorni
Al Nair	Alpha Gruis
Al Niyat	Sigma Scorpii
Aladfar	Eta Lyrae
Alamak	Gamma Andromedae
Alathfar	Mu Lyrae
Albaldah	Pi Sagittarii
Albali	Epsilon Aquarii
Albireo	Beta Cygni
Alchiba	Alpha Corvi
Alcor	80 Ursae Majoris
Alcyone	Eta Tauri
Aldebaran	Alpha Tauri
Alderamin	Alpha Cephei
Aldhafera	Zeta Leonis
Aldhanab	Gamma Gruis
Aldhibah	Zeta Draconis
Alfecca Meridiana	Alpha Coronae Australis
Alfirk	Beta Cephei
Algedi	Alpha Capricorni
Algenib	Alpha Persei and Gamma Pegasi
Algieba	Gamma Leonis
Algol	Beta Persei
Algorab	Delta Corvi
Alhena	Gamma Geminorum
Alioth	Epsilon Ursae Majoris
Alkaid	Eta Ursae Majoris
Alkalurops	Mu Bootis
Al Kaphrah	Chi Ursae Maioris
Alkes	Alpha Crateris
Alkurah	Xi Cephei
Almach	Gamma Andromedae
Alnilam	Epsilon Orionis
Alnitak	Zeta Orionis
Alniyat	Tau Scorpii
Alpha Centauri	
Alphard	
Alpheratz	Alpha Andromedae
Alrakis	Mu Draconis
Alrischa	Alpha Piscium
Alsafi	Sigma Draconis
Alschain	Beta Aquilae
Alshat	Nu Capricorni
Alsciaukat	31 Lyncis
Altarf	Beta Cancri
Altair	Alpha Aquilae
Altais	Delta Draconis
Alterf	Lambda Leonis
Al Thalimain	Lambda Aquilae
Aludra	Eta Canis Majoris
Alula Australis	Xi Ursae Majoris
Alula Borealis	Nu Ursae Majoris
Alwaid	Beta Draconis
Alya	Theta Serpentis
Alzir	Xi Geminorum
Ancha	Theta Aquarii
Angetenar	Tau2 Eridani

Proper Name	Designation
Ankaa	Alpha Phoenicis
Antares	Alpha Scorpii
Arcturus	Alpha Bootis
Alphecca	Alpha Coronae Borealis
Arkab Prior	Beta 1 Sagittarii
Arkab Posterior	Beta 2 Sagittarii
Arm	Eta Capricorni
Arneb	Alpha Leporis
Arrakis	Mu Draconis
Arkab	Beta Sagittarii
Ascella	Zeta Sagittarii
Asellus Australis	Delta Cancri
Asellus Borealis	Gamma Cancri
Asellus Primus	Theta Bootis
Asellus Secundus	Iota Bootis
Asellus Tertius	Kappa Bootis
Askella	Zeta Sagittarii
Aspidiske	Iota Carinae
Asterion	Beta Canum Venaticorum
Asterope	21 Tauri
Atik	Omicron Persei
Atlas	27 Tauri
Atria	Alpha Trianguli Australis
Avior	Epsilon Carinae
Azaleh	Zeta Aurigae
Azelfafage	Pi1 Cygni
Azha	Eta Eridani
Azmidiske	Xi Puppis
	B
Baham	Theta Pegasi
Baten Kaitos	Zeta Ceti
Becrux	Mimosa, Beta Crucis
Beid	Omicron1 Eridani
Bellatrix	Gamma Orionis
Benetnasch	Eta Ursae Majoris
Betelgeuse	Alpha Orionis
Betria	Beta Trianguli Australis
Bharani (star)	41 Arietis
Botein	Delta Arietis
Brachium	Sigma Librae
Bunda	Xi Aquarii
	C
Canopus	Alpha Carinae
Caph	Beta Cassiopeiae
Capella	Alpha Aurigae
Caph	Beta Cassiopeiae
Castor	Alpha Geminorum
Cebalrai	Beta Ophiuchi
Celaeno	16 Tauri
Chara	Alpha Canum Venaticorum or sometimes Beta
Cheleb	Beta Ophiuchi
Chertan	Theta Leonis
Chort	Theta Leonis
Chow	Beta Serpentis
Cursa	Beta Eridani
	D
Dabih	Beta Capricorni
Decrux	Delta Crucis
Deneb	Alpha Cygni
Deneb Algedi	Delta Capricorni
Deneb Dulfim	Epsilon Delphini
Deneb el Okab	Zeta Aquilae
Denebola	Beta Leonis
Deneb Kaitos	Beta Ceti
Deneb Kaitos Schemali	Iota Ceti
Dheneb	Eta Ceti
Diadem	Alpha Comae Berenices

Zaniah	Eta Virginis
Zaurak	Gamma Eridani
Zavijava	Beta Virginis
Zuben-el-Akrab	Gamma Librae
Zuben-el-Akribi	Delta Librae
Zubenelgenubi	Alpha Librae
Zuben-el-schemali or Zubeneschamali	Beta Librae

slightly less bright but "interesting" stars (Algol, Polaris, Mira, etc). For other naked eye stars, the Bayer designation is often preferred.

In addition to the traditional names, a small number of stars that are "interesting" can have modern English names. For instance Barnard's star has the highest known proper motion of any star and is thus notable even though it is far too faint to be seen with the naked eye.

STAR CATALOGUES. Any listing of stars, usually arranged in order of increasing right ascension. Originally, star catalogues were intended merely for the purpose of providing accurate positions of the stars for use by navigators, but many modern catalogues are designed to provide particular characteristics of the stars.

The world's first star catalogue was made by Gan De, a Chinese astronomer in 4th century B.C.

Although no longer in serious use, mention should be made of Ptolemy's star catalogue issued about 137 A.D. as part of his *Almagest*, which lists 1,022 stars visible from Alexandria. Ptolemy's catalogue was based almost entirely on an earlier one by Hipparchus from the 2nd century B.C. [Newton 1977 Rawlins 1982]. An even earlier star catalogue was that of Timocharis of Alexandria, which was written about 300 B.C. and later used by Hipparchus. The Almagest catalogue was the standard one used throughout the Middle East and Latin West to the end of the 15th Century. Tycho Brahe's catalogue of 1580 marks the dawn of the modern era of star catalogues, and since that time, many others have appeared. Probably the most comprehensive catalogue issued is the Bonner Durchmusterung, which first appeared about 1850, together with the various extensions that have since been published. During the last half of the nineteenth century the Astronomische Gesellschaft sponsored a catalogue of accurate positions of the majority of the stars contained in the Bonner Durchmusterung.

With application of photography to astronomy, several projects have been launched for obtaining comprehensive star catalogues. By far the most ambitious of all of the photographic catalogues is the so-called *Astrographic Catalogue*, which was started as a cooperative effort of 18 observatories in 1887. It is not entirely completed. However, there has been completed a photographic survey of the sky known as the Sky Atlas, the most recent such atlas being the Palomar Sky Atlas, and European Southern Observatory Atlas.

As part of the Space Telescope project, a general catalogue of potential guide stars is being prepared. This will also serve as a permanent archival data set for future magnitude and positional studies. The European Space Agency astrometric satellite (*HIPPARCHOS*) was designed to observe positions and motions of several hundred thousand stars over the next decade. See also **Hipparchos Mission**.

Not all catalogues are restricted to positional and magnitude data. The largest spectroscopic catalogue is the Henry Draper project, first completed in the 1920s and currently being revised. The document contains information on the spectral characteristics of over 200,000 stars.

Two systems introduced in historical catalogues remain in use to the present day. The first system comes from Bayer's *Uranometria* and is for bright stars. These are given a Greek letter followed by the genitive case of the constellation in which they are located; examples are Alpha Centauri or Gamma Cygni. The major problem with Bayer's naming system was the number of letters in the Greek alphabet (24). It was easy to run out of letters before running out of stars needing names, particularly for large constellations such as Argo Navis. Bayer extended his lists up to 67 stars by using lower-case Roman letters ("a" through "z") then upper-case ones ("A" through "Q"). Few of those designations have survived. It is worth mentioning, however, as it served as the starting point for variable star designations, which start with "R" through "Z", then "RR", "RS", "RT"…"RZ", "SS", "ST"…"ZZ" and beyond. See the article for more information. See also **Bayer Designation**.

The second system comes from John Flamsteed's *Historia coelestis Britannica*. It kept the genitive-of-the-constellation rule for the back end of his catalog names, but used numbers instead of the Greek alphabet for the front half. Examples include 61 Cygni and 47 Ursae Majoris. See also **Flamsteed Designation**.

Bayer and Flamsteed covered only a few thousand stars between them. In theory, full-sky catalogues try to list every star in the sky. There are, however, literally hundreds of millions, even billions of stars resolvable by telescopes, so this is an impossible goal; these kind of catalogues generally try to get every star brighter than a given magnitude. See also **Absolute Magnitude (Symbol M)**; **Apparent Magnitude**; and **Stellar Magnitude**.

Early Full-Sky Catalogues

The following is a list of early well known catalogs for astronomical data.

Henry Draper Catalogue. The Henry Draper Catalogue was published in the period 1918–1924. It covers the whole sky down to about ninth or tenth magnitude, and is notable as the first large-scale attempt to catalogue spectral types of stars. The catalogue was compiled by Annie Jump Cannon and her co-workers at Harvard College Observatory under the supervision of Edward Pickering, and was named in honor of Henry Draper, whose widow donated the money required to finance it.

HD numbers are widely used today for stars which have no Bayer or Flamsteed designation. Stars numbered 1–225300 are from the original catalogue and are numbered in order of right ascension for the 1900.0 epoch. Stars in the range 225301–359083 are from the 1949 extension of the catalogue. The notation HDE (Henry Draper catalogue Extension) can be used for stars in this extension, but they are usually denoted HD as the numbering ensures that there can be no ambiguity.

BD/CD/CPD Catalogues. The *Bonner Durchmusterung* (*german*: Bonn sampling) and follow-ups were the most complete of the pre-photographic star catalogues.

The *Bonner Durchmusterung* itself was published by Friedrich Wilhelm Argelander, Adalbert Krüger, and Eduard Schönfeld between 1852 and 1859. It covered 320,000 stars in epoch 1855.0.

As it covered only the northern sky and some of the south (being compiled from the Bonn observatory), this was then supplemented by the *Südliche Durchmusterung* (SD), which covers stars between declinations −1 and −23 degrees (1886, 120,000 stars). It was further supplemented by the *Cordoba Durchmusterung* (580,000 stars), which began to be compiled at Córdoba, Argentina in 1892 under the initiative of John M. Thome and covers declinations −22 to −90. Lastly, the *Cape Photographic Durchmusterung* catalogue (450,000 stars, 1896). Compiled at the Cape, South Africa covers declinations −18 to −90.

Astronomers preferentially use the HD designation of a star, as that catalogue also gives spectroscopic information, but as the Durchmusterungs cover more stars they occasionally fall back on the older designations when dealing with one not found in Draper. Unfortunately, a lot of catalogues cross-reference the Durchmusterungs without specifying which one is used in the zones of overlap, so some confusion often remains.

Star names from these catalogues include the initials of which of the four catalogues they are from (though the *Southern* follows the example of the *Bonner* and uses BD; CPD is often shortened to CP), followed by the angle of declination of the star (rounded down, and thus ranging from +00 to +89 and −00 to −89), followed by an arbitrary number as there are always thousands of stars at each angle. Examples include BD + 50°1725 or CD−45°13677. See also **Bonner Durchmusterung**.

Full-Sky Catalogues

The following is a list of recommended, individual catalogs for astrometric applications.

Astrographic Catalogue. The *Catalogue astrographique* (Astrographic Catalogue) was part of the international *Carte du Ciel* programme designed to photograph and measure the positions of all stars brighter than magnitude 11.0. In total, over 4.6 million stars were observed, many as faint as 13th magnitude. This project was started in the late 1800s. The observations were made between 1891 and 1950. To observe the entire celestial sphere without burdening only a handful of institutions, the sky was divided among 20 observatories, by declination zones. Each observatory exposed

and measured the plates of its zone, using a standardized telescope so each plate photographed had a similar scale of approximately 60 arcsecs/mm. The U.S. Naval Observatory took over custody of the catalogue, now in its 2000.2 edition. http://ad.usno.navy.mil/proj/AC/.

U.S. Naval Observatory. The USNO-B1.0 is an all-sky catalog created by researchers at the U.S. Naval Observatory that presents positions, proper motions, magnitudes in various optical passbands, and star/galaxy estimators for 1,042,618,261 objects derived from 3,643,201,733 separate observations. The data were obtained from scans of 7,435 Schmidt plates taken for the various sky surveys during the last 50 years. USNO-B1.0 is believed to provide all-sky coverage, completeness down to $V = 21$, 0.2 arcsecond astrometric accuracy at J2000.0, 0.3 magnitude photometric accuracy in up to five colors, and 85% accuracy for distinguishing stars from non-stellar objects.

Hipparcos Catalogue. This catalog contains 118,218 stars that were observed by the European Space Agency's Hipparcos Satellite, operational from late 1989 to 1993. It is complete to $V = 7.3$. The positional accuracies of 1 to 3 mas at epoch 1991.25 are unsurpassed in the optical. Proper motion accuracies, of around 1 to 2 mas/yr, remain state of the art. Thus typical positional errors at a 2005 epoch are around 15 mas. By international agreement, the Hipparcos catalog is the standard reference catalog for optical astrometry, representing the ICRF in the optical wavelengths. However, in 1999 this agreement was amended to exclude approximately 18,000 stars having flags in column 59, the so-called "problem" and double stars. Hipparcos also contains broad band visual photometric data including variability information. For the brighter stars, this is in the 1 to 2 millimagnitude range. Two color photometry from the Tycho experiment (also flown on the Hipparcos satellite) is also published and is estimated to be good to better than 0.1 magnitudes. The catalog is extensively documented. The Hipparcos Catalog Data is purely based on observations performed in space, except for the global orientation of its reference frame which was adjusted to the existing system by a variety of mainly ground-based techniques.

Tycho-2 Catalogue. This catalog is the result of a joint collaboration between (primarily) the Copenhagen University Observatory (CUO) and the USNO. CUO re-analyzed the Tycho data from the Hipparcos satellite, which led to better positions for the Tycho-1 stars, as well as extending the number of stars from 1 million to 2.5 million. The USNO was responsible for computing the proper motions, which was done by combining over 140 astrometric catalogs. The result is a global reference catalog that is 99% complete to $V = 11.0$ and 95% complete at $V = 11.5$. Positional accuracies range from about 10 to 100 mas, depending on magnitude. Proper motion accuracies are from 1 to 3 mas. Two color photometry from the Tycho experiment is published, as well. This catalog, along with documentation, is available by contacting the USNO (nz@usno.navy.mil). The Tycho-2 Catalogue is based on a mix of 1991 space-based data combined with early epoch ground-based astrometry.

UCAC2 (USNO CCD Astrograph Catalogue). The UCAC2 (2^{nd} release) is a preliminary catalog of stars covering 86% of the sky, from the South Celestial Pole to a ragged Northern boundary between about +40 and +50 degrees declination. It has 48 million stars which are primarily in the in the $R = 8.0$ to 16.0 magnitude range. Positions are based on recent observations taken at Cerro Tololo, Chile and Flagstaff, Arizona, using the USNO 8-inch astrograph. Proper motions for stars brighter than about 12.5 were derived in the same way as for the Tycho-2 stars including Hipparcos and Tycho data. Fainter stars utilized the positions in the "Yellow Sky" catalog, based on measures of the Lick Northern Proper Motion (NPM) and Yale/San Juan Southern Proper Motion (SPM) plates. Positional accuracies are 20 to 70 mas, dependent primarily on magnitude. Proper motion errors are 1 to 7 mas/yr, also magnitude dependent. UCAC2 is about 85% complete in the area covered. All "problem" stars, like blended images or extended galaxies were excluded from this release. Observed photometry is one color and should be used for identification purposes only; however, 2MASS near IR photometry and cross reference information are included. This catalog is available by contacting USNO. See also nz@usno.navy.mil; and http://ad.usno.navy.mil/uc/ac.html.

UCAC2 Bright Star Supplement. The UCAC2 Bright Star Supplement, UCAC2 BSS, is meant to be used with the Second U.S. Naval Observatory CCD Astrograph Catalog (UCAC2) to fill in the missing bright stars and not-yet published northern regions of the UCAC2. In total 430,000 stars, mostly from the region north of +40 degrees declination, make up this supplementary data set. All stars were extracted from either the Hipparcos Catalogue or Tycho-2 Catalogue. 2MASS photometry and cross-reference data are included. See also http://ad.usno.navy.mil/ucac/.

UCAC Final (USNO CCD Astrograph Catalogue. The UCAC final will be the culmination of the UCAC project, described above and below. It is expected that 80 million stars from V 7.5 to 16.5 covering the entire sky will be included. Errors in positions will be magnitude dependent and range from about 15 to 70 mas. Proper motion errors will be in the 1 to 5 mas/yr range.

Star Catalogues Superseded

The following is a list of widely used or well known catalogs which now are outdated for most applications.

FK5 Part I (Fifth Fundamental Catalog — The Basic Fundamental Stars). Status: Effectively replaced by Hipparcos. This catalog contains the same 1,535 stars as its predecessor, the FK4, but with improved zero points, more internal consistency and smaller individual errors in the stars' positions and motions. This part of the FK5 defined the FK5, J2000.0 system. The average density, however, is only one star per 27 square degrees. The errors quoted in the catalog indicate that on the average the errors at 2000 should be near 0.05 second of arc; however, current observations indicate that the errors may be as great as 0.10 second of arc, especially in the Southern Hemisphere. Results also show that there are systematic errors of 0.10 and more in parts of the sky, especially south of −50 degrees.

FK5 Part II (Fifth Fundamental Catalog — The FK5 Extension). Status: Effectively replaced by Hipparcos. This part of the FK5 was created for two reasons: First, in addition to the low density, Part I does not have a uniform distribution of stars. Second, the average magnitude in Part I is 4.8 and there are very few stars fainter than 6th magnitude. The USNO collaborated with the Astronomisches Rechen-Institut (Heidelberg) to produce this catalog of 3,117 stars. Thus, the complete FK5 catalogue has an average density of one star every 8.9 degrees. Great care was taken to ensure an even distribution over the sky and in both magnitude (to 9th) and spectral type. The positions and motions were compiled differentially on FK4 and transformed to the FK5, J2000.0 system. These stars represent the FK5 system sufficiently well to be part of the FK5 catalog. They have an average accuracy of 0.15 second of arc at 2000.

IRS (International Reference Stars). Status: Effectively replaced by Hipparcos. The IRS comprises a whole-sky catalog that, by international agreement, was the standard reference for reductions over limited areas. (Currently, the internationally agreed standard reference is the Hipparcos Catalogue). The list was formed by combining the AGK3 R in the north with the SRS in the south. The catalog was compiled at the USNO by combining 124 meridian circle catalogs and resulted in positions accurate to 0.22 second of arc for 36,027 stars (about one star every 1.1 square degrees), mostly in the 7th to 9th magnitude range. This extends the FK5 system to a much higher density. The positions and motions of 2,100 of the FK5 Extension stars come directly from the IRS. The catalogue is available referred to both FK5, J2000.0 and to FK4, B1950.0.

Smithsonian Astrophysical Observatory Star Catalogue. Status: Effectively replaced by Tycho-2. The SAO catalogue was compiled from various previous astrometric catalogues, and contains only the stars to about ninth magnitude for which accurate proper motions were known. There is considerable over lap with the Henry Draper catalogue, but any star lacking motion data is omitted. The epoch for the position measurements in the latest edition is J2000.0. See also **Epoch (Astronomy)**. The SAO catalogue contains this major piece of information not in Draper, the proper motion of the stars, so it is often used when that fact is of importance. The cross-references with the Draper and Durchmusterung catalogue numbers in the latest edition are also useful.

Names in the SAO catalogue start with the letters SAO, followed by a number. The numbers are assigned following 18 ten-degree bands in the sky, with stars sorted by right ascension within each band.

For some time there has been a general need for a replacement to the Smithsonian Astrophysical Observatory Star Catalog (SAOC), and

therefore the USNO compiled the Astrographic Catalog Reference Stars already discussed. This work was completed in 1991 and incorporated all suitable star catalogs available at the time. Some 1,700,000 star positions from 170 meridian circle and photographic catalogs were combined to produce 320,211 positions and proper motions. This gives an average density of 7.9 stars per square degree down to magnitude 10.5, and the average positional error is 0.23 second of arc at 2000. Like the IRS, the positions and motions are referred to both FK4, B1950 and to FK5, J2000.0.

The observational histories of some of the stars are not as good as others. Part I contains the stars with the better histories and generally more accurate positions and motions. Part II consists of stars with proper motions derived from only two positions or with high mean errors.

PPM (Catalogue of Positions and Proper Motions). Status: Effectively replaced by Tycho-2. The PPM catalog was compiled at the Astronomisches Rechen Institut in Germany and contains approximately the same stars as the ACRS north of -2.5 degrees, but more south of there due to the inclusion of a recent southern observing program. The catalog has 181,731 stars (8.6 per square degree) in the northern portion and 197,179 (9.7 per square degree) in the southern, for an overall density of 9.2 stars per square degree. The positions and proper motions are given for FK5, J2000.0 only. The northern and southern parts of the PPM were compiled separately and, thus, there may be a discontinuity at the -2.5 degree line. The formal errors quoted in the catalog give an estimated accuracy of 0.30 second of arc at 2000 for the northern half and 0.16 second of arc for the southern. Since both the ACRS and the PPM are based on the IRS, it is recommended that, for now, the ACRS be used north of -2 degrees and that the PPM be used south of there.

Tycho-1 Catalogue. Status: Effectively replaced by Tycho-2. This one million star catalog contains positional and photometric data from the "star mapper" flown on the Hipparcos satellite. The positional accuracies are 30 to 50 mas at mean epoch of 1991.25. However, the proper motion errors are quite large, at 20-30 mas/yr, making conversions to other epochs not recommended. The ACT reference catalog, compiled using positions from Tycho-1 and the Astrographic Catalogue (see description below), improved the proper motions ten-fold. Tycho-1 also contains two-color photometry (blue and visual) for most of its stars.

ACT Reference Catalogue. Status: Effectively replaced by Tycho-2. The ACT Reference Catalog was compiled at USNO for the express goal of improving the Tycho-1 proper motions. (Note that this is very similar to the Tycho Reference Catalogue, described below). To do this, data from the century-old Astrographic Catalogue was combined with the Tycho-1 positions to determine proper motions for 988,758 stars with about a 100 year base-line. Reductions of the Astrographic Catalogue data were made at USNO, independently of those used in the TRC. Photometry from Tycho-1 is included, as are cross-references with Tycho-1 and Hipparcos.

Tycho Reference Catalogue, TRC. Status: Effectively replaced by Tycho-2. The Tycho Reference Catalogue, TRC, was compiled to improve the proper motions of the Tycho-1 catalog. (Note that this is very similar to the ACT Reference Catalog, described above). TRC contains 990,182 stars whose proper motions are the result of combining the Tycho observations with those found in the Astrographic Catalogue. Reductions of the Astrographic Catalogue data were made in the former Soviet Union, independently of those used in the ACT Reference Catalog. Photometry from Tycho-1 is included, as are cross-references with Tycho-1, Hipparcos and the Henry Draper Catalog.

UCAC1 Catalogue (USNO CCD Astrograph Catalogue, 1st release). Status: Superseded by UCAC2. The UCAC1 is a preliminary catalog containing 27 million stars in most of the Southern Hemisphere in the R = 8.0 to 16.0 magnitude range. Positions are based on recent observations taken at Cerro Tololo, Chile using the USNO 8-inch astrograph. Proper motions for stars brighter than about 12.5 were derived in the same way as the Tycho-2 were. Fainter stars utilized the positions in the USNO A2.0 for proper motion determination. Positional accuracies are 20 to 70 mas, dependent primarily on magnitude. Proper motion errors are 1 to 12 mas/yr, also magnitude dependent. Photometry is one color and should be used for identification purposes only. This catalog is available by contacting USNO (ad.usno.navy.mil/star/star_cats_sec.shtml).

GSC 1.2 (Guide Star Catalogue version 1.2). Status: Effectively superseded by GSC 2.2 and USNO-B1.0. The Hubble Guide Star Catalog version 1.2 contains positions for 19 million stars down to 16th magnitude, although it is not complete to this level. No proper motions exist. It is based on plate measures made at Space Telescope Science Institute in Baltimore. Positional errors at the plate epoch are estimated to be near 500 mas.

USNO A2.0 Catalog. Status: Superseded by USNO B1-0. USNO-A2.0 contains entries for 526,230,881 stars which were detected in the digitized images of three photographic sky surveys. For the entire northern sky and the southern sky down to declinations of -30, all the photographic plates were part of the original Palomar Optical Sky Survey (POSS-I). Photographs were taken on blue- and red-sensitive emulsions. Only those stars which were detected in both colors were included in the USNO-A2.0 catalog. The rest of the southern sky was covered by the Science Research Council (SRC)-J survey and the European Southern Observatory (ESO)-R survey. Again, only stars appearing in both colors were accepted for the final catalogue. USNO-A2.0 is contained on 10 CD-ROMs. A2.0 presents right ascension and declination (J2000, epoch of the mean of the blue and red plate) and the blue and red magnitude for each star. It is estimated that the positional error at plate epoch is near 250 mas. Note that no proper motions are given.

Specialized Catalogues

Specialized catalogs make no effort to list all the stars in the sky, working instead to highlight a particular type of star, such as variables or nearby stars.

Aiken's Double Star Catalogue. Starting in 1899 Robert Grant Aiken and William J. Hussey used the Lick Observatory's 36″ refractor to survey the northern sky; yielding more than 4000 binaries in 16 years of work. Even after this survey was complete, in recent years, Paul Couteau, Wulff D. Heintz and Paul Muller re-surveyed the northern sky and located thousands of new pairs.

Washington Double Star Catalogue (WDS). The Washington Double Star Catalog maintained by the USNO is the official database of double and multiple star data for the International Astronomical Union. The WDS Catalog contains positions (ICRS), discoverer designations, epochs, position angles, separations, magnitudes, spectral types, proper motions, and, when available, Durchmusterung numbers and Notes for the components of 100,000 systems based on 650,000 means. The present WDS is a major revision of the 1984.0 and 1996.0 versions. More precise Hipparcos and Tycho magnitudes have been included where available, as have MK spectral types. A major observing effort at the USNO has increased the number of systems with accurate interferometric data, and has also reexamined many unconfirmed or long-neglected systems. Additionally, observations from Hipparcos and Tycho are included. The WDS Notes have been extensively revised to include information on orbital motion and multiplicity (including astrometric, photometric, and spectroscopic), variability, composite spectra, etc. Stars with Durchmusterung numbers have been individually compared with the SIMBAD database. Since new data are continually being added to the database, the WDS is updated on a nightly basis. Upon request, data from the catalog are supplied to users world-wide, ad.usno.navy.mil/wds.

General Catalogue of Trigonometric Stellar Parallaxes. The General Catalogue of Trigonometric Stellar Parallaxes has been prepared at the Yale University Observatory. This completely revised and enlarged two-volume edition contains 15,994 parallaxes for 8,112 stars published before the end of 1995. In this Fourth Edition, 1,722 (27%) new stars have been added to those contained in the previous edition by Jenkins (1963). The mode of the parallax accuracy for the newly added stars (0.004″ s.e.) is considerably better than in the previous editions (about 0.016″). Approximately half of the newly added stars are fainter than the Hipparcos Astrometric Satellite's magnitude limit of 13.0. Copies of the Catalogue are available from the Yale University Observatory.

Catalog of Positions for Infrared Stellar Sources (CPIRSS). The CPIRSS is the result of combining NASA's Infrared Astronomy Satellite Point Source Catalog (IRAS) with the data of the catalogs in Section I. The description of the original CPIRSS, released January 1994, can be found in the Astronomical Journal 107 1 pg 280–286. Two upgrades have been

made since the original release. In 1996, 4,022 new sources were added, bringing the total to 37,700. In 2000, better astrometry was substituted. Of the 37,700 stars, all but 105 were found in either the Hipparcos or Tycho-2 catalogs. The astrometry for these are given, as well as the observed IRAS fluxes at 12, 25, 60 and 100 microns. Computed fluxes at 2.2 microns are given for the 18,000 stars that show no evidence of excess emission in the infrared; however, 2MASS provides better 2.2 micron photometry. See also **Astrometry**.

Two-Micron All Sky Survey (2MASS). The 2MASS project released data from the entire sky in March 2003. Data fall primarily into 2 categories, point sources and extended sources. The point source catalog contains 470 million objects, mostly stars. The extended source catalog contains data on 1.6 million objects. Observations are in three photometric bands in the near infrared; J (1.25 microns), H (1.65 microns), and K_s (2.17 microns). The positions are good to about 70 mas, but do not have proper motions associated with them.

See also http://www.ipac.caltech.edu/2mass/overview/about2mass.html; and http://www.ipac.caltech.edu/2mass/index.html.

General Catalog of Variable Stars (GCVS). The GCVS was the long time standard source for these objects. However, the Hipparcos photometry superseded the accuracies that can easily be attained from the ground. However, since Hipparcos was only operational for three years, the data on the long-period and irregular variables found in the GCVS may prove more reliable. The GCVS gives star identifications and rough coordinates as well as maximum and minimum magnitudes for most stars listed. A period and epoch are given in some cases, but many of these values are derived from old sources and cannot be reliably extrapolated to the present. For currently accurate data a literature search is generally required. The notes section lists other data such as B-V colors for various parts of the light curve where these quantities have been determined.

STARCH. [CAS: 9005-25-8] Chemically, starch is a homopolymer of α-D-glucopyranoside of two distinct types. The linear polysaccharide, amylose, has a degree of polymerization on the order of several hundred glucose residues connected by alpha-D-(1 → 4)-glucosidic linkages. The branched polymer, amylopectin, has a DP (degree of polymerization) on the order of several hundred thousand glucose residues. The segments between the branched points average about 25 glucose residues linked by alpha-D-(1 → 4)-glucosidic bonds, while the branched points are linked by alpha-D-(1 → 6)-bonds. See Fig. 1.

Most cereal starches are made up of about 75% amylopectin and 25% amylose molecules. However, root starches are slightly higher in amylopectin, while waxy corn* and waxy milo starch contain almost 100% amylopectin. At the other extreme, high amylose corn starch and wrinkled pea starches contain 60–80% amylose. The molecules of amylose and amylopectin are synthesized by enzymes inside the living cell in plastids known as amyloplasts and are deposited as starch granules. These granules are microscopic in size, ranging from 3–8 micrometers in diameter for rice starch up to 100 micrometers for the larger potato starch granules. Corn starch usually falls in a range of 5–25 micrometers. An experienced observer usually can identify the genetic origin of a sample of starch by the size and shape of the granules. The granules are insoluble in cold water, but swell rapidly when heated to the gelatinization temperature range for the particular starch involved. As the granules swell, they lose

* With exception of North America, where the plant is called *corn*, other English-speaking people call it *maize*. French = *mais*; Spanish = *maiz*.

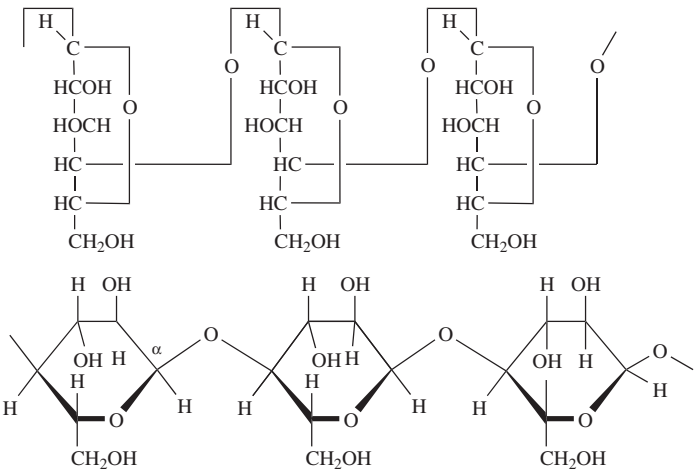

Fig. 1. A segment of the starch molecule.

their characteristic cross under polarized light and imbibe water rapidly until they are many times their original size. Upon continued heating or mechanical shear, the swollen granules begin to disintegrate and the viscosity, having reached a maximum, begins to decrease. However, there usually are some granules and some segments of granules that do not completely disperse in aqueous systems even under the most stringent conditions.

As the partially dissolved paste is cooled, the hydrated molecules and segments of granules begin to precipitate. In a dilute system (approximately 1%), the segments and molecules retrograde or precipitate. At higher concentrations, sufficient intermolecular and intersegment bonds form to fix the entire system into three-dimensional gel. The rigidity of this gel is affected by many factors, but the amylose content is perhaps the most significant. High amylose starches, when thoroughly cooked, form very rigid gels. Waxy corn or waxy milo starch paste form little, if any, gel structure when cooled.

While some wheat and potatoes are processed in the United States, over 90% of all starch is produced from corn in what is called the *corn wet milling industry*. Close to one-quarter of a billion bushels of corn, representing about 5% of the total corn crop, is converted into wet-process products. The corn refining process is illustrated in Fig. 2. Shelled corn is delivered to the wet-milling plant in boxcars containing an average of 2,000 bushels (50.8 metric tons) per car, and unloaded into a grated pit. The corn is elevated to temporary storage bins, and then to scale hoppers for weighing and sampling. The corn passes through mechanical cleaners designed to separate unwanted substances, such as pieces of cobs, sticks, and husks, as well as metal and stones. The cleaners agitate the kernels over a series of perforated metal sheets; the smaller foreign materials drop through the perforations, while a blast of air blows away chaff and dust, and electromagnets draw out nails and bits of metal. Coming out of the storage bins, the corn is given a second cleaning before going into very large "steep" tanks.

At this point, the use of water becomes an essential part of the corn refining process. The cleaned corn is typically moved into large wooden or metal tanks holding 2,000 to 6,000 bushels (50.8 to 152.4 metric tons), and soaked for 36 to 48 hours in circulating warm water 49 °C (120 °F) containing a small amount of sulfur dioxide to control fermentation and to facilitate softening. At the end of the steeping process, the steepwater contains much of the soluble protein, carbohydrates, and minerals of the corn kernel, and is drawn off as the first by-product of the process. Steepwater, unmodified and modified, is an essential nutrient for production of antibiotic drugs, vitamins, amino acids, and fermentation chemicals. See Fig. 3. It is also an effective growth supplement for animal feeds.

From the steeps, the softened kernels go through degerminating mills, which are designed not for fine grinding, but rather for tearing the soft kernels apart into coarse particles, freeing the rubbery oil-bearing germ without crushing it, and loosening the bran. The wet, macerated kernels then are sluiced into flotation tanks, called germ separators, or centrifugal hydrocyclones. The germs, lighter than the other components of the kernel,

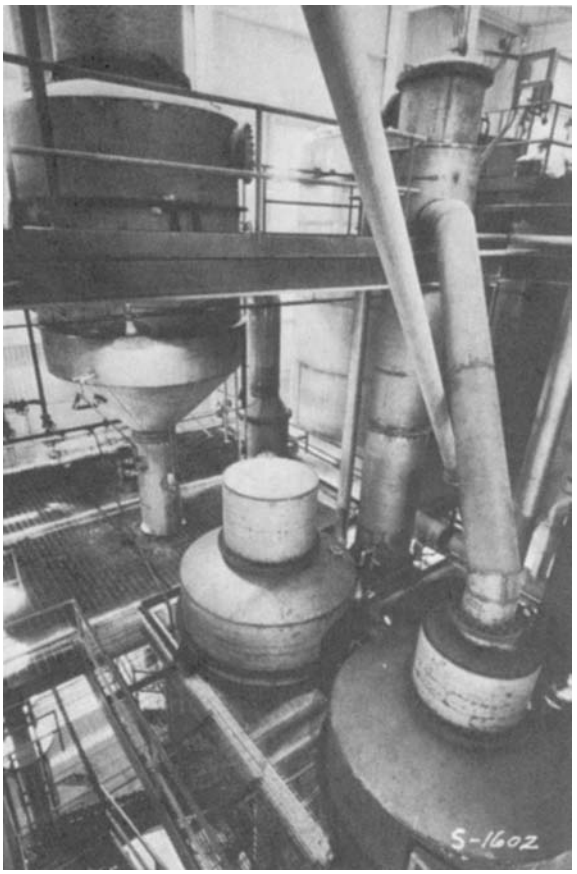

Fig. 3. Triple-effect steepwater evaporator. The third effect (forced circulation) is shown in background; second effect (falling-film, recirculating) is middle unit. The first effect vapor head is shown in foreground. (*Swenson, Whiting Corp.*)

float to the surface, and are skimmed off. By oil expellers or extractors (heat and pressure) and by means of solvents, practically all of the oil is removed as another byproduct to be settled, filtered, refined, and otherwise processed into clear, edible oil for salad dressing and frying, and "corn oil foods" or "soap stock" for soap manufacture. The residue of the germ, after oil-extraction, is ground and marketed as corn germ meal, or may become a part of corn gluten feed or meal.

The remaining mixture of starch, gluten, and bran (hull), which is finely ground, is washed through a series of screens to sieve the bran from the starch and gluten. The hull becomes part of corn gluten feed.

The remaining mixture of gluten and starch is pumped from the shakers to high speed centrifugal machines, which, because of the difference in specific gravity, separate the relatively heavier starch from the lighter gluten. After further processing, the protein-rich gluten is marketed as such, or becomes corn gluten meal, or may be mixed with steepwater, corn oil meal, and hulls to become corn gluten feed. Gluten may also be made to yield a highly versatile protein, *zein*; amino acids, such as glumatic acid, leucine, and tyrosine; and xanthophyll oil, for poultry rations.

Having been separated from the kernels, the starch is now ready for washing, drying, or further processing into numerous dry-starch products, or into dextrin, or for conversion into syrup and sugar. From a 56-pound (25 kilograms) bushel of corn, approximately 32 pounds (14.5 kilograms) of starch result, about 14.5 pounds (6.6 kilograms) of feed and feed products, about 2 pounds (0.9 kilogram) of oil, the remainder being water.

Starch Conversion. More than half of the total production of starch is converted into syrup dextrins or dextrose by acid hydrolysis and/or enzyme action or heat treatment.

Starch, mixed with water, and heated in the presence of weak hydrochloric acid, breaks down chemically by hydrolysis. If the hydrolysis or conversion of corn starch is interrupted before final conversion, a noncrystallizing corn syrup is obtained. Many varieties may be made by supplemental use of enzymes to meet specific functional requirements. The solids content is varied to suit the requirements of the users. Corn syrup is used in a wide variety of food products, including baby foods, breakfast foods, cheese spreads, chewing gum, chocolate products, confectionary, cordials, frostings and icings, peanut butter, sausage, and for numerous industrial products, including adhesives, dyes and inks, explosives, metal plating, plasticizers, polishes, textile finishes, and in leather tanning.

A process for converting starch to dextrose is shown in Fig. 4. The enzyme process shown overcomes flavor and color difficulties of the hydrochloric acid method. The enzyme is obtained by growing a mold (*Aspergillus phoenicis*, a member of the *Aspergillus niger* group). The mold yields the key glucoamylase as well as transglucosylase. The latter must be eliminated because it catalyzes the formation of undesirable glucosidic linkages. Through a special process, almost pure glucoamylase is obtained.

Purified starch slurry (30–40% solids), made from dent corn, is received in the converters from basic processing at the corn plant. A preliminary conversion using alpha-amylase enzyme or acid is carried out at 80–90 °C (176–194 °F), during which 15–25% of the starch is converted into dextrose. This thins the starch slurry, allowing easier addition of the glucoamylase enzyme. It also prevents formation of unhydrolyzable gelatinous material during the main conversion, and results in increased dextrose yields of from 3–4%. Thinning also reduces evaporation costs because starch concentrations of 30–40% can be handled compared with the 12–20% limit for the acid process. Before the main conversion, the starch-dextrose slurry is centrifuged to remove oil and protein by-products, which are processed for animal feed.

The slurry then goes to a 25,000-gallon (946-hectoliter) enzyme tank where, at pH 4.0–4.5 and 60 °C, the major reaction with the glucoamylase takes place. It is a batch operation requiring about 72 hours. When conversion is complete, the batch (97–98.5% dextrose on a dry basis) is passed through a preliminary decolorizing filter of powdered carbon and then pumped on to the first of three evaporators. The remaining operations are evaporation and crystallization, followed by centrifuging, and rotary drying for dextrose crystals; and by a remelting and filtering process for handling of outsize crystals, the resulting liquid being returned to the third effect evaporator for reprocessing.

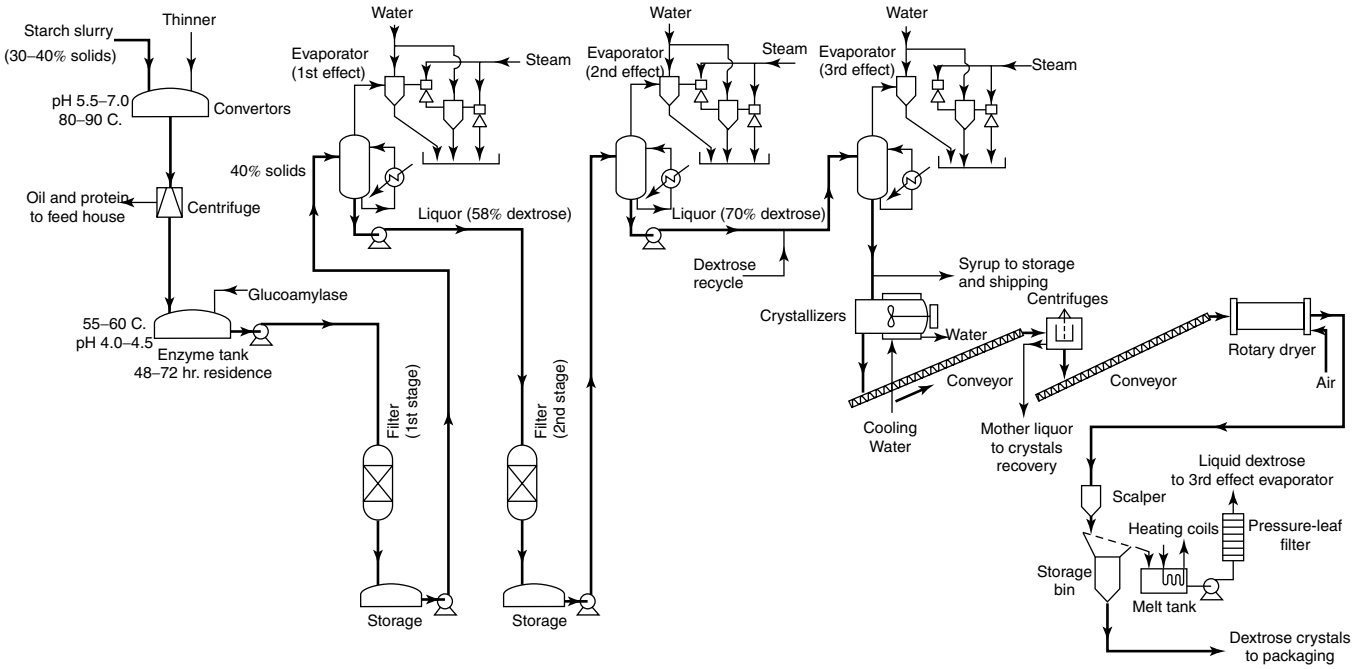

Fig. 4. Enzyme process for converting starch into dextrose. (*A.E. Staley Mfg. Co.*)

STAR CONNECTION. The connection of the various phases of an A.C. machine or circuit in which one end of all phases is connected to a common point, the other end of each phase going to a line. The *Y* is the three-phase star and is the most common example of this type connection.

STARDUST MISSION. NASA's *Stardust* mission launched on February 7, 1999, from Cape Canaveral Florida, will send a spacecraft flying through the cloud of dust that surrounds the nucleus of a comet, and for the first time ever, bring cometary material back to Earth.

Comets, which periodically grace our sky like celestial bottle rockets, are thought to hold many of the original ingredients of the recipe that created the planets and brought plentiful water to Earth. They are also rich in organic material, which provided our planet with many of the ready-to-mix molecules that could give rise to life. They may be the oldest, most primitive bodies in the solar system, a preserved record of the original nebula that formed the Sun and the planets.

"Scientists have long sought a sample directly from a known comet because of the unique chemical and physical information these bodies contain about the earliest history of the solar system," said Dr. Edward Weiler, NASA's associate administrator for space science. "Locked within comet molecules and atoms could be the record of the formation of the planets and the materials from which they were made."

Stardust is the first U.S. space mission dedicated solely to the exploration of a comet, and will be the first to return extraterrestrial material from outside the orbit of the Moon. The primary goal of *Stardust* is to collect dust and carbon-based samples from a well-preserved comet called *Wild 2*-pronounced "Vilt 2" after the name of its Swiss discoverer.

The spacecraft will also collect interstellar dust from a recently discovered flow of particles that passes through our solar system from interstellar space. As in the proverbial "from dust to dust," this interstellar dust represents the ultimate in recycled material; it is the stuff from which all solid objects in the universe are made, and the state to which everything eventually returns. Scientists want to discover the composition of this "stardust" to determine the history, chemistry, physics and mineralogy of nature's most fundamental building blocks.

Because it would be virtually impossible to equip a spacecraft with the most sophisticated lab instrumentation needed to analyze such material in space, the *Stardust* spacecraft is more of a robotic lab assistant whose job it is pick up and deliver a sample to scientists back on Earth. The spacecraft will, however, radio some on-the-spot analytical observations of the comet and interstellar dust.

The *Stardust* Mission is a collaborative effort between NASA, university and industry partners:

- The Principal Investigator is Dr. Donald E. Brownlee of the University of Washington, well known for his discovery of cosmic particles in the stratosphere known as Brownlee Particles. He also co-authored the bestseller "Rare Earth: Why Complex Life Is Uncommon," which puts forward a hypothesis predicting that simple, microbial life will be widespread in the universe, while complex animal or plant life will be extremely rare.
- Dr. Peter Tsou of the Jet Propulsion Lab (JPL), innovator in aerogel technology serves as Deputy Investigator.
- The contractor for the *Stardust* spacecraft is Lockheed Martin Astronautics, Denver, CO.
- The Jet Propulsion Laboratory has an experienced project management team, led by Thomas C. Duxbury. In addition, JPL provided the optical navigation camera.
- The Max Planck Institute (MPI) of Germany provided the real-time dust composition analyzer for the spacecraft.
- Ames Research Center provided the heat shield.
- Johnson Space Center will provide the planetary materials curatorial facility where the samples can be preserved and tests conducted.
- University of Chicago provided the Navigation Camera.

NASA's Discovery Program

Stardust is a mission under NASA's Discovery Program, which sponsors low-cost solar system exploration projects with highly focused science goals. Created in 1992, the Discovery Program competitively selects proposals submitted by teams led by scientists called principal investigators and supported by organizations, which provide project management and build and fly the spacecraft. In recent years, NASA has identified several finalists form dozens of mission proposals submitted. These finalists

receive funding to conduct feasibility studies for and additional period of time before a final selection is made. *Stardust* was competitively selected in the fall of 1995 under NASA's Discovery Program of low-cost, highly focused science missions. As the fourth Discovery mission chosen, *Stardust* has met a fast development schedule, which uses a small Delta launch vehicle, is cost-capped at less than $200 million, and is the product of a partnership involving NASA, academia and industry.

Other missions in the Discovery Program are:

- *Near Earth Asteroid Rendezvous* (NEAR) was launched in February 1996 and became the first spacecraft to orbit an asteroid when it reached Eros in February 2000. NEAR is managed by Johns Hopkins University's Applied Physics Laboratory.
- *Mars Pathfinder* was launched in December 1996 and reached Mars on July 4, 1997, demonstrating a unique way of landing with airbags to deliver a small robotic rover. The Jet Propulsion Laboratory, Pasadena, CA, managed the Mars Pathfinder. See also **Pathfinder Mission to Mars**.
- Launched in January 1998, *Lunar Prospector* entered orbit around Earth's Moon five days later, circling at an altitude of about 60 miles (100 kilometers). Principal investigator is Dr. Alan Binder of the Lunar Research Institute, Gilroy, CA, with project management by NASA's Ames Research Center. See also **Lunar Prospector Mission**.
- *Genesis* is a mission that will return samples of solar wind particles following launch in January 2001. Principal investigator is Dr. Donald Burnett of the California Institute of Technology, with project management by the Jet Propulsion Laboratory.
- *Comet Nucleus Tour (Contour)* will be launched in July 2002 to execute close flybys of three comets: Encke, Schwassmann-Wachmann-3 and d'Arrest. Principal investigator is Dr. Joseph Veverka of Cornell University, with project management by Johns Hopkins University's Applied Physics Laboratory.
- In November 1998, NASA selected five new Discovery proposals for feasibility studies before making a final selection of one or two missions in June 1999. The five are *Aladdin*, a mission to gather samples from Mars' moons Phobos and Deimos. *Deep Impact*, which would fire a projectile into Comet P/Tempel 1 to expose its pristine interior ice and rock. *Inside Jupiter*, an orbiter that would study the giant planet's interior, measuring its gravitational and magnetic fields. *Messenger*, an orbiter that would globally image and study Mercury; and *Vesper*, an orbiter that would study the atmosphere of Venus. In this round of selections, NASA also decided to fund part of an instrument to fly on the European Space Agency's *Mars Express* spacecraft in 2003 to study the interaction between the solar wind and Mars' atmosphere.

Why Stardust?

Far beyond the orbits of the planets on the outer fringes of the solar system, a vast swarm of perhaps a trillion dormant comets circles the Sun. Frozen balls of ice, rocks, and dust, they are the undercooked leftovers that remained after a sprawling cloud of gas and dust condensed to form the Sun and planets about 4.6 billion years ago. From time to time, the gravitational pull of a passing star will nudge some of them out of their orbits, plunging them into the inner solar system, where they erupt with glowing tails as they loop around the Sun.

Closer to home, a stream of interstellar dust flows continuously through the solar system. Each perhaps 1/50th the width of a human hair, these tiny particles are the pulverized flotsam of the galaxy, bits of ancient stars that exploded as they died. This "stardust" is literally the stuff of, which life on earth all made. It is the source of nearly all of the elements on Earth heavier than oxygen.

These two niches bearing clues of the dawn of the solar system are the target for NASA's *Stardust* mission. The spacecraft will use a collector mechanism that employs a unique substance called aerogel to snag comet particles as well as interstellar dust flowing through the solar system, returning them to Earth for detailed study in laboratories.

Data returned from the *Stardust* spacecraft and the precious samples it returns to Earth will provide opportunities for significant breakthroughs in areas of key interest to astrophysics, planetary science and astrobiology. The samples will provide scientists with direct information on the solid particles that permeate our galaxy.

Stardust's cometary dust and interstellar dust samples will help provide answers to fundamental questions about the origin of solar systems, planets and life: How and when did the elements that led to life enter the solar system? How were these materials transformed within the solar system by forces such as heating and exposure to ultraviolet light? How were they distributed among planetary bodies, and in what molecular and mineral-based forms? These questions are of major importance for astrobiology and the search for life-generating processes and environments elsewhere in the universe. See also **Astrobiology**.

Comets

Though frequently beautiful, comets traditionally have stricken terror as often as they have generated excitement as they wheel across the sky during their passage around the Sun. Astrologers interpreted the sudden appearances of the glowing visitors as ill omens presaging famine, flood or the death of kings. Even as recently as the 1910 appearance of Halley's Comet, entrepreneurs did a brisk business selling gas masks to people who feared Earth's passage through the comet's tail.

In the 4th century B.C., the Greek philosopher Aristotle concluded that comets were some kind of emission from Earth that rose into the sky. The heavens, he maintained, were perfect and orderly; a phenomenon as unexpected and erratic as a comet surely could not be part of the celestial vault. In 1577, Danish astronomer Tycho Brahe carefully examined the positions of a comet and the Moon against the stars during the evening and predawn morning. Due to parallax, a close object will appear to change its position against the stars more than a distant object will, similar to holding up a finger and looking at it while closing one eye and then the other. The Moon appeared to move more against the stars from evening to morning than the comet did, leading Tycho to conclude that the comet was at least four times farther away.

A hundred years later, the English physicist, Isaac Newton, established that a comet appearing in 1680 followed a nearly parabolic orbit. The English astronomer Edmund Halley used Newton's method to study the orbits of two dozen documented cometary visits. Three comet passages in 1531, 1607, and 1682 were so similar that he concluded they in fact were appearances of a single comet wheeling around the Sun in a closed ellipse every 75 years. He successfully predicted another visit in 1758–1759, and the comet thereafter bore his name.

Since then, astronomers have concluded that some comets return relatively frequently, in intervals ranging from 3 to 200 years; these are the so-called "short-period" comets. Others have enormous orbits that bring them back only once in many centuries.

In the mid-1800s, scientists also began to turn their attention to the question of comets' composition. Astronomers noted that several major meteor showers took place when Earth passed through the known orbits of comets, leading them to conclude that the objects are clumps of dust or sand. By the early 20th century, astronomers studied comets using the technique of spectroscopy, breaking down the color spectrum of light given off by an object to reveal the chemical makeup of the object. They concluded that comets also emitted gases as well as molecular ions.

In 1950, the American astronomer, Fred L. Whipple, authored a major paper proposing the "dirty snowball" model of the cometary nucleus. This model, which has since been widely adopted, pictures the nucleus as a mixture of dark organic material, rocky grains and water ice. ("Organic" means that the compound is carbon-based, but not necessarily biological in origin.) Most comets range in size from about 2 to 7 kilometers (1 to 5 miles) in diameter. Shields that protect the *Stardust* spacecraft from dust impacts were named for Whipple in honor of his role in cometary science.

If comets contain icy material, they must originate somewhere much colder than the relatively warm inner solar system. Also in 1950, the Dutch astronomer Jan Hendrick Oort (1900–1992) used indirect reasoning from observations to establish the existence of a vast cloud of comets orbiting many billions of miles from the Sun, perhaps 50,000 astronomical units (AU) away (one AU is the distance from Earth to the Sun), or nearly halfway to the nearest star. This region has since become known as the Oort Cloud.

A year later, the Dutch-born American astronomer, Gerard Kuiper (1905–1973), made the point that the Oort Cloud is too distant to act as

the nursery for short-period comets. He suggested the existence of a belt of dormant comets lying just outside the orbits of the planets at perhaps 30 to 100 AU from the Sun; this has become known as the Kuiper Belt. Jupiter's gravity periodically influences one of these bodies to take up a new orbit around the Sun. The Oort Cloud, by contrast, would be the home of long-period comets. They are periodically nudged from their orbits by any one of several influences, perhaps the gravitational pull of a passing star or giant molecular cloud, or tidal forces of the Milky Way Galaxy.

In addition to the length of time between their visits, another feature distinguishes short- and long-period comets. The orbits of short-period comets are all fairly close to the ecliptic, the plane in which Earth and most other planets orbit the sun. Long-period comets, by contrast, dive inwards toward the Sun from virtually any part of the sky. This suggests that the Kuiper Belt is a relatively flat belt, whereas the Oort Cloud is a three-dimensional sphere surrounding the solar system.

Where did the Oort Cloud and Kuiper Belt come from? Most astronomers now believe that the material that became comets condensed in the outer solar system around the orbits of Uranus and Neptune. Gravitational effects from those giant planets flung the comets outward.

Residing at the farthest reaches of the Sun's influence, comets did not undergo the same heating as the rest of the objects in the solar system, so they retain, largely unchanged, the original composition of solar system materials. As the preserved building blocks of the outer solar system, comets offer clues to the chemical mixture from which the planets formed some 4.6 billion years ago.

The geologic record of the planets shows that, about 3.9 billion years ago, a period of heavy comet and asteroid bombardment tapered off. The earliest evidence of life on Earth dates from just after the end of this heavy bombardment. The constant barrage of debris had vaporized Earth's oceans, leaving the planet too hot for the survival of fragile carbon-based molecules upon which life is based. Scientists therefore wonder: How could life form so quickly when there was so little liquid water or carbon-based molecules on Earth's surface? The answer may be that comets, which are abundant in both water and carbon-based molecules, delivered essential ingredients for life to begin.

Comets are also at least partially responsible for the replenishment of Earth's ocean after the vaporization of an early ocean during the late heavy bombardment. While Earth has long been regarded as the "water planet," it and the other terrestrial planets (Mercury, Venus and Mars) are actually poor in the percentage of water and in carbon-based molecules they contain when compared to objects that reside in the outer solar system at Jupiter's orbit or beyond. Comets are about 50 percent water by weight and about 10 to 20 percent carbon by weight. It has long been suspected that what little carbon and water there is on Earth was delivered here by objects such as comets that came from a more water-rich part of the solar system.

While comets are a likely source for life's building blocks, they have also played a devastating role in altering life on our planet. A comet or asteroid is credited as the likely source of the impact that changed Earth's climate, wiped out the dinosaurs and gave rise to the age of mammals 65 million years ago. A catastrophic collision between a comet or asteroid and Earth is estimated to happen at intervals of several tens of millions of years. See also **Comet**.

Other Comet Missions

Several other spacecraft have studied comets, not all of which were originally designed for that purpose. Several new missions to comets are being developed for launch in coming years.

Past comet missions include:

- In 1985, NASA modified the orbit of the International Sun-Earth Explorer (ISEE) spacecraft to execute a flyby of Comet Giacobini-Zinner. The spacecraft was renamed *International Comet Explorer* (ICE).
- An international armada of robotic spacecraft flew out to greet Halley's Comet during its return in 1986. The fleet included the European Space Agency's *Giotto*, the Soviet Union's *Vega 1* and *Vega 2*, and Japan's *Sakigake* and *Suisei* spacecraft.
- Comet Shoemaker-Levy 9's spectacular collision with Jupiter in 1994 was observed by NASA's Hubble Space Telescope, the Jupiter-bound *Galileo* spacecraft and the Sun-orbiting *Ulysses* spacecraft. See also **Hubble Space Telescope (HST)**; **Galileo Mission to Jupiter**; and **Ulysses Mission**.

Future comet missions are:

- *Comet Nucleus Tour* (Contour) will take images and comparative spectral maps of three comets — Encke, Schwassmann-Wachmann-3 and d'Arrest — following launch in July 2002.
- *Deep Space 4/Champollion* will perform the first landing on a cometary nucleus and demonstrate technologies for collecting samples when it reaches Comet Tempel 1 following launch in 2003.
- A European Space Agency mission, *Rosetta* will be launched in 2003 to orbit Comet Wirtanen and deliver a surface science package to the comet's surface. NASA is providing science instruments for the comet orbiter.

Interstellar Dust

In 1990, NASA launched the *Ulysses* spacecraft on a flight path that would take it close to Jupiter, flinging it into an orbit around the Sun far above and below the ecliptic plane. While en route from Earth to Jupiter, the spacecraft's dust detector measured a constant flow of particles, each about a micron in size, or 1/50th the diameter of a human hair, entering the solar system from interstellar space. This observation was corroborated by the similar dust detector on the *Galileo* spacecraft, which reached Jupiter in 1995.

Scientists believe that in fact interstellar dust is ubiquitous in the space between the stars of the Milky Way Galaxy. The dust curtains huge areas of the sky; the broad, dark line across the length of the Milky Way that can be seen with the naked eye is a blanket of interstellar dust. As the Sun orbits the galactic center, it cuts through the dust like a ship passing through waves. From our perspective within the solar system, the dust seems to be flowing from approximately the direction that the Sun is moving toward, a point called the ihsolar apexla in the constellation Hercules. Outward pressure from the solar wind sweeps the inner solar system near Earth clean, but interstellar dust is more easily detected beyond the orbit of Mars.

Interstellar dust provided the building blocks for solid materials on Earth and other planets. In the cycle of star formation and death, light elements such as hydrogen coalesce to form a star, which in time develops enough mass to burst into an ongoing nuclear reaction. Many stars die in a spectacular explosion, converting light elements into heavier elements. The resulting interstellar particles contain a record of the processes at work in their parent stars as well as the environments they have passed through in the galaxy. This information is retained in particles at a scale smaller than a micron.

Interstellar dust forms by condensation in circumstellar regions around evolved stars of many different types, including red giants, carbon stars, novas and supernovas. The process gives rise to silicate grains when there is more oxygen than carbon in the star, and carbon-based grains when the carbon content exceeds that of oxygen. Pristine grains will retain the radioactive signatures of the environment they formed in.

In the past decade, scientists have gained new understanding about the formation and early evolution of the solar system and the role of interstellar dust and comets in that process. Studies of interstellar dust have been conducted with Earth and space-based telescopes; in addition, scientists have collected and studied dust in the stratosphere and in Earth orbit. Since the late 1960s, collections of ocean sediment have brought up microscopic glass and metallic spherules, space particles that melted during atmospheric entry. The sample of interstellar dust returned by *Stardust* will be compared with these and others to help define how dust evolves from its interstellar state to help create stars, planets and life in the universe.

Infrared observations have also provided new knowledge of star-formation and the role that dust plays in that process. Scientists have found many similarities between interstellar dust and cometary composition. The same gases, ice particles and silicates believed to be in comets also are found in interstellar clouds.

Even though the interstellar dust samples will be small and partly eroded, they will open a significant new window of information on galactic and nebular processes, materials and environments. Having actual samples in hand provides many unique advantages. Just as the return of lunar

samples by the *Apollo* missions of the 1960s and 1970s revolutionized our understanding of the Moon, scientists expect that the *Stardust* mission's sample return will also have a profound impact on our knowledge of comets and stars.

Mission Overview

Stardust was launched (February 7, 1999) from Space Launch Complex 17A at Cape Canaveral Air Station, FL, on a variant of the Delta II launch vehicle known as a Delta 7426, one of the new series of launch vehicles procured under NASA's Med-Lite program.

Launch Vehicle. The first stage of the Delta II is augmented by four strap-on solid rocket motors. The solid rocket motors are designed to be jettisoned from the vehicle within 66 seconds after launch, after they have exhausted all of their solid propellant. Each of the four solid rocket motors is 1 meter (3.28 feet) in diameter and 13 meters (42.6 feet) long; each contains 11,765 kilograms (25,937 pounds) of hydroxyl-terminated polybutadiene (HTPB) propellant and provides an average thrust of 446,023 newtons (100,270 pounds) at sea level. The casings of the solid rocket motors are made of lightweight graphite epoxy.

The main body of the first stage is 2.4 meters (8 feet) in diameter and 26.1 meters (85.6 feet) long. It is powered by an RS-27A engine, which uses 96,160 kilograms (212,000 pounds) of RP-1 (rocket propellant 1, a highly refined kerosene) and liquid oxygen as its fuel and oxidizer.

The Delta II's second stage is 2.4 meters (8 feet) in diameter and 6 meters (19.7 feet) long, and is powered by an AJ10-118 K engine. The propellant is 5,900 kilograms (13,000 pounds) of Aerozine 50 (A-50), a mixture of hydrazine and unsymmetrical dimethyl hydrazine (UDMH), with nitrogen tetroxide as the oxidizer. This engine is restartable, and will perform two separate burns during *Stardust's* launch.

The launch vehicle's third and final stage is a Thiokol Star 37 FM booster, measuring 1.7 meter (5.5 feet) long and 0.9 meter (3 feet) wide. Its motor carries 1,090 kilograms (2,400 pounds) of solid propellant, composed of a mixture of aluminum, ammonium perchlorate and hydroxyl-terminated polybutadiene (HTPB). The third stage includes a spin table supporting small rockets, which are used to spin up the third stage itself and the attached Stardust spacecraft. After *Stardust* separates from the third stage, a weight on a cable unwinds to tumble the third stage to avoid recontact. See Fig. 1.

Launch Timing. The timing of Stardust's launch is based upon the trajectory the spacecraft must fly to rendezvous with Comet Wild-2 in 2004.

The launch period opened February 6 and would have continued through February 25, 1999. One near-instantaneous launch opportunity exists each day during the period. On February 6, the launch opportunity is at 4:07 p.m. Eastern Standard Time. The time of each daily opportunity varies (sometimes later or earlier) on later days of the launch period. *Stardust* was launched at 4:04 EST. February 7, 1999.

Launch Events. Launch occurred in three phases, consisting of liftoff and insertion into a 189-kilometer (102-mile) parking orbit; a coast of about a half hour until the vehicle position was properly aligned relative to the direction it must leave Earth; and final injection to an escape trajectory. The total time needed to complete the process was a little under an hour.

Sixty-six seconds after liftoff, the four solid rocket motors were discarded while the first stage continued to burn. About 4 minutes, 24 seconds after liftoff, the first stage stopped firing and was discarded eight seconds later. About five seconds later, the second stage engine ignited. The fairing or nose-cone enclosure of the launch vehicle was discarded 4 minutes, 42 seconds after liftoff. The first burn of the rocket's second stage ended about 11 minutes, 22 seconds after liftoff.

About 21 minutes after launch, the second stage was restarted. At about 24 minutes into the flight, the third stage separated and burned for about two minutes, after which the *Stardust* spacecraft separated from the third stage and began its first orbit of the Sun.

Immediately after separation from the Delta's third stage, *Stardust* stopped its own spinning by firing its thrusters. About 4 minutes after separation, the spacecraft's solar array unfolded and was pointed toward the Sun. Shortly thereafter, the 34-meter-diameter (112-foot) antenna at the Deep Space Network complex in Canberra, Australia acquired *Stardust's* signal. See Figs. 2 and 3.

Cruise. *Stardust's* first two years of flight included one orbital loop of the Sun. In March of 2000, when *Stardust* was between the orbits of Mars and Jupiter, the greatest distance that the spacecraft will be from the Sun, *Stardust's* onboard engines fired to put the spacecraft on course for a later gravity assist swingby of Earth.

As *Stardust* traveled back inward toward the Sun on the latter part of its first orbit, the spacecraft passed through a region where interstellar particles flow through the solar system. From March through May 2000,

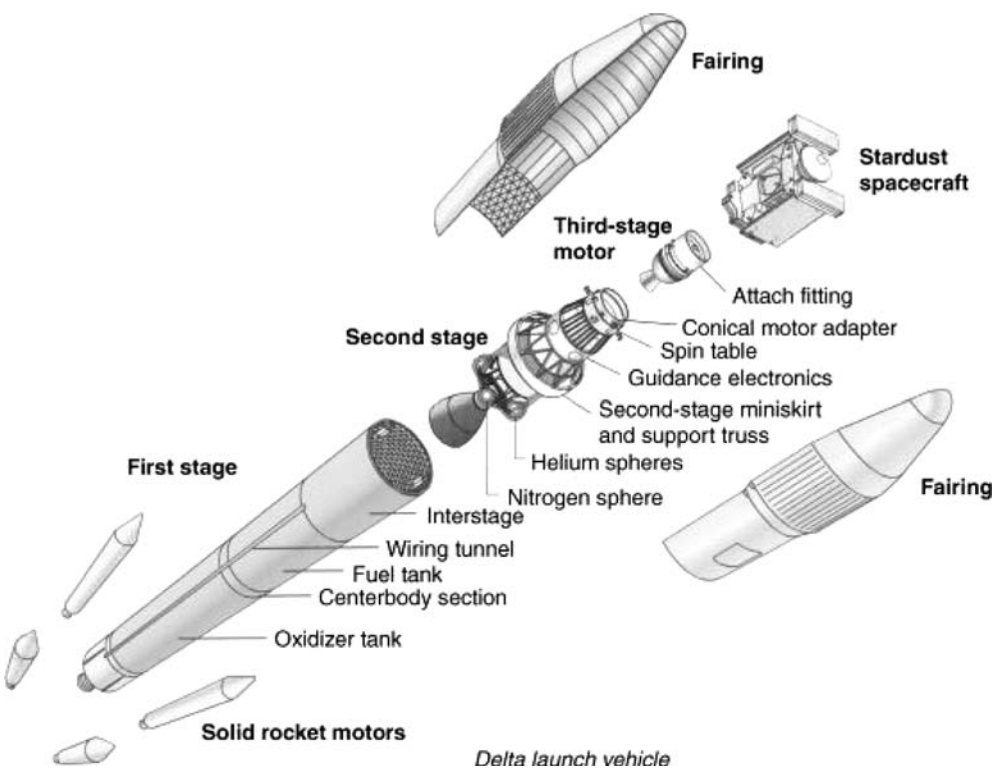

Fig. 1. Delta launch vehicle. (*Jet Propulsion Laboratory, Pasadena, CA.*)

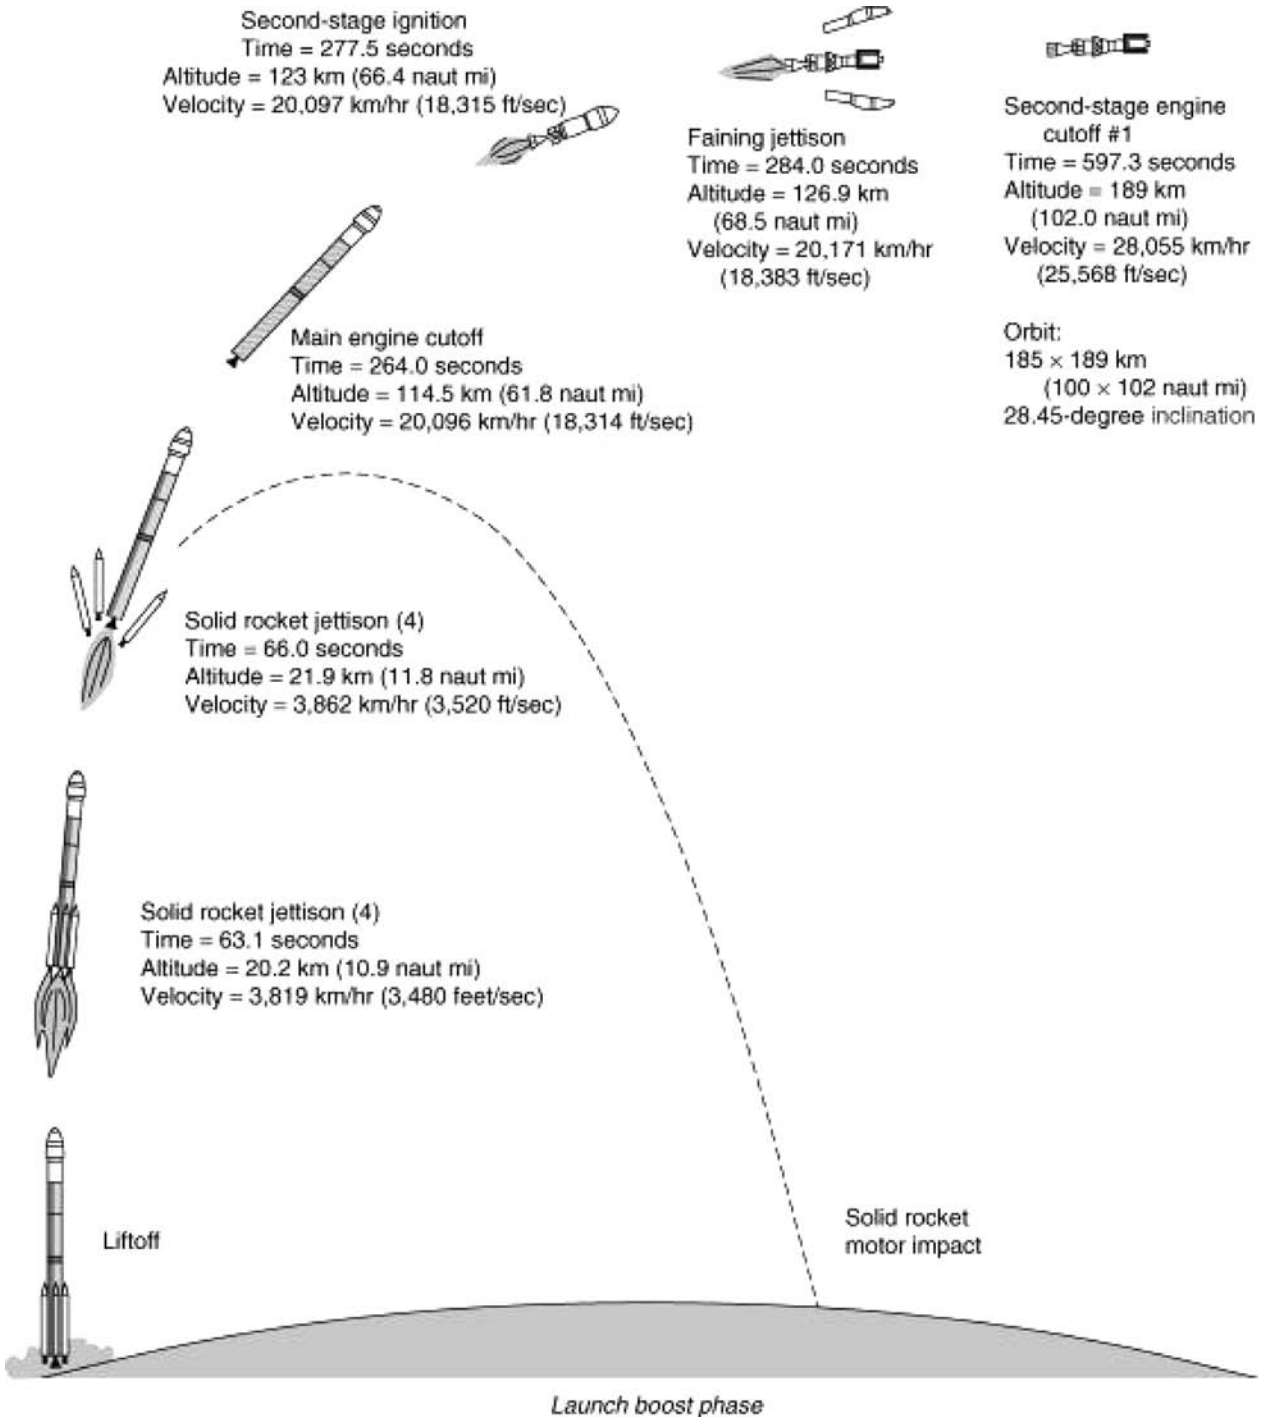

Fig. 2. Launch boost phase. (*Jet Propulsion Laboratory, Pasadena, CA*.)

the spacecraft opened its collector mechanism and captured such interstellar particles. The "B side" of the collector mechanism was used, reserving the "A side" for the spacecraft's later dust collection mission at Comet Wild-2.

At the conclusion of its first orbit of the Sun, the spacecraft flew past Earth on January 15, 2001 at an altitude of 5,964 kilometers (3,706 miles). This increased the size of *Stardust's* flight path to a 2-1/2-year loop of the Sun. The spacecraft will stay this course through two more orbits.

As the spacecraft travels back inward toward the Sun on the latter part of its second orbit, it again will collect interstellar particles flowing through the solar system from July through December 2002. See Fig. 4.

Comet Flyby. One hundred and sixty days before encountering Wild-2 or about July 25, 2003 the spacecraft is scheduled to fire its thrusters to fine-tune its flight path through the comet's coma, based on updated information on the position of the comet's nucleus provided by the navigation camera. The encounter of Wild-2 will occur on January 2, 2004, when the comet is 1.86 astronomical units from the Sun (almost twice Earth's distance from the Sun) and 97 days after the comet has rounded the Sun.

At its closest approach, *Stardust* will be traveling at a speed of 6.1 kilometers per second (about 13,650 miles per hour) relative to the comet. The velocity has been chosen to optimize the capture of particles by the aerogel collector; at this speed, it can "soft-catch" the comet samples without changing them greatly. The passage through the most intensive rain of debris within the coma will last about eight minutes.

Wild-2 will be far from its peak period of activity and be relatively safe for a close flyby. The spacecraft will approach Wild-2 from above the comet's orbital plane, then dip slightly below it. In effect, the comet will "run over" the spacecraft. Approaching from the sunlit side and northern portion of the comet, the spacecraft's flight path through the coma will take *Stardust* within about 150 kilometers (100 miles) of the comet's nucleus. This "miss distance" was selected to balance between the need to protect

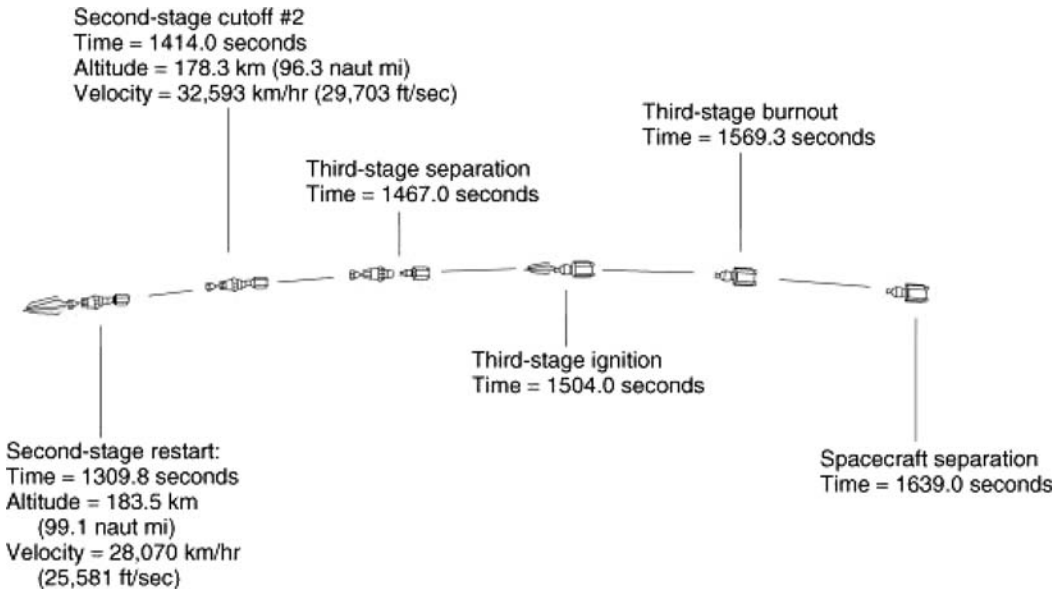

Fig. 3. Launch injection phase. (*Jet Propulsion Laboratory, Pasadena, CA*.)

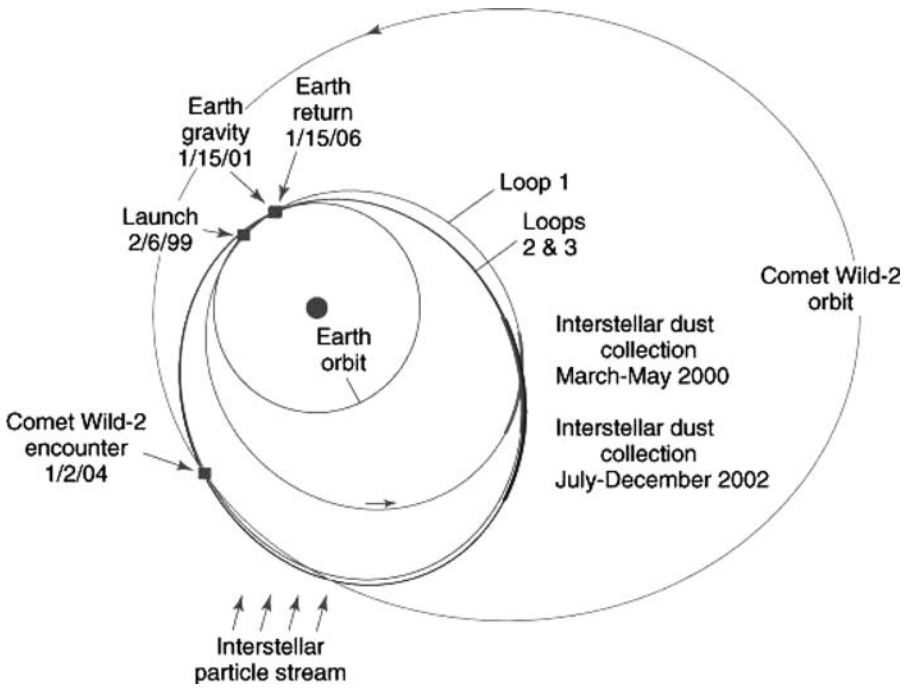

Fig. 4. Mission trajectory. (*Jet Propulsion Laboratory, Pasadena, CA*.)

the spacecraft and the objective of sampling the freshest possible material off the comet's nucleus.

Stardust's navigation camera, which is fixed to the spacecraft body, will take images of the comet nucleus. The camera will be protected from direct hits because it faces away from the direction of the particle onslaught. It will record images of the comet through the reflection in a movable mirror. The mirror will provide image-motion compensation, that is, it will move to keep the reflection of the comet in the camera's field-of-view and minimize image smearing during the flyby.

Wild-2 is an ideal target in part because it has only recently been deflected from a distant orbit into its current orbit, which brings it into the inner solar system. Its drastic orbit change resulted from a very close approach that the comet made to Jupiter in September 1974. Before that, the comet was in a much longer orbit and had made fewer passages of the Sun, so it is more pristine than most short-period comets. Since Comet Wild-2's orbit change in 1974, it has looped in toward the Sun three times. Comet scientists anticipate that 1 to 5 percent of Wild-2's nucleus surface could be active with gas and dust jets erupting from the surface. With a relatively slow flyby, the existence and activity of jets should be well observed.

Encounter Timeline. For planning purposes, the mission team has defined an encounter period spanning from 100 days before to 150 days after the comet flyby. This is divided into five time segments during which various mission activities are planned:

- **Far Encounter** −100 days to −1 day
- **Near Encounter** −1 day to −5 hours
- **Close Encounter** −5 hours to +5 hours
- **Closest Encounter** −240 seconds to +240 seconds
- **Post Encounter** −0 days to +150 days

During the segment beginning 100 days before the comet encounter, the navigation camera will image Wild-2 weekly to assist in targeting the spacecraft. *Stardust* will repeatedly image the comet through the

camera's eight different filters, acquiring as many images of the comet as can be practically returned until 12 hours before the closest approach to the nucleus. One closeup will be sent back to Earth near the point of closest approach. Subsequent imaging data will be recorded onboard the spacecraft for transmission to Earth after the fly-through of the coma has been completed.

The mission's core period for science data collection runs from about five hours before to five hours after its closest approach to the comet nucleus. Five hours and about 100,000 kilometers (60,000 miles) away from the nucleus, the spacecraft will begin to enter the coma. The comet's nucleus should begin to emerge in the navigation camera's field-of-view as an extended dark body. All comet science experiments will be taking data, and the spacecraft will be tracked continuously throughout this period.

Just before the spacecraft's closest approach to the nucleus, *Stardust* will deploy its aerogel collector, with the "A side" facing the direction of incoming comet particles. The main Whipple shield, equipped with its dust flux monitor, will be counting particle hits. The comet and interstellar dust analyzer will be measuring comet particle composition during the fly-through. From −5 hours through −4 minutes, and again from +4 minutes to +5 hours, the spacecraft will transmit a continuous stream of imaging and other observations. At −4 minutes, when the comet nucleus occupies 60 by 60 picture elements (pixels) in the camera's field-of-view, a final black-and-white picture of the nucleus will be transmitted directly to Earth. Any images taken from −4 minutes to +4 minutes will be stored onboard for later transmission.

From −3 minutes to +4 minutes, one major goal will be to keep the comet nucleus within the camera's field-of-view. To accomplish this, the scanning mirror can adjust its position from viewing forward to backward, and the spacecraft itself can tilt to add a second axis to the mirror's position. This is expected to result in significant spacecraft motion, so mission planners expect to temporarily lose radio contact with *Stardust*. Should this loss of signal occur, *Stardust's* medium-gain antenna will take over communications functions until the dish-shaped high-gain antenna can be pointed again at Earth.

Once *Stardust* has completed its voyage through the coma, Stardust's aerogel collector will be stowed for the final time, sealing its comet and interstellar samples inside the sample return capsule. Imaging and other science data recorded onboard during the coma fly-through will be transmitted to Earth, and *Stardust* will begin the final leg of its journey back toward Earth.

Earth Return. *Stardust* is scheduled to fire its thrusters three times as it approaches Earth to fine-tune its flight path. The first trajectory maneuver is scheduled 13 days before Earth entry, the second three days before entry and the final maneuver 3 hours before entry. Earth entry will take place on January 15, 2006.

Soon after the final trajectory maneuver at an altitude of 110,728 kilometers (68,805 miles), *Stardust* will release the sample return capsule. A spring mechanism will impart a spin to the capsule as it is pushed away from the spacecraft in order to stabilize it. After the capsule has been released, the main spacecraft will perform a maneuver to divert itself to avoid entering Earth's atmosphere. The spacecraft will remain in orbit around the Sun.

The capsule will enter Earth's atmosphere at a velocity of approximately 12.8 kilometers per second (28,600 miles per hour). The capsule's aerodynamic shape and center of gravity are designed like a badminton shuttlecock so that the capsule will automatically orient itself with its nose down as it enters the atmosphere.

As the capsule descends, its speed will be reduced by friction on its heat shield, a 60-degree half-angle blunt cone made of a graphite-epoxy composite covered with a new, light-weight thermal protection system. Additional ablative material on the back shell that is similar to material used on the Space Shuttle's external tank protects the capsule from the effects of recirculation flow of heat around the capsule.

The capsule will slow to a speed about 1.4 times the speed of sound at an altitude of about 30 kilometers (100,000 feet), at which time a small pyrotechnic charge will be fired, releasing a drogue parachute. After descending to about 3 kilometers (10,000 feet), a line holding the drogue chute will be cut, allowing the drogue to pull out a larger parachute that will carry the capsule to its soft landing. At touchdown, the capsule will be traveling at approximately 4.5 meters per second (14.8 feet per second), or about 16 kilometers per hour (10 miles per hour). In all, about 10 minutes will elapse between the beginning of the entry into Earth's atmosphere until the parachute is deployed.

The landing site at the Utah Test and Training Range near Salt Lake City was chosen because the area is a vast, desolate and unoccupied salt flat controlled by the U.S. Air Force with the Army. The landing footprint for the sample return capsule will be about 30 by 84 kilometers (18 by 52 miles), an ample space to allow for aerodynamic uncertainties and winds that might affect the direction the capsule travels in the atmosphere. To land within the footprint, the capsule's trajectory must achieve an entry accuracy of 0.08 degree. The sample return capsule will approach the landing zone on a heading of approximately 122 degrees on a northwest to southeast trajectory. Landing time will take place at 3 a.m. Mountain Standard Time on January 15, 2006.

The actual landing footprint will be predicted by tracking the spacecraft just before the capsule's release. Roughly six hours before entry, an updated footprint will be provided to the capsule recovery team.

Ground Recovery. A UHF radio beacon on the capsule will transmit a signal as the capsule descends to Earth, while the parachute and capsule will be tracked by radar. A helicopter will be used to fly the retrieval crew to the landing site. Given the small size and mass of the capsule, mission planners do not expect that its recovery and transportation will require extraordinary handling measures or hardware other than a specialized handling fixture to cradle the capsule during transport. The capsule will be transported to a staging area at the Utah Test and Training Range where the sample canister will be extracted. The sample canister then will be transported to its final destination, the planetary material curatorial facility at NASA's Johnson Space Center, Houston, TX.

Planetary Protection. The U.S. is a signatory to the United Nations' 1966 Treaty of Principles Governing the Activities of States in the Exploration and Use of Outer Space, Including the Moon and Other Celestial Bodies. Known as the "Outer Space Treaty," this document states in part that exploration of the Moon and other celestial bodies shall be conducted "so as to avoid their harmful contamination and also adverse changes in the environment of the Earth resulting from the introduction of extraterrestrial matter."

Comets are believed to be primordial bodies made up of material that is virtually unchanged since their creation when the solar system formed 4.6 billion years ago. This means that any evolutionary processes leading to the emergence of life have not occurred. There is no scientific reason to believe that bacteria or viruses or any other life exist on comets. One of the objectives of the *Stardust* mission is to investigate whether the chemical building blocks of life exist on comets. But even if such building blocks do reside there, comets have not provided the hospitable environment required over millions of years to accommodate the complex processes that could result in the emergence of even single-celled organic life.

On *Stardust*, all comet particles that are collected will be heated to extremely high temperature due to their impact speed on the aerogel collector. The temperature caused by the compression interaction between aerogel and any given particle is calculated to be at least 10,000 °C (more than 18,000 °F). In fact, the collector material literally melts to encapsulate the captured particles. Such high temperatures are naturally sterilizing. As a particle hits the aerogel sample collector, it will come to a dead stop within a microsecond, having traveled about 3 centimeters (1.2 inches) into the aerogel. By that point, the aerogel, which is silica-based, will have melted around the particle, trapping it in glass.

It should be noted that particles from space, including material from comets, fall onto Earth's surface at a rate of approximately 40,000 tons per year, and some of this material is believed to survive atmospheric entry without severe heating.

Outreach. The *Stardust* project has forged partnerships with several educational enterprises to increase public awareness of the mission's goals and strategy, and to broaden the distribution of new knowledge the mission will produce:

- **Challenger Center**, based in Alexandria, VA, has partnered with the project to manage the Stardust Educator Fellowship program. Twenty-five educators selected from across the country were trained in the science and engineering behind the mission. They also received a workshop package and educational materials, and will conduct their own

teacher training on *Stardust* throughout the mission. More information about Challenger Center is available at http://www.challenger.org/

- The **Jason Project**, founded by oceanographer and underwater explorer Dr. Robert Ballard after he found the wreckage of the Titanic on the sea floor, has created the "Jason IX Curriculum" in partnership with the *Stardust* project. The curriculum focuses on a study of life on Earth and in its oceans. The tie that links *Stardust* to oceanography is the presence of particles from space that lie on the ocean floor. Students will work with representatives of the *Stardust* mission to help find answers to the three key questions of the Jason Project: What are Earth's physical systems? How do these systems affect life on Earth? What technologies do we use to study these systems, and why? More information about The Jason Project is available at http://www.jasonproject.org.
- The Kirkpatrick Science and Air Space Museum, also known as **Omniplex**, is a hands-on science center located in Oklahoma City, OK. In partnership with the *Stardust* project, Omniplex has produced a planetarium show and a traveling "Stardust Café" exhibit dedicated to the science topics *Stardust* will investigate. More information about Omniplex is available at http://www.omniplex.org

The Stardust project sponsored a "Send Your Name to a Comet" campaign that invited people from around the world to submit their names via the Internet to fly onboard the *Stardust* spacecraft. Two microchips bearing the names of more than 1.136 million people are onboard the *Stardust* spacecraft.

The names were electronically etched onto fingernail-size silicon chips at JPL's Microdevices Lab. Writing on the microchips is so small that about 80 letters would equal the width of a human hair. The names can be read only with the aid of an electron microscope.

The first *Stardust* microchip contains 136,000 names collected from October through November 1997 from persons all over the world. That microchip has been placed inside the sample return capsule. The second microchip contains more than a million names from members of the public, and was placed on the back of the arm that holds the dust collector. In addition to holding names from the public-at-large, the second microchip contains all 58,214 names inscribed on the Vietnam Veterans Memorial in Washington, DC, as a tribute to those who died in that war.

Spacecraft Profile

The *Stardust* spacecraft incorporates innovative, state-of-the-art technologies pioneered by other recent missions with off-the-shelf spacecraft components and, in some cases, spare parts and instrumentation left over from previous missions.

The *Stardust* spacecraft is derived from a rectangular deep-space bus called SpaceProbe developed by Lockheed Martin Astronautics, Denver, CO. The total weight of the spacecraft, including the sample return capsule and propellant carried onboard for trajectory adjustments, is 385 kilograms (848 pounds). The main bus is 1.7 meters (5.6 feet) high, 0.66 meter (2.16 feet) wide and 0.66 meter (2.16 feet) deep, about the size of an average office desk. Panels are made of a core of aluminum honeycomb, with outer layers of graphite fibers and polycyanate face sheets. When its two parallel solar panels are deployed in space, the spacecraft takes on the shape of a letter H. See Fig. 5.

There are three dedicated science packages on *Stardust*; the two-sided dust collector, the comet and interstellar dust analyzer, and the dust flux monitor. Science data are also obtained without dedicated hardware. The navigation camera, for example, will provide images of the comet both for targeting accuracy and scientific analysis.

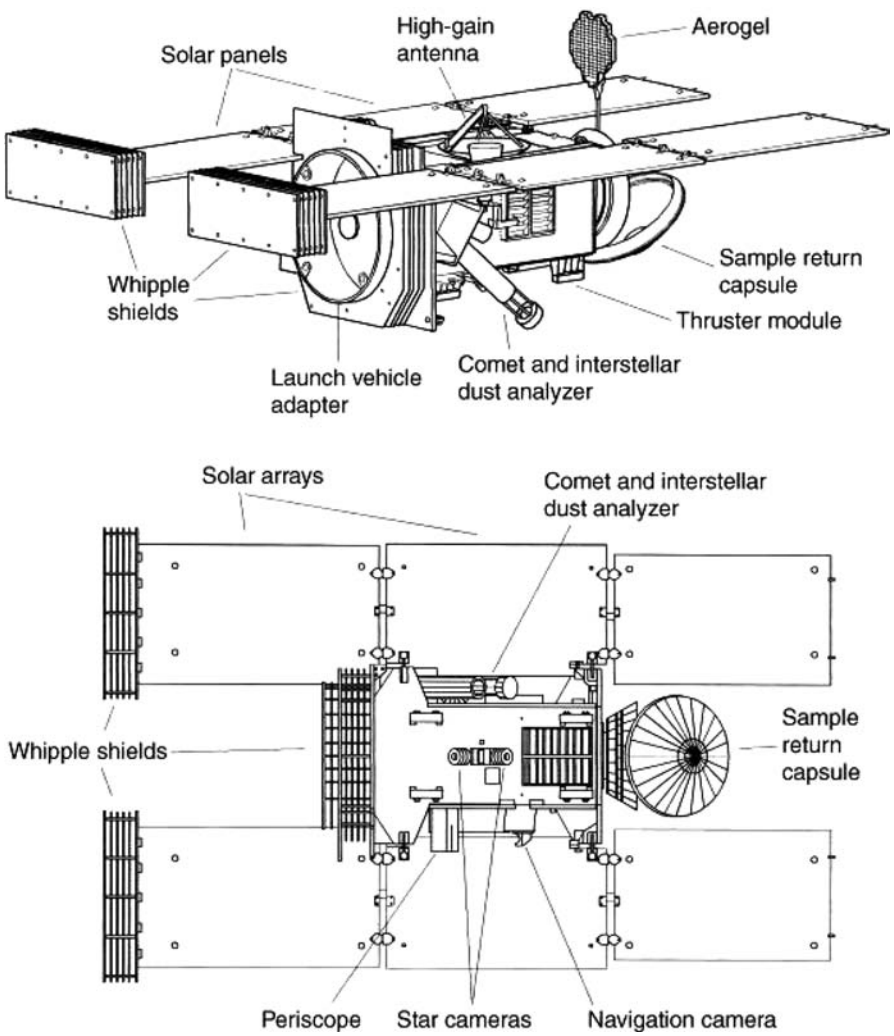

Fig. 5. *Stardust* spacecraft. (*Jet Propulsion Laboratory, Pasadena, CA.*)

Aerogel Dust Collectors

To collect particles without damaging them, Stardust will use an extraordinary substance called *aerogel*, a silicon-based solid with a porous, sponge-like structure in which 99 percent of the volume is empty space. Originally invented in 1933 by a researcher at the College of the Pacific in Northern California, aerogel is made from fine silica mixed with a solvent. The mixture is set in molds of the desired shape and thickness, and then pressure-cooked at high temperature. Over the past several years, aerogel has been made and flight-qualified at the Jet Propulsion Laboratory for space missions. See Fig. 6.

Fig. 6. This photograph illustrates the excellent insulating properties of aerogel. The crayons on top of the aerogel are protected from the flame underneath, and are not melting. (*Jet Propulsion Laboratory, Pasadena, CA*.)

A cube of aerogel looks like solid, pale-blue smoke. It is the lightest-weight, lowest-mass solid known, and has been found to be ideal for capturing tiny particles in space. There is extensive experience, both in laboratory and space flight experiments, in using aerogel to collect hypervelocity particles. Eight Space Shuttle flights have been equipped with aerogel collectors.

The exotic material has many unusual properties, such as uniquely low thermal and sound conductivity, in addition to its exceptional ability to capture hypervelocity dust. Aerogel was also used as a lightweight thermal insulator on Mars *Pathfinder's Sojourner* rover.

When *Stardust* flies through the comet's coma, the impact velocity of particles as they are captured will be up to six times the speed of a bullet fired from a high-powered rifle. The Whipple shields can protect the spacecraft from impacts of particles the size of a pea, but larger particles present a more severe hazard.

Although the particles captured in aerogel will each be smaller than a grain of sand, high-speed capture in most substances would alter their shape and chemical composition, or vaporize them entirely. With aerogel, however, particles are softly caught in the material and slowed to a stop. When a particle hits the aerogel, it will bury itself, creating a carrot-shaped track in the aerogel up to 200 times its own length as it slows down and comes to a stop. The aerogel made for the *Stardust* mission has extraordinary, water-like clarity that will allow scientists to locate a particle at the end of each track etched in the substance. Each narrow, hollow cone leading to a particle will easily be seen in the aerogel with a stereo microscope.

The sizes of the particles collected in the aerogel are expected to range mostly from about a micron (a millionth of a meter, or 1/25,000th of an inch, or about 1/50th of the width of a human hair) to 100 microns (a tenth of a millimeter, or 1/250th of an inch, or about twice the width of a human hair). *Stardust* scientists anticipate that the aerogel will return a few particles at the upper end of this size range, and a million particles in the submicron range.

Most of the scientific analysis will be devoted to particles that are 15 microns (about 1/1,700th of an inch, or about one-third the width of a human hair) in size. The Stardust science team expects that the samples returned will be profoundly complex, and each particle will be probed for years in research labs.

One side of the dust collection module, called the "A side," will be used for the comet encounter, while the opposite side ("B side") will be used for interstellar collection. More than 1,000 square centimeters (160 square inches) of collection area is provided on each side. Stardust's cometary and interstellar dust collectors each have 130 rectangular blocks of aerogel measuring 2 by 4 centimeters (0.8 by 1.6 inches), plus two slightly smaller rhomboidal blocks. The thickness of the aerogel on the cometary particle collection side is 3 centimeters (1.2 inches), while the thickness of the aerogel on the interstellar dust particle collection side is 1 centimeter (0.4 inch). The density of the aerogel is graded — less dense at the point of particle entry, and progressively denser deeper in the material. Each block of aerogel is held in a frame with thin aluminum sheeting. See Fig. 7.

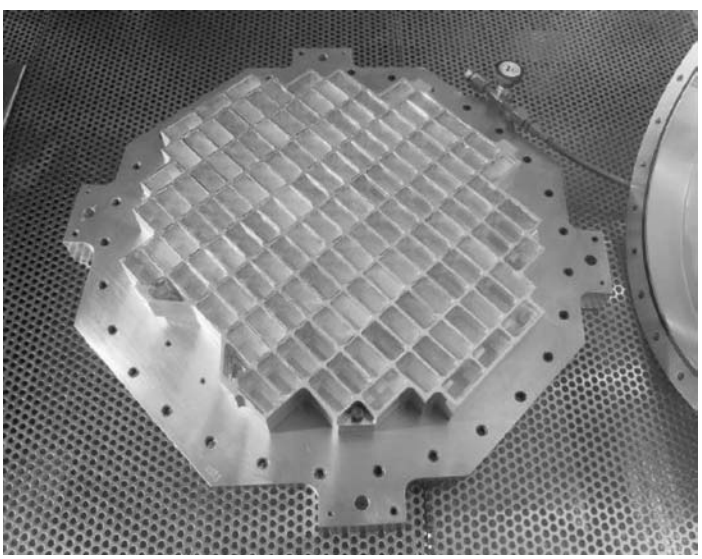

Fig. 7. Dust collector with aerogel. (*Jet Propulsion Laboratory, Pasadena, CA*.)

Overall, the collection unit resembles a metal ice tray set in an oversize tennis racket. It is similar to previous systems used to collect particles in Earth orbit on SpaceHab and other Space Shuttle-borne experiments. The sample return capsule is a little less than a meter (or yard) in diameter, and opens like a clamshell to extend the dust collector into the dust stream. After collecting samples, the cell assembly will fold down for stowage into the sample return capsule.

Sample Return Capsule

The sample return capsule is a blunt-nosed cone with a diameter of 81 centimeters (32 inches). It has five major components: a heat shield, back shell, sample canister, parachute system and avionics. The total mass of the capsule, including the parachute system, is 45.7 kilograms (101 pounds).

A hinged clamshell mechanism opens and closes the capsule. The dust collector fits inside, extending on hinges to collect samples and retracting to fold down back inside the capsule. The capsule is encased in ablative materials to protect the samples stowed in its interior from the heat of reentry.

The heat shield is made of a graphite-epoxy composite covered with a thermal protection system. The thermal protection system is made of a phenolic-impregnated carbon ablator developed by NASA's Ames Research Center for use on high-speed reentry vehicles. The capsule's heat shield will remain attached to the capsule throughout descent and serves as a protective cover for the sample canister at touchdown.

The back-shell structure is also made of a graphite-epoxy composite covered with a thermal protection system that is made of a cork-based material called *SLA 561V*. This material was developed by Lockheed Martin for use on the *Viking* missions to Mars in the 1970s, and is currently used on the Space Shuttle's external tank. The back shell provides the attach points for the parachute system.

The sample canister is an aluminum enclosure that holds the aerogel and the mechanism used to deploy and stow the aerogel collector during the mission. The canister is mounted on an equipment deck suspended between the backshell and heat shield.

The parachute system incorporates a drogue and main parachute inside a single canister. As the capsule descends toward Earth, a gravity-switch sensor and timer will trigger a pyrotechnic gas cartridge that will pressurize a mortar tube and expel the drogue chute. The drogue chute will be deployed at an altitude of approximately 30 kilometers (100,000 feet) at a speed of about mach 1.4 to provide stability to the capsule. Based on information from timer and backup pressure transducers, a small pyrotechnic device will cut the drogue chute from the capsule at an altitude of approximately 3 kilometers (10,000 feet). As the drogue chute moves away, it will extract the 8.2-meter-diameter (27-foot) main chute from the canister. Upon touchdown, cutters will fire to cut the main chute cables so that winds do not drag the capsule across the terrain. See Fig. 8.

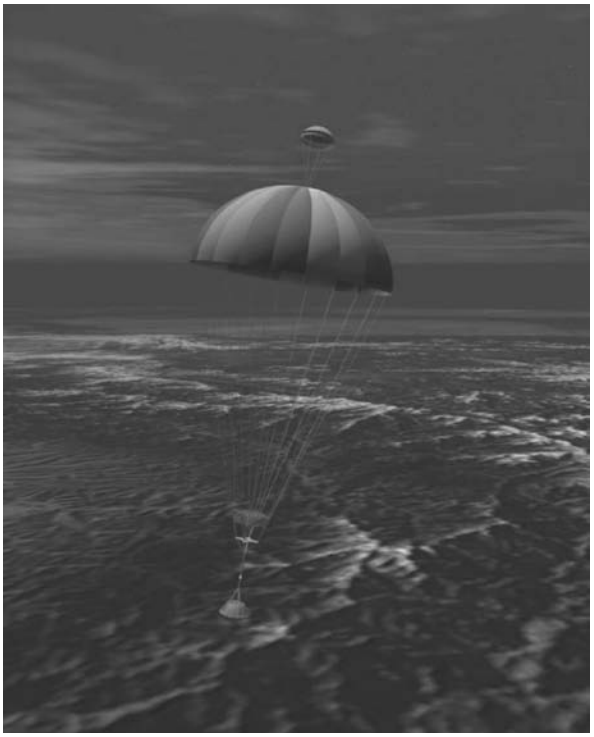

Fig. 8. Sample return capsule parachuting down to earth. (*Jet Propulsion Laboratory, Pasadena, CA*.)

The capsule carries an ultra-high-frequency (UHF) radio locator beacon to be used in conjunction with locator equipment on the recovery helicopters. The beacon will be turned on at main parachute deployment and will remain on until turned off by recovery personnel. The beacon is powered by redundant sets of lithium sulfur dioxide batteries, which have long shelf life and tolerance to wide temperature extremes, and are safe to handle. The capsule carries sufficient battery capacity to operate the UHF beacon for at least 40 hours. See Fig. 9.

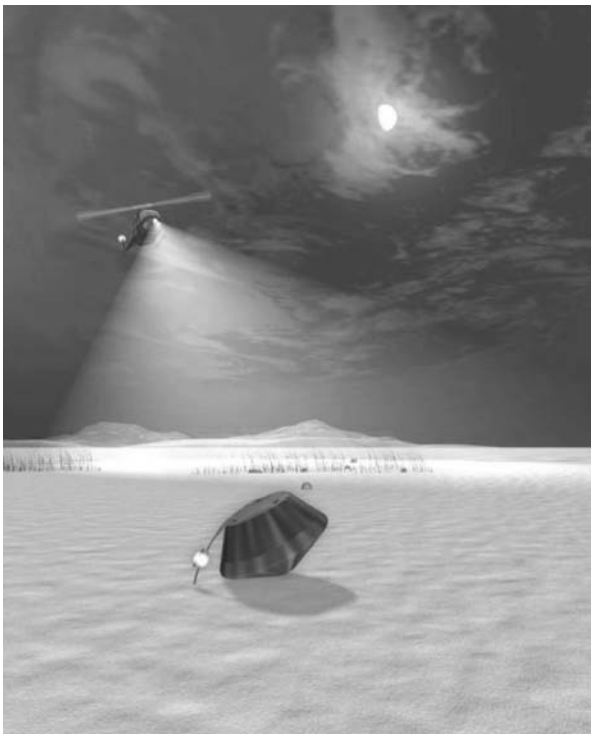

Fig. 9. Sample return capsule landing. (*Jet Propulsion Laboratory, Pasadena, CA*.)

Comet and Interstellar Dust Analyzer

The comet and interstellar dust analyzer is derived from the design of an instrument that flew on the European Space Agency's *Giotto* spacecraft and the Soviet Union's *Vega* spacecraft when they encountered Comet Halley in 1986. The instrument obtained unique data on the chemical composition of individual particulates in Halley's coma. *Stardust's* version of the instrument will study the chemical composition of particulates in the coma of Comet Wild-2.

The purpose of the analyzer instrument is to intercept and perform instantaneous compositional analysis of dust as it is encountered by the spacecraft. Data will be transmitted to Earth as soon as a communication link is available.

The instrument is a mass spectrometer, which separates the masses of ions by comparing differences in their flight times. When a dust particle hits the instrument's target, the impact creates ions, which are extracted from the particle by an electrostatic grid. Depending on the polarity of the target, positive or negative ions can be extracted. As extracted ions move through the instrument, they are reflected and then detected. Heavier ions take more time to travel through the instrument than lighter ones, so the flight times of the ions are then used to calculate their masses. From this information, the ion's chemical identification can be made. See Fig. 10.

In all, the instrument consists of a particle inlet, a target, an ion extractor, a mass spectrometer and an ion detector.

Co-investigator in charge of the comet and interstellar dust analyzer is Dr. Jochen Kissel of the Max-Planck-Institut für Extraterrestrische Physik, Garching, Germany. The instrument was developed and fabricated by von Hoerner & Sulger GmbH, Schwetzingen, Germany, under contract to the German Space Agency and the Max-Plank-Institut. Software for the instrument was developed by the Finnish Meteorological Institute, Helsinki, Finland, under subcontract to von Hoerner & Sulger.

Dust Flux Monitor

The dust flux monitor measures the size and frequency of dust particles in the comet's coma. The instrument consists of two film sensors and two vibration sensors. The film material responds to particle impacts by generating a small electrical signal when penetrated by dust particles. The mass of the particle is determined by measuring the size of the electrical signals. The number of particles is determined by counting the number of signals. By using two film sensors with different diameters and thicknesses,

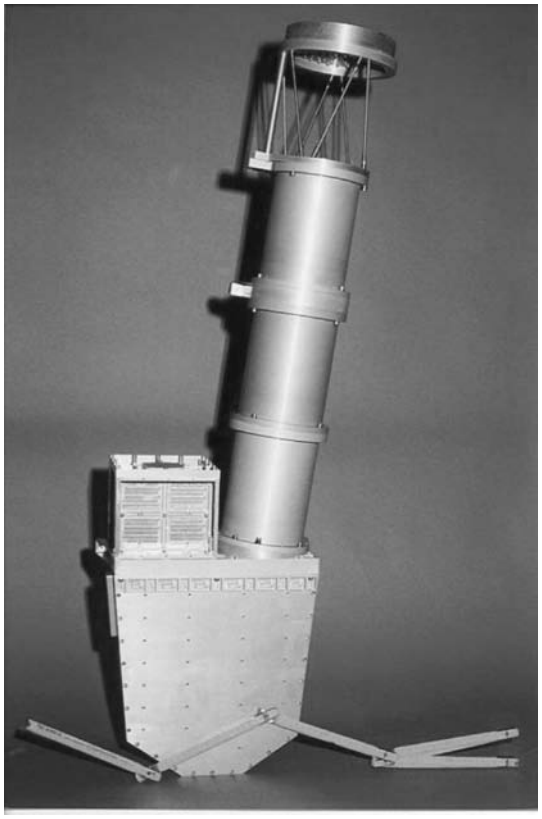

Fig. 10. Comet and Interstellar Dust Analyzer (CIDA). (*Jet Propulsion Laboratory, Pasadena, CA*.)

the instrument will provide data on what particle sizes were encountered and what the size distribution of the particles is.

The two vibration sensors are designed to provide similar data for larger particles, and are installed on the Whipple shield that protect the spacecraft's main bus. These sensors will detect the impact of large comet dust particles that penetrate the outer layers of the shield. This system, essentially a particle impact counter, will give mission engineers information about the potential dust hazard when the spacecraft flies through the coma environment. Co-investigator in charge of the dust flux monitor is Dr. Anthony Tuzzolino of the University of Chicago, where the monitor was developed and constructed.

Navigation Camera

The navigation camera is capable of acquiring images with a resolution of 6 meters (21.6 feet) per pixel at a distance of 100 kilometers (62 miles).

The camera is a combination of adapted spare components left over from previous space missions. The main camera is a spare wide-angle unit left over from the two *Voyager* spacecraft missions launched to the outer planets in 1977. The camera uses a single *Voyager* eight-position filter wheel, thermal housing, and spare optics and mechanisms. Designers added a thermal radiator to the *Voyager* camera. Combined with it is a modernized sensor head left over from the *Galileo* mission to Jupiter launched in 1989. The sensor head uses the existing *Galileo* design updated with a 1024-by-1024-pixel array charge-coupled device (CCD) from the *Cassini* mission to Saturn, but has been modified to use new miniature electronics.

The eight-position filter wheel is fitted with three gas filters, three dust filters, a high-resolution filter and a clear filter. The gas filters will permit study of the comet's dust jets as possible sources of gas, as well as a comparison of the sources of gas and dust on the surface of the comet nucleus. The three dust filters will allow study of the color and scattering properties of the dust. The high-resolution filter will be used for the highest-resolution imaging of the comet nucleus. The clear filter will be used for the study of structure and brightness differences on the comet nucleus. See Fig. 11.

During distant imaging of the comet's coma, the camera will take pictures through a periscope in order to protect the camera's primary

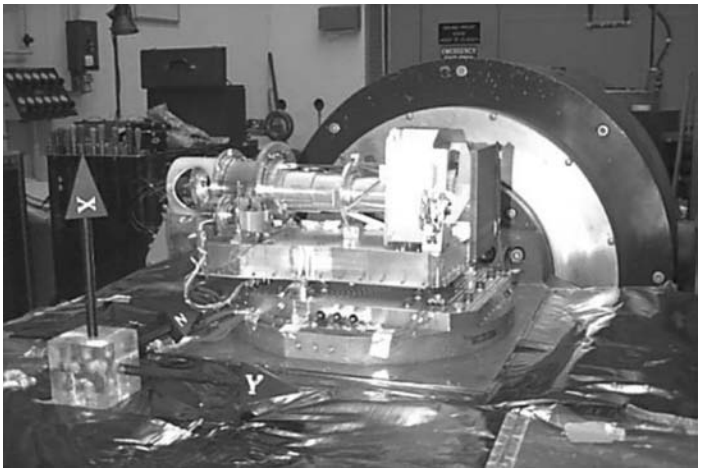

Fig. 11. *Stardust* navigation camera. (*Jet Propulsion Laboratory, Pasadena, CA*.)

optics as the spacecraft enters the coma. In the periscope, light is reflected off mirrors made of highly polished metals designed to minimize image degradation while withstanding particle impacts. During close approach, the nucleus is tracked and several images taken with a rotating mirror that no longer views through the periscope.

Propulsion System

The *Stardust* spacecraft needs only a relatively modest propulsion system because it is on a low-energy trajectory for its flyby of Comet Wild-2 and subsequent return to Earth, and because it is aided by a gravity-assisted boost maneuver when it flies by the Earth for the first time.

The spacecraft is equipped with two sets of thrusters, which use hydrazine as a monopropellant. Eight larger thrusters, each of, which puts out 4.4 newtons (1 pound) of thrust, will be used for trajectory correction maneuvers or turning the spacecraft. Eight smaller thrusters producing 0.9 newton (0.2 pound) of thrust each will be used for attitude control. The thrusters are in four clusters located on the opposite side of the spacecraft from the deployed aerogel. In all, the spacecraft carries 85 kilograms (187 pounds) of hydrazine propellant.

Attitude Control

The attitude control system manages the spacecraft's orientation in space. Like most planetary spacecraft, *Stardust* is three-axis stabilized, meaning that its orientation is held fixed in relation to space, as opposed to spacecraft that stabilize themselves by spinning.

Stardust determines its orientation at any given time using a star camera or one of two inertial measurement units, each of which consists of three ring-laser gyroscopes and three accelerometers. The spacecraft's orientation is changed by firing thrusters. The inertial measurement units are needed only during trajectory correction maneuvers and during the fly-through of the cometary coma when stars may be difficult to detect. Otherwise, the vehicle can be operated in a mode using only stellar guidance for spacecraft positioning. Two Sun sensors will serve as backup units, coming into play if needed to augment or replace the information provided by the rest of the attitude control system's elements.

Command and Data Handling

The spacecraft's computer is embedded in the spacecraft's command and data-handling subsystem, and provides computing capability for all spacecraft subsystems. At its heart is a RAD6000 processor, a radiation-hardened version of the PowerPC chip used on some models of Macintosh computers. It can be switched between clock speeds of 5, 10 or 20 MHz. The computer includes 128 megabytes of random-access memory (RAM); unlike many other spacecraft, *Stardust* does not have an onboard tape recorder, but instead stores data in its RAM for transmission to Earth. The computer also has 3 megabytes of programmable memory that can store data even when the computer is powered off.

The spacecraft uses about 20 percent of the 128 megabytes of data storage for its own internal housekeeping. The rest of the memory is used to store science data and for computer programs, which control science observations. Memory allocated to specific instruments includes about 75 megabytes for images taken by the navigation camera, 13 megabytes for data from the comet and interstellar dust analyzer, and 2 megabytes for data from the dust flux monitor.

Power

Two solar array panels affixed to the spacecraft are deployed shortly after launch. Together they provide 6.6 square meters (7.9 square yards) of solar collecting area using high-efficiency silicon solar cells. One 16-amp-hour nickel-hydrogen battery provides power when the solar arrays are pointed away from the Sun and during peak power operations. See also **Spacecraft Power Systems**.

Thermal Control

Stardust's thermal control subsystem uses louvers to control the temperature of the inertial measurement units and the telecommunications system's solid-state power amplifiers. Thermal coatings and multi-layer insulation blankets and heaters are used to control the temperature of other parts of the spacecraft.

Telecommunications

Stardust is equipped with a transponder (radio transmitter/receiver) originally developed for the *Cassini* mission to Saturn, as well as a 15-watt radio frequency solid-state amplifier. Communications will be mainly conducted through the spacecraft's medium-gain antenna. Three low-gain antennas are used for initial communications near Earth and to receive commands when the spacecraft is in nearly any orientation. Data rates will range from 40 to 4,000 bits per second.

A 0.6-meter-diameter (2-foot) high-gain dish antenna is used primarily for communication during the comet encounter. *Stardust* will use it to transmit images of the comet nucleus, as well as data from the comet and interstellar dust analyzer and the dust flux monitor, at a high data rate to minimize the transmission time and the risk of losing data during the extended time that would be required to transmit the data through the medium-gain antenna.

Most data from the spacecraft will be received through the Deep Space Network's 34- meter-diameter (112-foot) ground antennas, but 70-meter (230-foot) antennas will be used during some critical telecommunications phases, such as when *Stardust* transmits science data during and after the comet encounter. See also **Deep Space Network**.

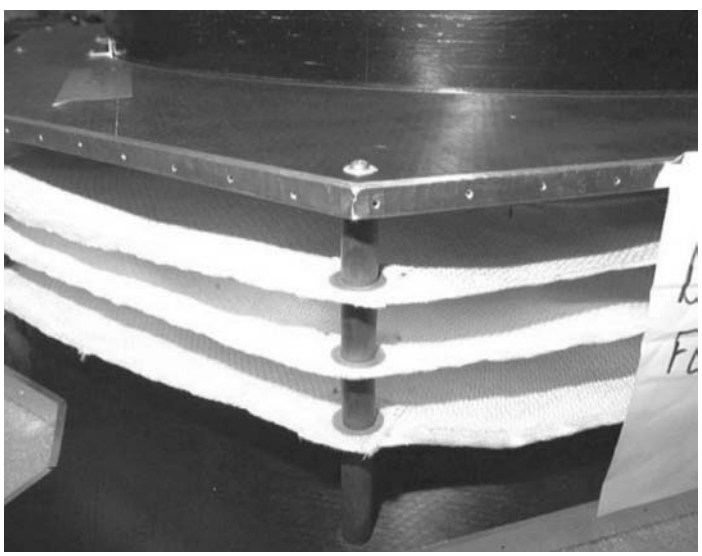

Fig. 12. Whipple Shields. (*Jet Propulsion Laboratory, Pasadena, CA.*)

Redundancy

Virtually all spacecraft components are redundant, with critical items "cross-strapped," or interconnected so that they can be switched in or out most efficiently. The battery includes an extra pair of cells. Fault protection software is designed so that the spacecraft is protected from reasonable, credible faults without unnecessarily putting the spacecraft into a safe mode due to unanticipated but probably benign glitches.

Whipple Shields

The shields that will protect *Stardust* from the blast of cometary particles is named for American astronomer, Dr. Fred L. Whipple, who in 1950 accurately predicted the "dirty snow-ball" model of the cometary nucleus as a mixture of dark organic material, rocky grains and water ice. The system includes two bumpers at the front of the spacecraft, which protect the solar panels, and another shield protecting the main spacecraft body. Each of the shields is built around composite panels designed to disperse particles as they impact, augmented by blankets of Nextel ceramic cloth that further dissipate and spread particle debris. See Fig. 12.

STARK EFFECT. In 1913, Stark showed that every line in the Balmer series of hydrogen, when excited in a strong electric field of 100 kilovolts per square centimeter or more, is split into several components. If the spectrum is observed perpendicular to the field, some members of the line pattern are plane-polarized with the electric vector parallel to the field (p-components) and the others are polarized with the electric vector normal to the field (s-components). When the spectrum is observed parallel to the field, only unpolarized s-components are observed. A similar splitting of lines is noted in the cathode dark space of a discharge tube. The Stark effect is similar, in many respects, to the Zeeman effect but it is generally more difficult to study experimentally because of the high potential gradients needed in the light source. Its theory is quite different, and the observed spectral pattern varies markedly in character and in number of components as the field intensity increases. See also **Zeeman Effect**.

STARLING *(Aves, Passeriformes).* A bird of any of several species native to Europe, Asia, and northern Africa. The African glossy starlings

belong to a family containing also the Asiatic grackles of hill mynas, while the true starlings are placed in a closely related family.

The one species common in North America is the common European starling, *Sturnus vulgaris*, which was introduced into New York in 1890 and has since spread more than a third of the way across the continent. The males are black with green and blue iridescence and light tips on many of the smaller feathers, and the females are brownish-gray. The beak is rather large. In Europe the starlings are valued as destroyers of insects and for their song. They are able mimics. The same good qualities are worthy of consideration in America, but the birds are also destructive of native species, and in the fall they become a nuisance by gathering in great flocks to roost in countless thousands in the trees of residential districts. The net verdict is against them, and they are commonly regarded as pests.

STARLING, ERNEST HENRY (1866–1927). E. H. Starling was an English physiologist who worked on body functions and their regulation, especially the activity of the heart. Starling was born and educated in London, and in 1889 qualified in medicine from Guy's Hospital, and was appointed lecturer in physiology there in the same year. He travelled frequently to Germany to study in laboratories of the eminent Continental physiologists Willy Kühn and Rudolf Heidenhain. He also used laboratory facilities at University College, London, where he met his future brother-in-law William (later Sir William) Bayliss, with whom he was to enjoy a life-long professional and personal association. In 1899, the year in which he was elected a Fellow of the Royal Society, he moved to University College as the Jodrell Professor of Physiology. He retained this post until 1923, when he became Foulerton Research Professor of the Royal Society, although remaining at University College until his death in 1927. See also **Bayliss, William Maddock (1860–1924)**.

At the turn of the century there was considerable scientific interest in how visceral organs were controlled by the nervous system, the work on gastric secretion by the Russian physiologist Ivan Pavlov, who won the Nobel Prize for Physiology or Medicine in 1904, being particularly influential in this direction. Working with Bayliss, Starling examined the control of pancreatic secretion, but they were unable to identify a neural mechanism. Instead, in 1902, they discovered a chemical mediator released by cells in the duodenum, which travelled in the bloodstream, to exert a stimulatory effect in the pancreas. Bayliss and Starling called this substance secretin, and for this and similar chemical messengers they coined the word 'hormone'. See also **Pavlov, Ivan Petrovitch (1849–1936)**.

Starling is equally well remembered for his work in cardiovascular physiology which elucidated much of the physiology of the circulation and the mechanisms of cardiac activity. He devised a surgical procedure in which the heart and lungs of an experimental animal could be isolated from other organs, and using this preparation, Starling demonstrated that the more the heart is filled with blood during diastole, the relaxation period, the stronger is the contraction (systole) that follows. This established that the heart can automatically alter the strength of its beat in response to changes in blood flow, a mechanism that is still known as 'Starling's law of the heart'. Starling is also commemorated eponymously for his work on capillary function. 'Starling's equilibrium' equated intravascular pressure, which encouraged fluid to pass out of the capillary, and the osmotic forces that caused fluid to be absorbed into the capillary from surrounding tissues.

As an author, his influence extended well beyond his own laboratory and his own time: his *Principles of Human Physiology* first appeared in 1912, and went through many editions during his lifetime, and continued for many years after his death under the editorial direction of former colleagues. See also **Physiology (The History)**.

STARVATION. A state of existence without food or with inadequate food. When animals are completely deprived of food their only source of energy for the essential processes of metabolism is the material already present in the body. The carbohydrate stored as glycogen is quickly used up, leaving only the stored fat, the circulating protein (see also **Amino Acids**), and the protein of the tissues. Studies of the progress of starvation in mammals have shown that the fat is almost completely used up and that the greatest loss of tissue proteins is from the muscles, due to their great bulk. In percentages, however, the liver, spleen, and gonads lose more of their bulk than other parts of the body, and the heart and central nervous system are maintained at the expense of the other parts with very little loss of substance. Extensive observations of the details of metabolism and bodily changes during starvation allowed to continue to the death of the animal have been recorded.

A remarkable result of starvation in some of the lower invertebrates is a progressive shrinkage of the body as a whole, in contrast with the emaciation that results in vertebrates. Observations on the flatworm, *Planaria*, have shown that ultimately it even retraces its development to assume an embryonic form.

STATE. 1. In its fundamental connotation, this term refers to the condition of a substance, as its state of aggregation, which may be solid, liquid, or gaseous — compact or dispersed.

2. As extended to a particle, the state may denote its condition of oxidation, as the state of oxidation of an atom, or the energy level, as the orbital of an electron, or in fact, the energy level of any particle.

3. In quantum mechanics, the word state is used in its most general context to refer to the condition of a system described by a wave function satisfying the Schrödinger equation for the system, when this wave function is simultaneously an eigenfunction of one or more quantum mechanical operators corresponding to one or more dynamical variables. If this set of operators includes all those which will commute with the ones in the set, then the state of the system is as completely specified as the Heisenberg uncertainty principle (see also **Uncertainty Principle**) allows and is characterized by the eigenvalues of these operators. These eigenvalues are the results which will always be found if measurements of the corresponding dynamical variables are made. In its more limited sense, the word state is used to refer to the condition of the system when its wave function is simultaneously an eigenfunction of the Hamiltonian operator. In this case the system is characterized by a definite value of the energy, i.e., the eigenvalue of the Hamiltonian operator, and is said to be an *energy eigenstate*, a *stationary state*, or a definite *energy state*.

STATIC AND NOISE. Names commonly applied to all the various random electrical disturbances picked up by a radio receiver. These can be divided into two general classes, natural and artificially generated (as from machines) static. The first is caused by various types of natural electrical discharges, the most pronounced being those of lightning. However, a static-producing discharge is not necessarily, or even usually, a visible lightning discharge. Various static charges are often continually building up and discharging in the atmosphere and hence inducing disturbances in the receiver. Cosmic radiations are also responsible for static. These types of natural static are often called atmospherics. The types of artificial static are almost as numerous as the electrical machines which people have developed. Any sparking contact or poor electrical connection will produce static which will be picked up by nearby receivers. Unfortunately many types of this interference may be fed back along the power lines and directly into the receiver. X-ray and diathermy machines are also sources of interference but cannot be properly classed as static.

The elimination of static presents a particularly difficult problem since the frequencies in the static pulse cover a wide band, certain types being more prevalent in some frequency ranges than others. Artificial static is best eliminated by correcting the fault at the source although a filter in the power line often helps if the disturbance is coming into the set through the line. Natural static can be minimized, but not eliminated. For amplitude modulation systems limiting the frequency band to which the receiver responds will reduce the noise. Various types of limiters will also reduce the effect since the static signal is frequently greater than the desired one.

Frequency modulation is inherently less susceptible to interfering noise and offers almost noise-free reception.

Noise in Industrial Measurement Systems.[1] Signals entering a data acquisition and control system include unwanted noise. Whether this noise is troublesome depends on the signal-to-noise ratio and the specific application. In general it is desirable to minimize noise to achieve high accuracy. Digital signals are relatively immune to noise because of their discrete (and high-level) nature. In contrast, analog signals are directly influenced by relatively low-level disturbances. The major noise-transfer mechanisms include conductive, inductive (magnetic), and capacitive coupling. Examples include the following:

- Switching of high-current loads in nearby wiring can induce noise signals by magnetic coupling (transformer action).
- Signal wires running close to ac power cables can pick up 50- or 60-Hz noise by capacitive coupling.
- Allowing more than one power or signal return path can produce ground loops that inject errors by conduction.

Conductance involves current flowing through ohmic paths (direct contact), as opposed to inductance or capacitance.

Interference via capacitive or magnetic mechanisms usually requires that the disturbing source be close to the affected circuit. At high frequencies, however, radiated emissions (electromagnetic signals) can be propagated over long distances.

In all cases, the induced noise level will depend on several user-influenced factors:

- Signal source output impedance.
- Signal source load impedance (input impedance to the data-acquisition system).
- Lead-wire length, shielding, and grounding.
- Proximity to noise source or sources.
- Signal and noise amplitude

Transducers that can be modeled by a current source are inherently less sensitive to magnetically induced noise pickup than are voltage-driven devices. An error voltage coupled magnetically into the connecting wires appears in series with the signal source. This has the effect of modulating the voltage across the transducer. However, if the transducer approaches ideal current-source characteristics, no significant change in the signal current will result. When the transducer appears as a voltage source (regardless of impedance), the magnetically induced errors add directly to the signal source without attenuation.

Errors also are caused by capacitive coupling in both current and voltage transducer circuits. With capacitive coupling, a voltage divider is formed by the coupling capacitor and the load impedance. The error signal induced is proportional to $2\pi fRC$, where R is the load resistor, C is the coupling capacitance, and f is the interfering frequency. Clearly, the smaller the capacitance (or frequency), the smaller the induced error voltage. However, reducing the resistance only improves voltage-type transducer circuits.

Example. Assume that the interfering signal is a 110-volt ac 60-Hz power line, the equivalent coupling capacitance is 100 pF, and the terminating resistance is 250 ohms (typical for a 4- to 20-mA current loop). The resulting induced error voltage will be about 1 mV, which is less than 1 LSB in a 12-bit 10-volt system.

If the load impedance were 100 kΩ, as it could be in a voltage input application, the induced error could be much larger. The equivalent R seen by the interfering source depends on not only the load impedance, but also the source impedance and the distributed nature of the connecting wires. Under worst-case conditions, where the wire inductance separates the load and source impedances, the induced error could be as large as 0.4 volt. This represents about an 8% full-scale error.

Even though current-type signals are usually converted to a voltage at the input to the data-acquisition system, with a low-value resistor this does not improve noise performance. This is because both the noise and the transducer signals are proportional to the same load impedance.

[1] Information furnished by H.L. Skolnik, *Intelligent Instrumentation, Inc.*, Tucson, Arizona.

It should be pointed out that this example does not take advantage of or benefit from shielding, grounding, and filtering techniques.

STATIC PRESSURE. In engineering fluid mechanics, the pressure in a homogeneous incompressible fluid in steady flow along a level streamline at points other than the stagnation point.

Thus if p is the static pressure, Bernoulli's equation gives

$$p + \frac{1}{2}\rho V^2 = p_1,$$

where ρ is the density of the fluid, V the speed, and p_1 the pressure at the stagnation point, called the total pressure. The kinetic energy per unit volume $(1/2)\rho V^2$ is also called the dynamic pressure. The static pressure is that measured by a barometer moving with the fluid. Since the static pressure is the pressure in the moving fluid and is distributed along the streamline exactly as the hydrodynamic pressure, the terminology is most unfortunately chosen. Since it is rigorously defined only when Bernoulli's equation applies, meteorologists do well in avoiding the term. The unqualified term "pressure" is quite satisfactory in this connection. However, the instrumental precautions taken in measuring the static pressure in fluid mechanics must also be applied to meteorological barometers so that it is the pressure and not the wind speed that is being measured. The measured meteorological pressure is in approximate hydrostatic equilibrium because of the relatively small vertical accelerations in the atmosphere, but this condition does not ordinarily obtain in those studies in which the concept of static pressure is used. Thus static pressure and hydrostatic pressure must be distinguished.

STATICS. Statics is the branch of mechanics that deals with particles or bodies in equilibrium under the action of forces or of torques. It embraces the composition and resolution of forces, the equilibrium of bodies under balanced forces, and such properties of bodies as center of gravity and moment of inertia.

Statics is the oldest branch of mechanics, some of its principles having been used by the ancient Egyptians and Babylonians in their constructions of temples and pyramids. As a science it was established by Archytas of Taras (ca. 380 B.C.) and primarily by Archimedes (287–212 B.C.). It was further developed by medieval writers on the "science of weights," such as Jordanus de Nemore (thirteenth century) and Blasius of Parma (fourteenth century). In the sixteenth century, it was revived by Leonardo da Vinci, Guido Ubaldi, and particularly by Simon Stevin (1548–1620) who laid the foundations of modern statics (inclined plane, equilibrium of pulleys, parallelogram of forces, etc.).

Although the laws of statics can in principle be derived from those of dynamics as a limiting case for vanished velocities or accelerations, statics has been developed, since the end of the eighteenth century, independently of dynamics. Its fundamental theme, like that of dynamics, is the concept of force, representing the action of one body on another and characterized by its point of application, its magnitude, and its direction (line of action), or briefly by a vector.

The following four principles may serve as the basic postulates for statics: (1) The principle of composition (addition) of forces; (2) the principle of transmissibility of force; (3) the principle of equilibrium; and (4) the principle of action and reaction.

Statistical analysis of framed structures or trusses, collections of straight members pinned or jointed together at the ends, is based on these principles.

STATICS (Graphical). The equilibrium of forces is often treated graphically in such practical problems as the stresses in the members of a framed structure. If three concurrent forces are in equilibrium, the three vectors drawn to a common scale to represent them may be made to form a closed triangle (Fig. 1); or if more than three, a closed polygon (Fig. 2). The principle may be extended and is much used in the calculation of the forces in a truss by means of the so-called stress diagram. A simple example is shown in Fig. 3, which represents a small roof-truss with equal loads resting on it at the joints A, B, C, D, E, and supported by the upward reactions of the walls at A and E. The several compartments of the figure are numbered, and both the external forces and the forces acting along the members between these compartments are represented, both in magnitude

and direction, by the lines joining the corresponding numbers in the stress diagram. For example, the compressive force in the strut BF is represented by the line 8–9, while the tension in the vertical rod CF is given by 9–10. The closed figure 5–4–10–9–5 in the stress diagram indicates the equilibrium of the forces acting at the joint C. This method of analysis is attributed to Maxwell. See also **Bow's Notation**.

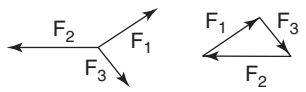

Fig. 1. Three forces in equilibrium.

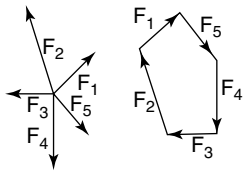

Fig. 2. Five forces in equilibrium.

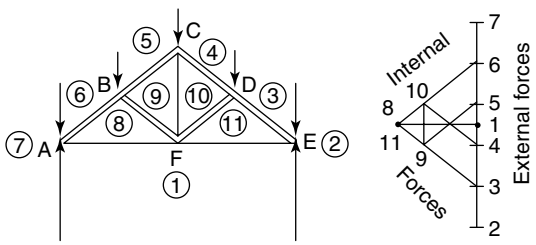

Fig. 3. Elevation of truss with corresponding stress diagram.

In the graphical solution of some types of trusses, it is found, on reaching a particular joint, that the arrangement of members is such that there are more than two unknowns. It is then necessary to replace the unknowns by a substitute system, which reduces the number of unknowns at the joint to two. The substitute system consists of a single member inserted in such a way that the truss remains stable and determinate. See also **Determinate Structure**. This member is called a substitute, fictitious or phantom member. When the solution reaches a joint where the stress in the members is unaffected by the substitution, the substitute arrangement is replaced by the original arrangement. The graphic procedure is reversed in direction to find the stress in the original members.

STATIC STABILITY. The ability of a fluid at rest to become turbulent or laminar due to the effects of buoyancy. Also called *hydrostatic stability*, *vertical stability*.

A fluid, such as air, tending to become or remain turbulent is said to be statically unstable; one tending to become or remain laminar is statically stable; and one on the borderline between the two (which might remain laminar or turbulent depending on its history) is statically neutral. The concept of static stability can also be applied to air not at rest by considering only the buoyant effects and neglecting all other shear and inertial effects of motion. However, if any of these other dynamic stability effects would indicate that the flow is dynamically unstable, then the flow will become turbulent regardless of the static stability. That is, turbulence has physical priority, when considering all possible measures of flow stability (e.g., the air is turbulent if any one or more of static, dynamic, inertial, barotropic, etc., effects indicates instability). Turbulence that forms in statically unstable air will act to reduce or eliminate the instability that caused it by moving less dense fluid up and more dense fluid down, and by creating a neutrally buoyant mixture. Thus, turbulence will tend to decay with time as static instabilities are eliminated, unless some outside forcing (such as heating of the bottom of a layer of air by contact with the warm ground during a sunny day) continually acts to destabilize the air. This latter mechanism is one of the reasons why the atmospheric boundary layer can be turbulent all day.

STATION. 1. In science generally, a permanent or temporary location where scientific observations and measurements are made.

In meteorology, several types of stations are officially defined, including first-order station; first-order climatological station; second-order station; second-order climatological station; third-order climatological station; climatological substation; ocean weather station. See also **Meteorology**.

2. In oceanography, the geographic location at which any set of oceanographic observations was taken; also, the observations recorded at the location.

STATIONARY STATE. 1. In a quantum-mechanical system, a state corresponding to a definite value of the energy.

2. A thermodynamic system is in a stationary state when its intensive variables are time-independent. The definition includes two classes of situations;

(1) *Equilibrium states*: the system is in thermodynamic equilibrium; no irreversible processes occur in it and there are no exchanges with the outside world. The entropy production vanishes.

(2) *Stationary nonequilibrium states*: in this case irreversible processes proceed in the system. The time-independence of the intensive properties is due to a compensation of the effect of the irreversible processes by exchanges with the outside world.

An isolated piece of metal initially at a nonuniform temperature will, of course, reach a state of thermodynamic equilibrium. But if we cool it at one end and heat it at the other, it will reach a stationary nonequilibrium state. Another example is afforded by a system that receives a component M from the outside environment and transforms it through a certain number of intermediate states into a final product F which is returned to the external environment. After some time a stationary state arises when the concentration of the intermediate components no longer vary with time.

One may say that stationary nonequilibrium states are reached when there exist some constraints that prevent the system from reaching true thermodynamic equilibrium. In the first example it is the difference of temperature at both ends, in the second, it is the value of the concentrations of the initial and final products in the external environment.

STATISTIC. A statistic is a function of the observations in a sample designed to estimate a parameter of the population from which the sample was drawn, or to carry out a test of significance of a hypothesis.

STATISTICAL MECHANICS. One major problem of physics involves the prediction of the macroscopic properties of matter in terms of the properties of the molecules of which it is composed. According to the ideas of classical physics, this could have been accomplished by a determination of the detailed motion of each molecule and by a subsequent superposition or summation of their effects. The Heisenberg indeterminacy principle now indicates that this process is impossible, since we cannot acquire sufficient information about the initial state of the molecules. Even if this were not so, the problem would be practically insoluble because of the extremely large numbers of molecules involved in nearly all observations. Many successful predictions can be made, however, by considering only the average, or most probable, behavior of the molecules, rather than the behavior of individuals. This is the method used in statistical mechanics.

In the general approach to classical statistical mechanics, each particle is considered to occupy a point in phase space, i.e., to have a definite position and momentum, at a given instant. The probability that the point corresponding to a particle will fall in any small volume of the phase space is taken proportional to the volume. The probability of a specific arrangement of points is proportional to the number of ways that the total ensemble of molecules could be permuted to achieve the arrangement. When this is done, and it is further required that the number of molecules

and their total energy remain constant, one can obtain a description of the most probable distribution of the molecules in phase space. The Maxwell-Boltzmann distribution law results.

When the ideas of symmetry and of microscopic reversibility are combined with those of probability, statistical mechanics can deal with many stationary state nonequilibrium problems as well as with equilibrium distributions. Equations for such properties as viscosity, thermal conductivity, diffusion, and others are derived in this way.

The development of quantum theory, particularly of quantum mechanics, forced certain changes in statistical mechanics. In the development of the resulting quantum statistics, the phase space is divided into cells of volume h^f, where h is the Planck constant and f is the number of degrees of freedom. In considering the permutations of the molecules, it is recognized that the interchange of two identical particles does not lead to a new state. With these two new ideas, one arrives at the Bose-Einstein statistics. These statistics must be further modified for particles, such as electrons, to which the Pauli exclusion principle applies, and the Fermi-Dirac statistics follow.

It is often possible to obtain similar or identical results from statistical mechanics and from thermodynamics, and the assumption that a system will be in a state of maximal probability in equilibrium is equivalent to the law of entropy. The major difference between the two approaches is that thermodynamics starts with macroscopic laws of great generality and its results are independent of any particular molecular model of the system, while statistical methods always depend on some such model.

STATOR. In machinery, a part or assembly that remains stationary with respect to a rotating or moving part or assembly, such as the field frame of an electric motor or generator, or the stationary casing and blades surrounding an axial-flow compressor rotor or turbine wheel; a stator blade.

STAUROLITE. The mineral staurolite is a complex silicate of iron and aluminum corresponding to the formula $(Fe,Mg,Zn)_2Al_9Si_4O_{23}$ (OH) but somewhat varying and may carry magnesium or zinc. It is orthorhombic, prismatic, twins common, often producing cruciform crystals. It is a brittle mineral; fracture, subconchoidal; hardness, 7–7.5; specific gravity, 3.65–3.83; luster, subvitreous to resinous; color, dark brown, sometimes reddish to nearly black; grayish streak; translucent to opaque. Staurolite is a metamorphic mineral usually the result of regional rather than contact metamorphism, and is common in schists, phyllites and gneisses together with garnet, kyanite, and tourmaline.

Well-known European localities are in Switzerland and Brittany; and in the United States this mineral is common in the schists of New England, and those of the southern Alleghenies. Frequently the crystals are found loose in the soil after the disintegration of the country rock. The name staurolite is derived from the Greek meaning a cross, in reference to the twin crystals, the more nearly perfect crosses being somewhat in demand as curios.

STAYBOLT. The surfaces of pressure vessels, such as boiler drums and tanks, which are not of a natural bulged shape, such as the cylinder or the sphere, must be stayed against bulging by special tension rods called staybolts.

STEADY STATE. A characteristic of a condition, such as value, rate, periodicity, or amplitude, exhibiting only negligible change over an arbitrary long period of time. It may describe a condition in which some characteristics are static; others dynamic. The *steady-state deviation* of a system may be defined as the system deviation after transients have expired.

In medical parlance, a relatively steady condition of processes within the body sometimes is referred to as *homeostasis*.

STEAM. Steam [CAS: 7732-18-5], gaseous H_2O, is the most important industrially used vapor and, after water, the most common and important fluid used in chemical technology. Steam is generated from water by boiling, flash evaporation, and throttling from high to low pressure. The phase change occurs along the saturation line such that the specific volume of steam is larger than that of the boiling water. Thermal energy, i.e., the heat of evaporation, is absorbed during the process. At the critical and supercritical pressures, the water–steam distinction disappears, and the fluid can go from water-like properties to steam-like properties without an abrupt change in density or enthalpy. Properties of steam can be divided into thermodynamic, transport, physical, and chemical properties. See also **Evaporation**; and **Water**.

Physical Properties

Official Properties. The International Association for Properties of Water and Steam (IAPWS), an association of national committees that maintains the official standard properties of steam and water for power cycle use, maintains two formulations of the properties of water and steam. The first is an industrial formulation, the official properties for the calculation of steam power plant cycles. This formulation is appropriate from 0.001 to 100 MPa (0.12–1450 psia) and from 0 to 800 °C (32–1472 °F) and also from 0.001 to 10 MPa (0.12–145 psia) between 800 and 2000 °C (1472–3632 °F). This formulation is used in the design of steam turbines and power cycles. IAPWS maintains a second formulation of the properties of water and steam for scientific and general use from 0.01 MPa (extrapolating to ideal gas) at 0 °C (1.45 psia at 32 °F) to the highest temperatures and pressures for which reliable information is available. See also **Water**.

Thermodynamic Properties. Ordinary water contains three isotopes of hydrogen [CAS: 1333-74-0], i.e., ^1H, ^2H, and ^3H, and three of oxygen [CAS: 7782-44-7], i.e., ^{16}O, ^{17}O, and ^{18}O. The bulk of water is composed of ^1H and ^{16}O. Tritium [CAS: 15086-10-9], ^3H, and ^{17}O are present only in extremely minute concentrations, but there is about 200-ppm deuterium [CAS: 16873-17-9], ^2H, and 1000-ppm ^{18}O in water and steam. See **Deuterium** and **Tritium**. The thermodynamic properties of heavy water are subtly different from those of ordinary water. The properties given herein are for ordinary water having the usual mix of isotopes.

Vapor pressure is one of the most fundamental properties of steam. Figure 1 shows the vapor pressure as a function of temperature for temperatures between the melting point of water and the critical point. This line is called the saturation line. Liquid at the saturation line is called saturated liquid; liquid below the saturation line is called subcooled. Similarly, steam at the saturation line is saturated steam; steam at higher temperature is superheated. Properties of the liquid and vapor converge at the critical point, such that at temperatures above the critical point, there is only one fluid. Along the saturation line, the fraction of the fluid that is vapor is defined by its quality, which ranges from 0 to 100% steam.

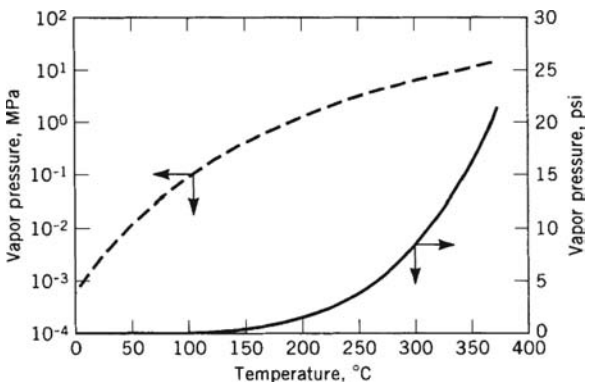

Fig. 1. Vapor pressure of ordinary water, where (_____) represents linear and (– – –) logarithmic scale. To convert MPa to psi, multiply

The density of saturated water and steam is a function of temperature. As the temperature approaches the critical point, the densities of the liquid and vapor phase approach each other. This fact is crucial to boiler construction and steam purity, because the efficiency of separation of water from steam depends on the density difference.

The enthalpies and internal energies of steam and water also converge at the critical point. The heat capacity at constant pressure, C_p, is defined as the derivative of enthalpy with respect to temperature. The value of C_p

becomes very large in the vicinity of the critical point. The variation is much smaller for the heat capacity at constant volume, C_v.

Transport Properties. Viscosity, thermal conductivity, the speed of sound, and various combinations of these with other properties are called steam transport properties, which are important in engineering calculations. The speed of sound is important to choking phenomena, where the flow of steam is no longer simply related to the difference in pressure. Thermal conductivity is important to the design of heat-transfer apparatus. See **Heat-exchange Technology**. The viscosity, ie, the resistance to flow under pressure, is shown in Figure 2. The sharp declines evident in each of these properties occur at the transition from liquid to gas phase, i.e., from water to steam. The surface tension between water and steam is shown in Figure 3.

Miscellaneous Properties. The dielectric constant is a physical property having great importance to the chemical properties of hot water and steam. Along the saturation line, the steam and water values converge at the critical point. The ability of water to dissolve salts results from the high dielectric constant. The precipitous drop in water dielectric constant in the region of the critical point is very important to the solubility of salts in water near the critical temperature. Many salts exhibit declining solubilities as the critical temperature is approached and then exceeded. The drop in dielectric constant is largely a result of the decline in density.

The ion product of water is the product of the molality of the hydrogen and hydroxide ions, $K_w = m_{\mathrm{H}} + m_{\mathrm{OH}}-$. The ion product increases with temperature to 250 °C and then declines. The initial increase is the temperature effect, and the later decline is on account of the decline in the dielectric constant of water. This variation means that neutral pH, which is the square root of the ion product, varies with temperature.

Chemical Properties

Molecular Nature of Steam. The molecular structure of steam is not as well known as that of ice or water. There are indications that in the steam phase some H_2O molecules are associated in small clusters of two or more molecules.

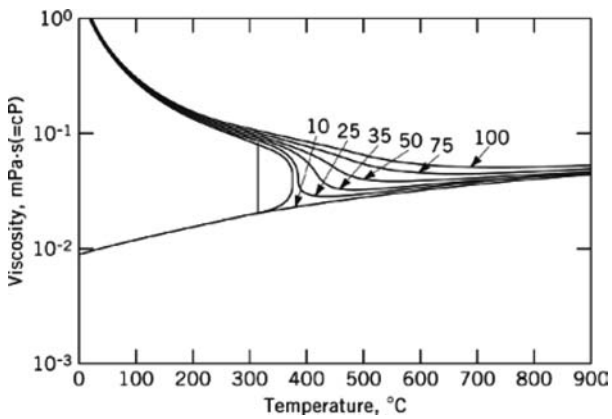

Fig. 2. Viscosity of water and steam as a function of temperature. Values given correspond to pressures in MPa. To convert MPa to psi, multiply by 145.

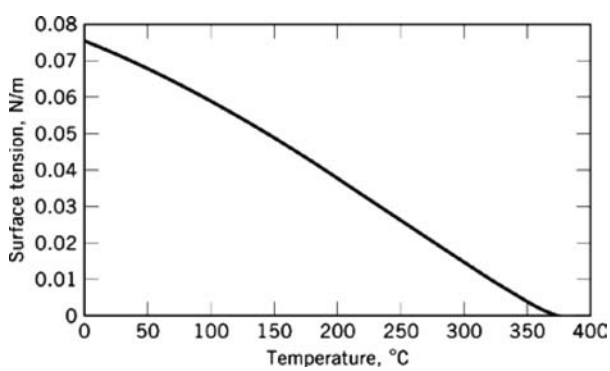

Fig. 3. Surface tension between liquid water and steam along the saturation line.

Solvent. The solvent properties of water and steam are a consequence of the dielectric constant. At 25 °C (77 °F), the dielectric constant of water is 78.4, which enables ready dissolution of salts. As the temperature increases, the dielectric constant decreases. The solubility of many salts declines at high temperatures. As a consequence, steam is a poor solvent for salts. Although the solubility of salts in steam is small, it has great significance to corrosion of steam system components, particularly steam turbines. At the critical point and above, water is a good solvent for organic molecules.

Reactant. Steam can behave as an oxidant. Steam reacts with salts so that the salts dissociate into the respective hydroxide and acid. For sodium salts, the sodium hydroxide is largely in a liquid solution and the acid is volatile. STEAM CYCLES (Diagram Factor). This is a factor relating particularly to piston and cylinder engines. Although it has a meaning applied to internal combustion engines, diagram factor is principally a dimension of the steam engine. Certain analyses of the steam engine, especially those concerned with predicting the performance of a given unit under stated steam conditions, are most easily made with the use of the diagram factor. This factor is defined as the ratio of the actual mean effective pressure to the theoretical effective pressure; also as the actual work to the theoretical work. The theoretical case is that of a steam engine having no compression, no wire drawing, and no clearance.

The ratio of the area of this cycle to that of the actual engine operating between the same pressure limits, is typical for any one class of engine. The following table gives some values of diagram factor for steam engines. Knowing the steam conditions, and the type of engine, the probable pressure and horsepower realizable can be closely estimated by calculating the theoretical quantities and multiplying them by the diagram factor. In this light, diagram factor is a means of modifying theoretical calculations to bring them in line with actual experience.

DIAGRAM FACTORS

High-speed, simple automatic	0.70–0.85
Low-speed, releasing gear	0.80–0.90
Uniflows	
Full compression, condensing	0.75–0.85
Full compression, noncondensing	0.70–0.80
Controlled compression, condensing	0.85–0.90
Controlled compression, noncondensing	0.80–0.85

$$P_a = P_t \times f$$

$$IHP = \frac{2P_aLAN}{33{,}000}$$

P_a = actual mean effective pressure, in pounds per square inch
P_t = theoretical mean effective pressure, in pounds per square inch
f = diagram factor
IHP = indicated horsepower (steam engine)
L = stroke in feet
A = piston area, in square inches
N = rotative speed, in revolutions per minute

STEAM ENGINE. A positive displacement piston and cylinder machine, which, when supplied with steam at a pressure above its exhaust pressure, uses that steam expansively for the production of power that it makes available as a rotating torque at a crankshaft or flywheel. The steam engine is, with few exceptions, double acting. The steam engine is characterized by moderate or low speeds (100–500 rpm), the use of atmospheric exhaust (or a moderate vacuum), high starting torque, and ease of conversion to reversible operation if desired. The excellence of the steam turbine when a large amount of power is to be generated, especially where the exhaust is at a high vacuum, coupled with the high efficiency of the diesel engine as a prime mover, has restricted the steam engine as a prime mover. However, where a boiler must be supplied anyway, as for the generation of heating steam, the steam engine is usually superior to the diesel engine as a source of power. And, where exhaust pressures are high (often the case in industry, where the exhaust is process steam), the steam engine offers advantages which are not seriously challenged by the other types of prime movers.

The principal parts of a steam engine are:

1. The frame or bedplate. In a multicylindered engine, this takes the form of a crankcase to which the cylinders are attached, but in a single-cylindered engine, the cylinder is often integral with the frame.
2. Cylinder, with valve chest.
3. Piston, piston rod, crosshead, connecting rod. This mechanical linkage receives a push from steam pressure at one end, and delivers it as a torque force on the crank.
4. Crankshaft, bearings, and flywheel. This part of the engine accomplishes the conversion of reciprocating to rotary motion, supports the shaft for power offtake, and steadies the speed.
5. Valves and valve gear. The device for admission and release of the steam to and from the cylinder, together with the means for actuating it from the crankshaft.
6. Governor. Stationary engines are automatically regulated for constant speed by means of a governor.
7. Lubrication. The piston and cylinder are lubricated by oil mixed with the steam.

A steam engine converts from 5 to 15% of the heat supplied to it into work, depending on the state of the steam supplied, and on the exhaust pressure. The heat unconverted is composed: first, of heat remaining in the exhaust steam; second, initial condensation; third, incomplete expansion; fourth, wire drawing; fifth, friction; and sixth, radiation (negligible). The first of these is the largest, and is reducible only within certain limits. Incomplete expansion results from the release of the steam at the end of the stroke at a pressure higher than the exhaust. By using a longer stroke, this could be eliminated, but there is a point beyond which the increased cost of the engine more than offsets the gain derived by eliminating this loss.

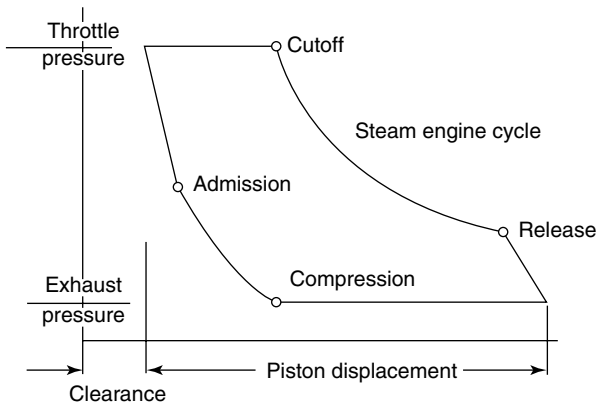

Fig. 1. Steam engine cycle.

The cycle upon which the engine operates is briefly described as follows (Fig. 1): slightly before the piston reaches the dead-center position corresponding to minimum cylinder volume, the valve connects the cylinder with the steam line so that as the piston starts on its outward travel, the full steam pressure is acting on it. The beginning of this action is known as the event of *admission*. When some 20 to 30% of the stroke has been completed, the valve closes the port on the event known as *cutoff*, and during the remainder of the stroke, the steam is expanded adiabatically to the accompaniment of decreasing pressure. Near the end of its stroke, the valve again opens the port, this time connecting the cylinder with the exhaust line. This event is known as *release*. The cylinder remains connected with the exhaust during the return stroke of the piston, and the steam is expelled until approximately $\frac{2}{3}$ of the return stroke has been completed. The valve then closes the port, and the remaining steam is trapped in the cylinder and compressed. The beginning of this process is known as the event of *compression*. The four events just described govern the form of the steam engine cycle. The engine using it will be able to develop a horsepower hour using from 10 to 25 pounds of steam, depending upon the expansion permitted by the terminal conditions of the steam.

The steam engine may be mechanically controlled to give variable output so that when it is connected to a load that varies, it maintains nearly constant speed. There are two methods of accomplishing this result. In one, called cutoff governing, the percent of the stroke during which the valve connects the cylinder with the boiler is varied, and in this way, different amounts of steam are admitted to the cylinder at one pressure. The mechanism to effect this type of control is incorporated in the valve drive. The other method, called throttling governing, consists of interposing an artificial resistance to create a pressure drop between the boiler and the engine, so that although the same volume is admitted on each stroke (the cutoff being constant), the weight of steam admitted will vary because of the variation in density created by throttling. The governor, in this case, operates on a throttle valve located at the steam inlet.

STEAM FOG. See **Fog and Fog Clearing**.

STEARIC ACID AND STEARATES. [CAS: 57-11-4]. Stearic acid $H \cdot C_{18}H_{35}O_2$ or $C_{17}H_{35} \cdot COOH$ or $CH_3(CH_2)_{16} \cdot COOH$ is a white solid, melting point 69 °C, boiling point 383 °C, insoluble in water, slightly soluble in alcohol, soluble in ether. Stearic acid may be obtained from glyceryl tristearate, present in many solid fats such as tallow, and in smaller percentage in semisolid fats (lard) and liquid vegetable oils (cottonseed oil, corn oil), by hydrolysis. The crude stearic acid, after separation of the water solution of glycerol, is cooled to fractionally crystallize the stearic and palmitic acids, which are then separated by filtration (oleic acid in the liquid), and fractional distillation under diminished pressure. With sodium hydroxide, stearic acid forms sodium stearate, a soap. Most soaps are mixtures of sodium stearate, palmitate and oleate.

The following are representative esters of stearic acid: Methyl stearate $C_{17}H_{35}COOCH_3$, melting point 38 °C, boiling point 215 °C at 15 millimeters pressure; ethyl stearate $C_{17}H_{35}COOC_2H_5$, melting point 35 °C, boiling point 200 °C at 10 millimeters pressure; glyceryl tristearate [tristearin $C_3H_5(COOC_{17}H_{35})_3$], melting point 70 °C approximately.

Stearic acid is used (1) in the preparation of metallic stearates, such as aluminum stearate for thickening lubricating oils, for waterproofing materials, and for varnish driers, (2) in the manufacture of "stearin" candles, and is added in small amounts to paraffin wax candles. As the glyceryl ester, stearic acid is one of the constituents of many vegetable and animal oils and fats.

See also **Rubber (Natural)**.

STEARONE. An aliphatic ketone, insoluble in water, stable to high temperatures, acids, and alkalies; compatible with high-melting vegetable waxes, paraffins, and fatty acids; incompatible with resins, polymers and organic solvents at room temperature but compatible with them at high temperature.

STEELYARD. An early type of scale that employs an unequal first class lever arm constructed so that the fulcrum point can be suspended from above, such as by a hook on the end of a chain, the other end of the chain being fastened to a ceiling support. The load is suspended from the end of the short lever arm. A sliding poise on the long end of the lever arm is positioned to balance the load. Although largely replaced by spring scales, the steelyard, because of its portability and low cost, still finds limited, use, particularly in underdeveloped nations. See Fig. 1.

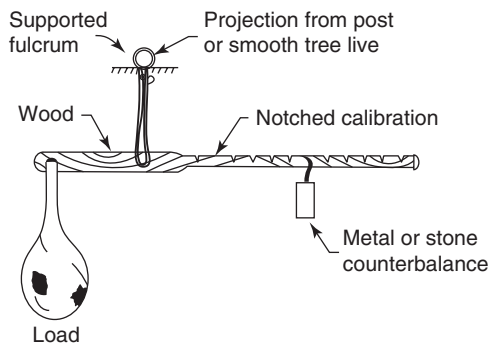

Fig. 1. Steelyard used for weighing since ancient times.

STEENSTRUP, J. JAPETUS S. (1813–1897). J. Japetus S. Steenstrup was a Danish naturalist best known for his work on the type of development that he called the *alternation of generations*.

Steenstrup, a classic example of a broadly based nineteenth century naturalist, was born in northern Jutland, the son of a parson, and graduated from the University of Copenhagen in 1837. In 1841, after participating in a government-sponsored geological investigation of Iceland, then a Danish colony, he was appointed Lecturer in Botany and Geology at the Academy of Soroe. There he published his most famous works: one on postglacial succession in Danish bogs (1842), another on the existence of hermaphroditism (1845), translated into German (1846), and his most influential, translated into German (1844) and into English (1845) as *On the Alternation of Generations*.

It described how cnidarians, salps, and the parasitic trematodes and cestodes developed quite differently from other animals. Whereas in most animals then known an egg developed directly into an adult, or, as in insects and some recently discovered benthic invertebrates, the egg developed into a larval stage which then changed slowly or suddenly into the adult form, in these animals the parent produced offspring that not only differed in form from the parent but also reproduced asexually to produce again many parent animals. Thus each life cycle showed an alternation between the adult generation and what he called a *nurse generation*, in that he believed that they nursed the eggs produced by the adult. Because of Steenstrup's vague definition of the phenomenon, the alternation of generations became a much-debated topic during the nineteenth century. What was the essential nature of this phenomenon? Did it also occur in plants?

In 1846, as a result of these publications, he gained the chair of Zoology at the University of Copenhagen, where he remained until his retirement in 1885. There he gained many honors and published very widely in natural history. These included studies on marine invertebrates, fishes, marine mammals, parasites, paleontology of peat bogs and Danish archaeology.

STELE. The vascular tissue of the axis of a plant is called the stele or central cylinder. The principal tissues composing it are the xylem and the phloem. Others are pith, pith rays, cambium, and pericycle. The most primitive type is the protostele, which consists of a solid central mass of xylem surrounded by a cylinder of phloem. There is no pith in a protostele. Protosteles are found in the roots of all plants and in the stems of some of the ferns. Many would set off the stele of the root as a separate type known as a radial stele, since the central mass of xylem is not a cylinder, but has several arms projecting outward from its surface, with the phloem concentrated between these arms. In stems, only those of certain Lycopsida like *Lycopodium*, have radial steles.

STELLAR HEAT INDEX. As applied to a star, the difference between the visual and radiometric magnitudes: i.e.,

$$\text{heat index} = m_v - m_r$$

where m_r is the radiometric magnitude and m_v is the visual magnitude. A radiometric magnitude is obtained by measuring the overall energy brightness of a star by means of a thermocouple or bolometer, and by reducing the readings to outside atmosphere after correcting for losses in the optical system.

STELLAR LUMINOSITY. The intrinsic brightness of a star may be expressed either in terms of its absolute magnitude or in terms of the sun's brightness as unity. The luminosity of a star is defined as its intrinsic brightness in terms of the brightness of the sun as unity. That is, if our sun were replaced by a star of luminosity 100, the light received by the earth would be 100 times as great.

STELLAR MAGNITUDE. In the first star catalogues issued by Hipparchus and Ptolemy, the relative apparent brightness of the stars was designated by a system of six numbers referred to as the magnitudes of the stars. Twenty of the brightest stars were referred to as first magnitude, and those at the limit of visibility were called sixth magnitude. The stars with brightness intermediate between the two extremes were assigned to a magnitude number with the numbers increasing with faintness of the stars. With the application of the telescope to astronomy, many faint stars were discovered and the need for additional magnitude numbers became evident. Unfortunately for modern astronomers, the attempt was made to amplify the ancient magnitude system not only to include the fainter stars, but also to indicate finer gradations of brightness by a decimal system. The result is that astronomers are now using a system that was started about 2,000 years ago and has all the clumsiness and inconvenience for modern observers that is characteristic of so many of the ancient scientific instruments.

There is no definite evidence that Hipparchus or Ptolemy had any idea in mind at the time they first used the magnitude system other than to provide a rough descriptive term for the stars. In the early part of the nineteenth century, Sir John Herschel found that the apparent brightness of a first magnitude star is about 100 times that of a sixth magnitude star. In 1850 Pogson proposed a fixed scale of stellar magnitudes based upon the original scale of Hipparchus and Ptolemy, but so adjusted that it would agree at the sixth magnitude with the system employed by Argelander in his famous Bonner Durchmusterung. Adopting the announcement of Herschel that the ratio of brightness of a first and sixth magnitude star is approximately 100, Pogson proposed that the ratio between successive magnitudes should be $\sqrt[5]{100}$ or approximately 2.512. This leads to an analytical expression for the magnitude scale as follows:

Let I_1 be the intensity of a star of apparent magnitude m_1, and $I2$ the intensity of a star of apparent magnitude m_2; then

$$\frac{I_1}{I_2} = 2.512^{(m_2 - m_1)}$$

or

$$\log I_1 - \log I_2 = 0.4(m_2 - m_1)$$

Since the magnitude scale is a scale of relative brightness, it is necessary to establish a system of standards. For this purpose, a group of stars in

the immediate vicinity of the north celestial pole has been selected. The magnitudes of the stars in this "north polar sequence" have been very carefully determined and agreed upon by the International Astronomical Union. All magnitudes determined at the present time should be referred, either directly or indirectly, to this standard sequence. More recently, Johnson and Morgan have set up a series of "photometric standard stars" whose magnitudes are strictly given on a specified system.

The magnitude scale as originally established referred to the relative apparent visual brightnesses of the stars. With the application of photography to astronomy, difficulty with the magnitude scale immediately became evident. If we have two stars of the same visual magnitude, one of them blue and the other red, the photographic image of the blue star will be much stronger than the photographic image of the red star. The colors of the stars in the sky vary with the different spectral types, and the visual magnitude differences between a number of stars of different spectral types will differ considerably from the magnitude differences obtained by photographic means. Furthermore, the photographic magnitudes, so-called, will be different, depending upon the type of plate used and the characteristics of different telescopes, and it becomes necessary to be very explicit in defining the particular range of wavelengths of spectral energy that are to be used in any magnitude scale. The difference between the photographic and visual magnitudes of a star is known as the color index of the star, the term arising from the fact that the color is the determining factor in the magnitude scale difference.

With the application of various other types of radiation measuring instruments, such as bolometers and radiometers, to the measurement of the apparent brightness of the stars, the necessity has arisen for various different magnitude scales, such as bolometric magnitude, radiometric magnitude, etc. The problem of the intercorrelation of the different systems is at present in a very confused state and much research is being carried on in this important field. It is hoped that in the future some system of expressing the apparent brightnesses of the stars may be devised that will replace the present complicated inverse logarithmic scale of magnitudes.

For the purpose of expressing the intrinsic brightness of a star, independent of the distance of the star from the earth, a system of absolute magnitudes has been devised.

The apparent brightness of a star, or any other luminous object, depends both upon the intrinsic brightness of the object and also upon its distance from the observer. In the case of the stars, the apparent brightness, expressed as stellar magnitude, may be determined by any one of the standard methods of stellar photometry. In case the distance of the star is known, the intrinsic brightness may be immediately calculated. Conversely, if there is any method available for determining the intrinsic brightness of a star independently of a knowledge of the distance, this distance may be computed from the ratio between the apparent and intrinsic brightness.

The absolute magnitude of a star is the apparent brightness, expressed on the magnitude scale, that a star would have if it were situated at a distance of ten parsecs from the sun or, in other words, if the stellar parallax of the star were $\frac{1}{10}$ of a second. Analytically, the absolute magnitude, M, of a star is connected with the apparent magnitude, m, and the stellar parallax, π, by:

$$M = m + 5 + 5 \log \pi$$

On this scale, we find the sun, with apparent magnitude -26.72 and parallax $206265''$, to have an absolute magnitude of 4.85. Antares with parallax $0''.009$ and apparent magnitude 1.22 is found to have an absolute magnitude of -4.0. On the basis of these absolute magnitudes and the defining relation of the magnitude scale, we find that the brightness ratio of Antares to the sun is 3470, or that the star Antares is actually 3470 times brighter than the sun.

The zero point of the absolute magnitude scale is arbitrary. By convention, a normal A0 main sequence star has an absolute magnitude of zero and a color index of zero, as well.

STELLAR PARALLAX. A term used by astronomers as a means for expressing the distance of a given star. Technically defined, stellar parallax is the angle that would be subtended by the mean distance of the Earth from the sun (one astronomical unit) at the distance of the star from the sun. The symbol π is used, and as the angle is always small, it is always given in seconds of arc; this measure is understood unless explicitly stated otherwise.

From the earliest days of the Pythagoreans, any theory of the structure of the universe that postulated that the Earth might move about the sun was objected to, on the ground that such motion should produce an apparent motion of the stars. Copernicus, in proposing his heliocentric theory, met this objection by postulating that the distances of the stars were so incomparably greater than the distance of the Earth from the sun that no instrumental methods would be capable of detecting the motion even if it did exist. The attempts to test the Copernican doctrine by searching for this so-called stellar parallax gave a tremendous impetus to the design of accurate instruments, but even with the improvement in instrumental equipment, the effect was not observed, and the Copernican theory lost ground. It was not until 1838 that Bessel was able definitely to prove that the effect is present.

The type of effect to be looked for is illustrated in Fig. 1. The type of curve that the stars should apparently follow due to the Earth's motion about the sun varies from an eclipse with eccentricity equal to that of the Earth's orbit for stars at the pole of the ecliptic, to oscillations back and forth along a straight line for stars in the plane of the ecliptic.

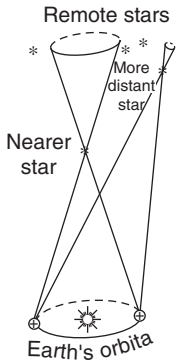

Fig. 1. Parallaxes of the stars. Owing to Earth's revolution, the nearer stars describe parallax orbits annually with respect to the remote stars.

The problem of determination of stellar parallax is theoretically very simple. All that is necessary is to make a series of observations of the positions of a star on any system of spherical coordinates (e.g., right ascension and declination) and from the observed changes in position throughout the year determine the stellar parallax. This so-called absolute method was attempted many times but failed to reveal any definite value because of the fact that the instrumental errors were larger than the effect sought. This is not surprising when we consider that the largest stellar parallax ever found (for the star Proxima Centauri) has a value of $0''.783$, equivalent to the angle subtended by a ten-cent piece at a distance of approximately 3 miles. (See also **Spherical Polar Coordinates**.)

With the failure of the absolute method to yield values for the parallaxes of the stars, Bessel and Struve decided upon an indirect or relative method for determining the desired quantity. This method is based upon the assumption that certain stars are at such a great distance that their parallaxes are too small for detection, but that there are other stars closer to the sun which should show motion relative to the distant background. Bessel selected the star 61 Cygni, which was assumed to be relatively close to the Earth from a large proper motion, while Struve selected the star Vega, which has an appreciable proper motion and is also so bright as to imply closeness to the Earth. Proceeding by different methods, both Bessel and Struve, in 1838, were able to show that the stars they had selected showed parallactic motion relative to the background of stars.

Until the application of photography to astronomy, the problem of determination of stellar parallaxes was very tedious and laborious, and up to 1880, the distances of fewer than 25 stars had been determined. With the application of photography, the progress of parallax determination became much more rapid, and at present, a number of long programs of observations in both the northern and southern hemispheres have been completed.

The photographic method consists in first selecting stars that are suspected, either from proper motion, spectral type, or other characteristics, to be relatively close to the sun. Plates are taken of these stars, great care being exercised in the guiding, and the brightness of the "parallax star" is reduced until its photographic image compares favorably with the images of the fainter "background stars." The plates are all taken at the same hour angle, either east or west, to eliminate so far as possible atmospheric effects, and the dates on which the plates are taken are separated as much as they can be, to make the effect of the Earth's motion as large as possible. Twenty or thirty plates, extending over several years, are taken, and the position of the parallax star is carefully measured with reference to half-a-dozen background stars. A least squares solution will yield the motion of the star relative to the background. This motion will consist both of the proper motion and the parallactic shift. The former may be separated from the latter, because proper motion is linear in character, whereas the parallactic shift is periodic. For stars within 5 million times the sun's distance from the earth (parallax $0''.04$), the mean of two or three determinations will be correct within 20 percent. For twice this distance, the results are only accurate enough for statistical purposes, and beyond this distance, the trigonometric method is practically valueless. Occasionally, due to an unfortunate choice of parallax star or comparison stars, the value of the stellar parallax comes out to be a negative quantity. Such a "negative parallax" simply means that the star under observation is more distant than those selected for comparison purposes. For the more distant stars beyond the range of the trigonometric method, certain other methods are available, such as: parallaxes of members of moving clusters; mean parallaxes; dynamical parallaxes of double stars; and spectroscopic parallaxes.

See also **Dynamical Parallax**; and **Star**.

STEM (Plant). The stem of a plant is that part that bears the leaves and flowers and later fruits. Commonly it grows erect, lifting these various organs up above the ground. It is readily distinguished from the root by being separated into joints or nodes and internodes, and by bearing leaves or by having on its surface scars left by the falling of leaves.

Stems may be classified in several ways. If one considers the duration of the stem, it becomes an annual lasting but one year, a biennial living 2 years, or a perennial stem, which grows for several years. If one considers the internal structure of the stem, he finds it to be herbaceous or woody. An herbaceous stem is one which is largely made up of parenchymatous cells, without a great mass of woody tissue. In temperate regions such stems last but a single year, at the end of which they die. In annuals, the entire plant dies, while in herbaceous perennials the top dies, but the basal portion including the root and the lower stem lives on. Woody plants are those in which the stem is predominantly composed of vascular tissues. Such plants are either trees or shrubs or vines. Trees are commonly distinguished by the existence of a single stem or trunk, which does not branch at its base, whereas in shrubs no single trunk exists, but several of equal size result from basal branchings. Branching is either excurrent or deliquescent. When excurrent, the trunk is distinctly recognizable throughout its length, the branches coming from it being much smaller, as in many conifers such as spruce or fir. Usually such trees have a conical shape, due to the progressively smaller branches from bottom to top of the tree. In deliquescent branching, the main trunk branches into several large branches, which in turn divide, as in the elm. Vines are distinguished by their long relatively slender stems, which usually require external support. Another classification separates erect stems from those which are procumbent or trailing on the ground, from stems which clamber over supports, and from twining stems, which wind tightly around any supporting object.

In many plants the stem is very much reduced in size, appearing as a small often flattened ball, as in the common Cyclamen or in certain Cactus plants. Other plants are said to be stemless, the stem existing only as a small object at the top of the root, the leaves arising from it seeming to come directly from the top of the root. A familiar example is the dandelion. The first year of growth in many biennials results in a similarly stemless plant; carrots, beets, and parsnips are common examples.

As previously noted, one of the functions of the stem is to elevate the leaves into a position where they may function most efficiently, and to elevate the flowers to a position where they may become more conspicuous, and where the resulting fruits may be better scattered. Not only does the stem perform this function, but it also permits a great increase in the number of leaves and flowers which may be borne. The stem is the organ through which sap ascends from the root to the leaves, and through which organic materials elaborated in the leaves pass to the place of storage. The stem itself may be the place in which materials are stored.

The stem develops from a bud. In the seeds, the embryo has a terminal rudimentary bud, the plumule, from which the first stem develops. The tip of this stem bears a terminal bud, from which further increase in the stem is developed. In the axils of the leaves lateral buds are formed which develop into branches. Elongation of the stem takes place only in the tip, extending downward therefrom a few inches, and is caused by the cellular changes like those that occur also in the elongating root. In some plants, as in Grasses, intercalary growth also occurs. This is growth in the region of the older nodes of the stem. Increase in diameter of the stem results from the divisions of special cells called cambium cells.

When the extreme variations of stem are considered, with their range from tiny plants less than half an inch in height to forest giants towering 300 feet (91 meters) and over, and from vines with slender wiry stem less than $\frac{1}{16}$ inch in diameter through succulent herbs to sturdy trunks 40 feet or more through, it is not surprising that stem structure should be very variable and often complex. Yet they are all composed of the same types of cells and are all arranged on two fundamental patterns, one found in dicotyledonous plants, the other characterizing the monocotyledons.

In dicotyledons, the growing tip of the young stem has cells that are all alike, having a dense cytoplasm, and large nuclei, which, if the stem is growing, will be dividing frequently. These cells comprise the promeristem, the region where active cell division occurs, but little change in cell form.

As these cells increase in number, some are carried ahead, while others remain unchanged in position. The latter gradually show very evident changes in size and shape, and in the nature of their walls. The outermost layer, called the dermatogen or protoderm, is made up of somewhat flattened cells which will become the epidermis, a protective covering against entrance of disease-producing organisms and against excessive loss of water. Within the body of the stem tip certain strands of cells become distinct by their elongate shape and dense protoplasmic content. These procambium strands are the beginnings of the vascular tissue presently to appear. In cross sections of the stem the procambium appears as a ring of separate masses of cells. The remaining cells of the growing tip are parenchymatous cells, called the ground meristem, changed but little from the promeristem condition.

As the procambial cells grow older, they gradually change in form. Those cells which are nearest the center of the stem become xylem cells, those toward the circumference of the stem become phloem, with cambium cells separating the two types. In some stems the differentiation of cells continues until the procambial strands have united to form a continuous cylinder which gives place to concentric rings of xylem and phloem cells separated by a band of cambium cells. In other stems, the strands remain distinct, forming separate vascular bundles. The ground meristem or parenchyma in the center of the stem becomes the pith, that surrounding the strands becomes the cortex and pericycle, while the radiating masses of parenchyma cells between the separate strands make up the pith rays. All these tissues, derived indirectly from the differentiation of the promeristem cells, form the primary body, composed of primary tissues.

The epidermal cells are often somewhat elongated in the direction of the length of the stem. The outer wall of an epidermal cell is frequently much thickened and cutinized, so that it becomes impervious to water. Many stomata are found in the epidermis. As the diameter of the stem increases, the epidermal cells gradually become stretched until they finally break apart and are lost.

The cortex inside the epidermis is comprised of several kinds of cells. See Fig. 1. Those nearest the surface are the collenchyma cells. These are modified parenchyma cells, the walls of which are thickened in their angles. These cells usually contain chloroplasts. Because of their thickened walls, collenchyma cells give support to the stem, while at the same time they manufacture food. The parenchyma cells of the cortex are thin-walled, and either rounded in shape or, through mutual pressure, more or less angular. Those near the surface of the stem often contain chloroplasts, and carry on photosynthesis. They give rigidity to the stem because of their turgor

Fig. 1. (*After Stevens*.)

pressure, and also serve as storage tissue. In some stems there are also found in the cortex thick-walled sclerenchyma cells. These may be either long slender fibers or short stone cells. In a few plants the innermost cells of the cortex form a definite endodermis, the walls of each cell being much thickened.

The tissues inside the cortex include the pericycle, the vascular bundles, pith rays, and the pith. This is the stele.

The cells of the pericycle are very similar to those of the cortex, so much so that it is often very difficult to distinguish one from the other. In the pericycle of stems, which usually is much thicker than that in roots, sclerenchyma cells, both fibers and stone cells, may be found along with the parenchyma, just as in the cortex.

The cells comprising the vascular system — xylem and phloem — are very much modified. The procambial cells toward the center of the stem first elongate greatly, without appreciably increasing in diameter. Soon changes appear in the wall, secondary deposits of cellulose being laid down against the primary wall. The manner in which the wall is thickened varies in different cells. In some the thick deposits are in rings: these are formed while the cell is still elongating and so are gradually separated. Such cells are called annular cells. In other cells of the first-formed xylem, which is called protoxylem, the wall thickenings are in the form of spirals, producing spiral cells, which allow a certain amount of growth even when the thick wall is formed. In cells that differentiate later, when elongation has been completed, the thickening of the wall will be much more extensive, only irregularly distributed, narrow slits being left unthickened. These slits extend transversely in the wall of the cell. Such cells are called scalariform or reticulate cells. Differentiation of the xylem cells continues until most of the inner part of the procambial strand has been changed to xylem cells. Those that form after the narrow protoxylem cells are called metaxylem cells. Protoxylem and metaxylem together make up the primary xylem. It should be understood that, as the xylem cells develop, the end walls are cut away forming long tubes, called vessels or tracheae. Water moves rapidly through such tubes.

The cells on the outside of the procambial strand become the primary phloem cells. These are the sieve tubes and companion cells. Early stages in the formation of these cells are much like those of xylem cells, elongation first occurring and then changes in the cell wall. In the formation of phloem cells, a single cell divides into two, which become very unequal; the larger one continues to increase in size and loses its nucleus; the smaller one frequently divides again. The walls of these cells remain comparatively thin, with characteristic perforated thin places, called sieve plates, in the end walls of the larger cells, which form the sieve tubes. The smaller cells, called companion cells, are characterized by a dense cytoplasmic content, small vacuoles and prominent nucleus. They are connected with the sieve tubes by numerous small thin places, called simple pits, in their walls. Phloem cells are channels in which food passes through the stem. In addition to these various cells, the phloem contains parenchyma cells, which are used for storage of materials and in some plants long thick-walled fibers, called phloem or bast fibers.

Parenchyma and fibers also occur in the xylem. Between the xylem and phloem elements, there is a band of cells that remains unmodified and becomes an important tissue in many stems. This is the cambium, which by its divisions gives rise to the secondary tissues, which compose the bulk of the stems of woody plants. These secondary tissues are the secondary xylem and phloem, and differ only slightly from the primary xylem and phloem, being unlike mainly in their origin. Secondary rays, which provide for lateral translocation of food, are also produced by the cambium.

In the center of the stem is the pith, composed of large, thin-walled cells arranged in irregular fashion. They function principally as places of storage of food.

In nearly all monocotyledons, no cambium is formed, therefore the monocot stem is composed entirely of primary tissues. The arrangement of these tissues is vastly different from that of the stems of dicotyledons. The vascular tissues occur in the form of separate small bundles scattered throughout the stem. It is impossible to distinguish any limit that separates cortex from pericycle and pith. In many monocots the central portion of the stem is entirely free from bundles and recognized as a pith. Often the pith breaks up, forming a hollow stem.

All gymnosperms have woody stems. The development and structure of these are quite similar to that of dicotyledons, but, except in a few uncommon species, the xylem is composed entirely of tracheids, distinguished from the tracheae of the angiosperms by the fact that they are elongated cells instead of long tubes formed from many cells, and no companion cells are formed in the phloem.

In most plants, the function of the stem is to display the leaves and reproductive organs in the most favorable position and to carry materials from one part of the plant to another. In many plants, the stem is a highly specialized structure with different functions. Often these specialized stems take over the function of one of the other organs of the plant.

The outer tissues of the young stems of nearly all plants are green. Therefore some photosynthesis takes place in these tissues. There are many plants in which the stem is the principal, if not the only, place where photosynthesis occurs. In many cases, as in some of the cacti, the appearance of the stem differs very little from that of any other plant; but leaves are very much reduced or entirely lacking, all photosynthesis occurring in the stem. In other species of cactus, such as the Prickly Pear and the widely cultivated crab or Christmas cactus, the stem is very much flattened, but still distinctly recognizable as a stem. In some plants, however, the modification has become extreme. The ultimate branches of the stem have become very much flattened and have a shape which gives them every appearance of a leaf. Only their position in the axil of a tiny scale, the real leaf, betrays their true nature. The dainty Smilax, *Asparagus asparagoides*, of the florist, has branches of this kind. So also does the Butcher's Broom, a marsh plant of Europe, which is widely cultivated and appears during the Christmas season, stained a brilliant scarlet. The inconspicuous greenish-white flowers of this plant occur in the center of that part which is commonly assumed to be a leaf. The tiny needle-like "leaves" of the garden asparagus are really branches.

In a few plants, the stem becomes a very important reproductive part. See Fig. 2. Runners, long slender branches from the base of the stem, grow out horizontally over the surface of the ground, and root at their tip. There a new plant is formed. With death and disintegration of the connecting stem, the young plant becomes separate from its parent. This is a form of vegetative reproduction. A stolon differs very little from a runner; it is a prostrate branch, which regularly roots at its nodes, and sends up new plants not only at its tip but also from the nodes. Rootstocks or rhizomes are spreading underground branches, which produce adventitious roots at their nodes and often spread widely.

Many rhizomes become very fleshy because of an accumulation in them of food materials. Their principal function then is storage. Storage occurs in the stems of many different plants. If only a portion of the rhizome becomes enlarged, it is called a tuber. The common white potato is a very familiar tuber, which is formed at the tip of a slender rhizome. The "eyes" of the potato are really the nodes of the stem; from them buds will give rise to branches when the potato grows. More modified than the tuber is

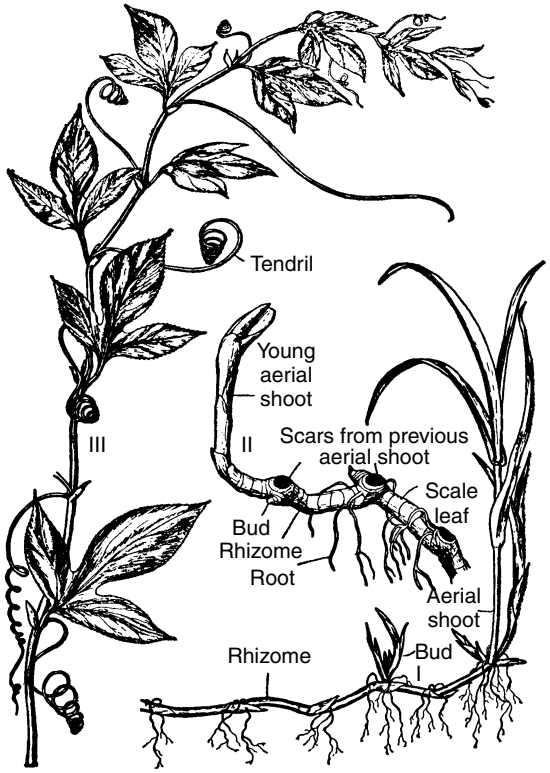

Fig. 2. Types of modified stems: (1) rhizome or quack grass (*Agropyron repens*); (II) rhizome of Solomon's Seal (*Polygonatum commutatum*); (III) stem of passion flower (*Passiflora incarnata*) with tendrils that are modified stems.

the corm. This is a short thick erect rootstock. Often it is much broader than it is long. Buds are formed on the upper surface of the corm. Each of these buds grows into a new plant, exhausting the substance of the old corm. New corms form at the base of the old one. Corms known to all are those of *gladiolus* and *crocus*. These are usually incorrectly called bulbs. See Fig. 3. A bulb is a fleshy bud, composed of a short thick stem and many fleshy or scaly leaves or leaf bases. Onions form true bulbs, as do tulips, hyacinths and many lilies.

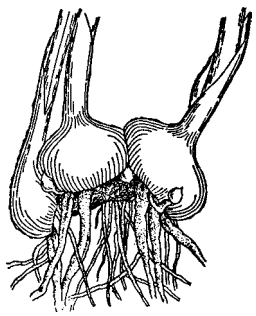

Fig. 3. Corms of Gladiolus, consisting chiefly of fleshy stems.

The materials stored in the stems so far considered are mainly reserve food. Other stems become swollen with stored water. Many cacti and Euphorbias have stems of this sort.

Thorns are usually stems or branches that have become stiff and pointed and serve to protect the plant. Tendrils are organs that support a plant as it grows up through other plants. Not all tendrils are stems. Some, like those of the grape, are definitely so; others are leaves or parts of leaves. Usually plants which have tendrils have slender stems which lack sufficient strength to support themselves. Plants of this type are vines. There are several types of vines, or climbing plants. One of them supports itself by twining tightly around any available support. The direction of twining is very constant for any species, some invariably turning in a clockwise direction and others counterclockwise.

Other climbers support themselves by adventitious roots, which form in abundance and cling tightly to any support. Other climbing plants are supported solely by the presence of many spines or prickles, often hooked, or pointed backwards so that the stem does not easily slide off any object on which it rests. Climbing roses illustrate this type of climber. But many tropical vines are much better illustrations. Often these grow to great lengths, hanging in long festoons from the tops of tall trees, or growing in tangled masses over low shrubby plants. In these tropical climbers, which are commonly called lianas, the stems often assume curious flattened or fluted or irregular shapes. In diameter they vary from a fraction of an inch to many inches; they may attain a length of 400 or 500 feet (122 or 152 meters). They are one of the most characteristic and annoying features of the tropical rain forest.

STENGEL PROCESS. A method of making ammonium nitrate fertilizer from anhydrous ammonia and nitric acid. The fertilizer particles can be made in different sizes according to use.

STEPHANITE. The mineral stephanite, silver antimony sulfide, Ag_5-SbS_4, is found in short prismatic or tabular orthorhombic crystals. It is a brittle mineral; hardness, 2–2.5; specific gravity, 6.25; metallic luster; color, black; streak, black; opaque.

Stephanite occurs associated with other silver minerals and is believed to be primary in character. Localities are in the Czech Republic and Slovakia, Saxony, the Harz Mountains, Sardinia; Cornwall, England; Chile and Mexico. In the United States it is found in Nevada, where it is an important silver ore. It was named for the Archduke Stephan of Austria, mining director of that country at the time this mineral was first described.

STEPHEN ALDEHYDE SYNTHESIS. Preparation of aldehydes from nitriles by reduction with stannous chloride in ether saturated with hydrochloric acid. The intermediate aldimine salts have to be hydrolyzed. The best results are obtained in the aromatic series.

STEPPE. An extensive, treeless grassland area in southeastern Europe and Asia developing in the semiarid mid-latitudes of that region. They are generally considered drier than the prairie that develops in the subhumid mid-latitudes of the United States.

STEPPE CLIMATE. See **Climate**.

STEPPER MOTORS. The importance and usage of the electric stepper motor has increased immensely during the past two decades. Stepper motors, for example, are widely used in modern electronic typewriters, word processors, and other computerized products. They are important components of industrial robotic systems, large and small, and in other machines where repeatable positioning control is required. Stepper motors for most applications must be designed to work reliably over hundreds of thousands to millions of cycles.

The advantages of stepper motors are low cost, ruggedness, construction simplicity, high reliability, no maintenance, wide acceptance, no "tweaking" to stabilize, and no feedback components needed; they are inherently

fail-safe and tolerate most environments. Steppers are simple to drive and control in an open-loop configuration. They provide excellent torque at low speed, up to 5 times the continuous torque of a brush motor of the same frame size or double the torque of the equivalent brushless motor. Frequently, a gearbox can be eliminated. A stepper-driven system is inherently stiff, with known limits to the dynamic position error.

Types of Stepper Motors

Permanent-Magnet Motors. The tin-can, or "canstack," motor shown in Fig. 1 is perhaps the most widely used type in commercial, nonindustrial applications. It is essentially a low-cost, low-torque, low-speed device ideally suited for use in computer peripherals, for example. The motor construction results in relatively large step angles, but the overall simplicity favors high-volume, low-cost production. The axial-air gap or disk motor is a variant of the permanent-magnet design, which achieves higher performance mainly because of its very low rotor inertia. This does restrict the applications of the motor to those situations involving little inertia, such as positioning the print wheel in a daisy-wheel printer.

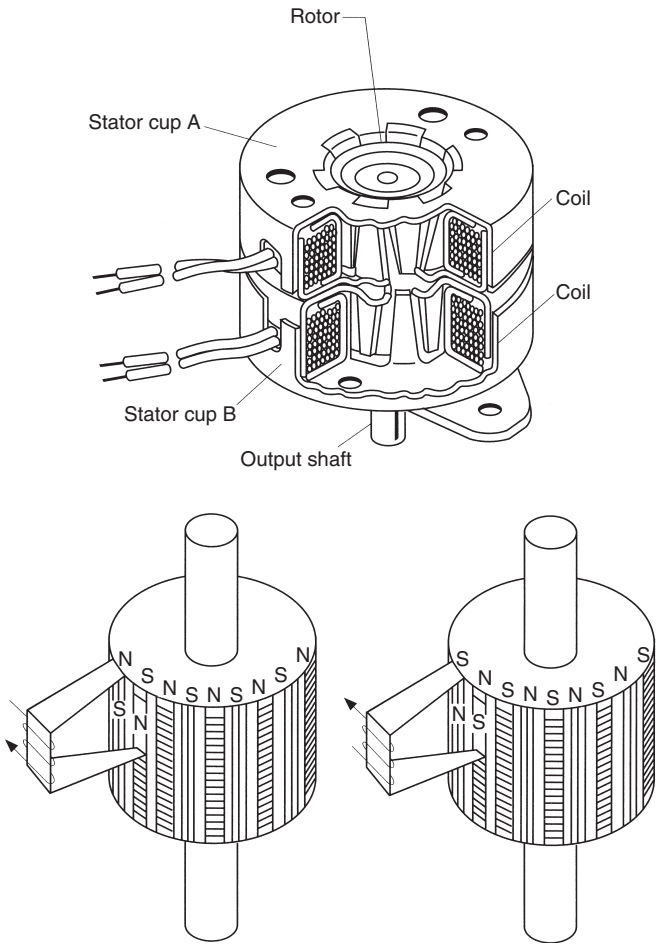

Fig. 1. Canstack, or permanent-magnet, stepper motor. (*Top*) sectional view; (*bottom*) as used for positioning print wheel in a daisy-wheel printer. (*Airpax Corp., U.S.*)

Disadvantages of the stepper motor include resonance effects, relatively long settling times, and rough performance unless a microstepper is used. Undetected position loss may result in open-loop systems. Steppers consume current regardless of load conditions, and they tend to run hot. Steppers tend to be noisy, especially when operated at high speeds. Some of the foregoing limitations can be overcome by use of a closed-loop system.

Variable-Reluctance Motors. There is no permanent magnet in a variable-reluctance motor. Thus the rotor spins freely without detent torque. Torque output for a given frame size is restricted, although the torque-to-inertia ratio is good. This type of motor is frequently used in small sizes for applications such as micropositioning tables. Variable-reluctance motors are seldom used in industrial applications. Having no permanent magnet, these motors are not sensitive to current polarity and thus require a different driving arrangement compared to other types. See Fig. 2.

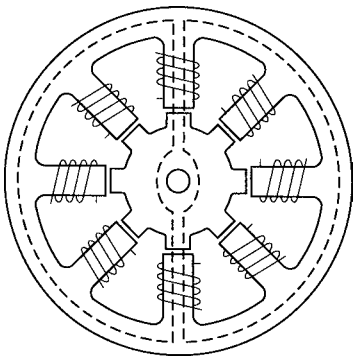

Fig. 2. Variable-reluctance motor.

Hybrid Stepper Motors. The hybrid motor is the most widely used stepper motor in industrial applications. Most hybrid motors are two-phase, although five-phase designs are available. A recent development is the enhanced hybrid, which uses flux-focusing magnets to give a significant improvement in performance, but at extra cost.

The rotor of the "model" hybrid stepper illustrated in Fig. 3 consists of two pole pieces with three teeth on each. Between the pole pieces is a permanent magnet that is magnetized along the axis of the motor, making one end a north pole, and the other a south pole. The teeth are offset at the north and south ends, as shown in the diagram.

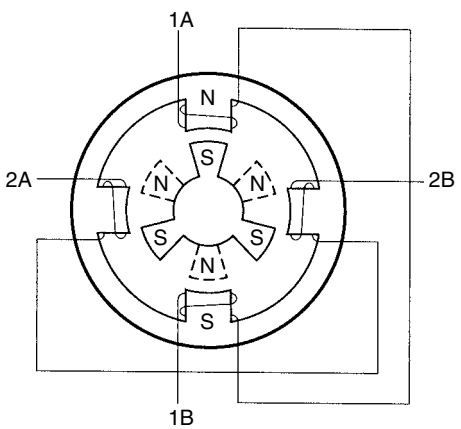

Fig. 3. Simple 12-step-per-revolution hybrid motor.

The stator consists of a shell having four teeth that run the full length of the rotor. Coils are wound on the stator teeth and are connected together in pairs.

With no current flowing in any of the motor windings, the rotor will tend to take up one of the five positions shown in the diagram. This is because the permanent magnet in the rotor attempts to minimize the reluctance, or magnetic resistance, of the flux path from one end to the other. This occurs when a pair of north- and south-pole rotor teeth are aligned with two of the stator poles. The torque, tending to hold the motor in one of these positions, is usually small and called the detent torque. The motor shown has 12 possible detent positions.

If current is passed through one pair of stator windings, as shown in Fig. 4(a), the resulting north and south stator poles will attract teeth of the opposite polarity on each end of the rotor. Thus there are only three stable

positions for the rotor, the same as the number of rotor teeth. The torque required to deflect the rotor from its stable position is thus much greater and is referred to as the holding torque.

By changing the current flow from the first to the second set of stator windings [Fig. 4(b)], the stator field rotates through 90° and attracts a new pair of rotor poles. This results in the rotor turning through 30°, corresponding to one full step. Reverting to the first set of stator windings, but energizing them in the opposite direction, the stator field will be rotated through another 90° and the rotor will take another 30° step, as shown in Fig. 4(c). Finally, the second set of windings is energized in the opposite direction [Fig. 4(d)] to give a third step position. Returning to the first condition [Fig. 4(a)] and after these four steps, the rotor will have moved through one tooth pitch. This simple motor, therefore, performs 12 steps per revolution. Obviously, if the coils are energized in the reverse sequence, the motor will change direction.

If the two coils are energized simultaneously (Fig. 5), the rotor takes up an intermediate position, since it is equally attracted to two stator poles.

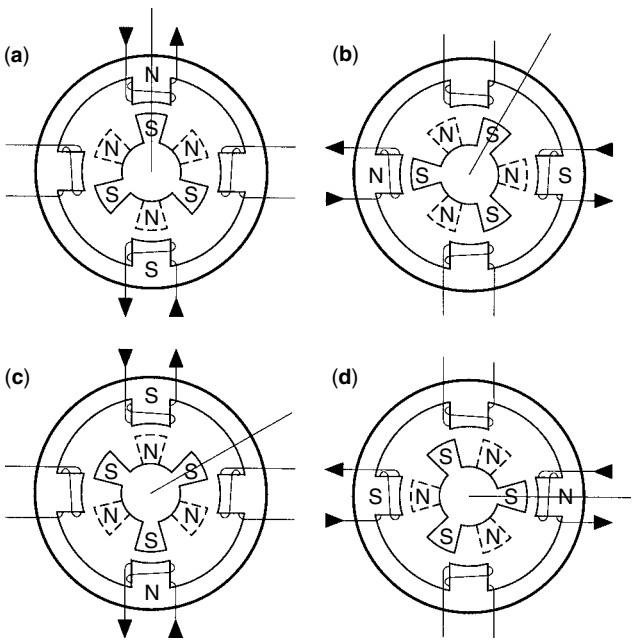

Fig. 4. Full stepping, one phase on. (*Parker-Hannifin Corp., Compumotor Div.*)

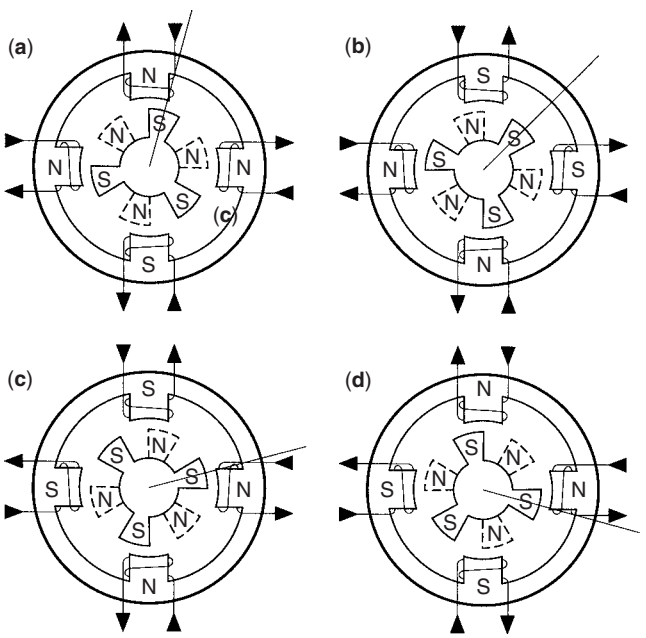

Fig. 5. Full stepping, two phases on. (*Parker-Hannifin Corp., Compumotor Div.*)

Greater torque is produced under these conditions because all the stator poles are influencing the motor. The motor can be made to take a full step simply by reversing the current in one set of windings. This causes a 90° rotation of the stator field, as before. In fact, this would be the normal way of driving the motor in the full-step mode, always keeping two windings energized and reversing the current in each winding alternately.

By alternately energizing one winding and then two (Fig. 6), the rotor moves through only 15° at each stage, and the number of steps per revolution will be doubled. This is called half-stepping. Most industrial applications make use of this stepping mode. Although sometimes there is a slight loss of torque, this mode results in much better smoothness at low speeds, and less overshoot and ringing occur at the end of each step.

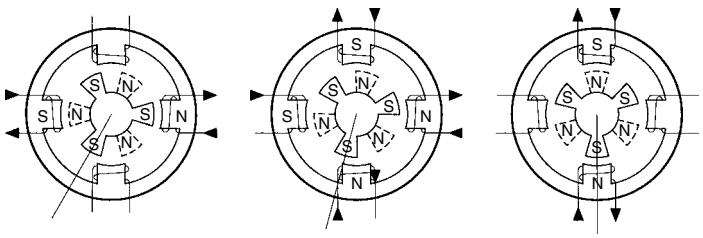

Fig. 6. Half stepping. (*Parker Hannifin Corp., Compumotor Div.*)

Current Patterns in Motor Winding. When the motor is driven in its full-step mode, energizing two windings, or phases, at a time (Fig. 7), the torque available on each step will be the same (subject to very small variations in the motor and drive characteristics). In the half-step mode, two phases are alternately energized and then only one, as shown in Fig. 8. Assuming the drive delivers the same winding current in each case, this will cause greater torque to be produced when there are two windings energized — that is, alternate steps will be strong and weak. Although the available torque obviously is limited by the weaker step, there is a improvement in low-speed smoothness over the full-step mode.

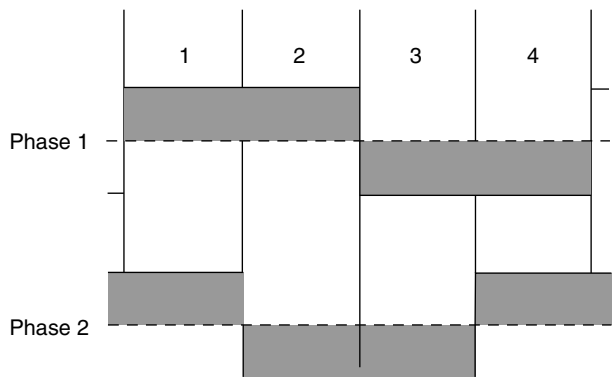

Fig. 7. Full step current, two phases on. (*Parker-Hannifin Corp., Compumotor Div.*)

The motor designer would like to produce approximately equal torque on every step and to have this torque be at the level of the stronger step. This goal can be achieved by using a higher current level when there is only one winding energized. This does not overly dissipate the motor because the manufacturer's current rating will assume two phases to be energized. (The current rating is based on the allowable case temperature.) With only one phase energized, the same total power will be dissipated if the current is increased by 40%. Using the higher current in the one-phase-on state produces approximately equal torque on alternate steps, as indicated in Fig. 9.

Microstepping. It will be noted from the prior discussion that energizing both phases with equal currents produces an intermediate step position halfway between the one-phase-on positions. If the two phase currents

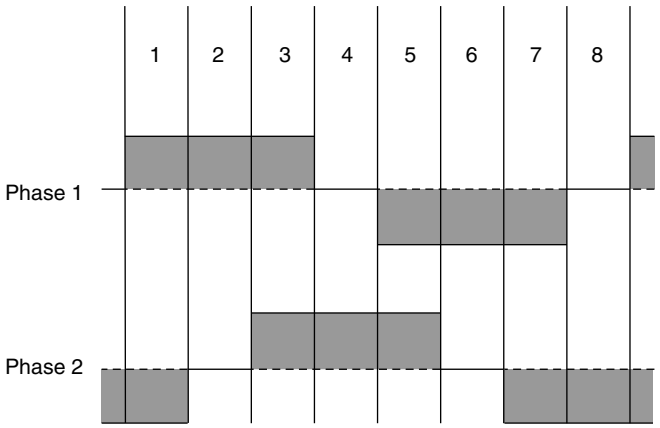

Fig. 8. Half-step current (*Parker-Hannifan Corp., Compumotor Div.*)

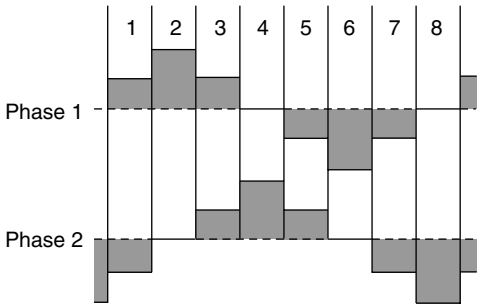

Fig. 9. Half-step current, profiled. (*Parker-Hannifin Corp., Compumotor Div.*)

are unequal, the rotor position will be shifted toward the stronger pole. This effect is utilized in the microstepping drive, which subdivides the basic motor step by proportioning the current in the two windings. In this way the step size is reduced and the low-speed smoothness is improved dramatically. High-resolution microstep drives divide the full motor step into as many as 500 microsteps, giving 100,000 steps per revolution. In this situation the current pattern in the windings closely resembles two sine waves with a 90° phase shift between them (Fig. 10). Thus the motor is driven very much as though it were a conventional ac synchronous motor. In fact, the stepper motor can be driven in this manner from a 60-Hz (U.S.) or 50-Hz (Europe) sine-wave source by including a capacitor in series with one phase. It will rotate at 60 r/min.

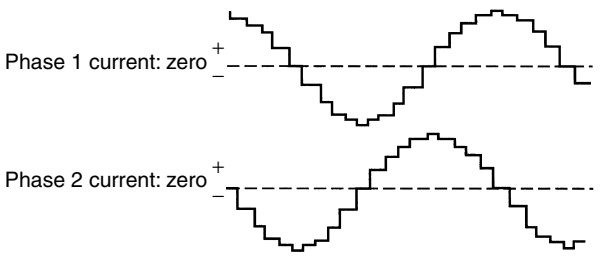

Fig. 10. Phase currents in microstep mode. (*Parker-Hannifin Corp., Compumotor Div.*)

Standard 200-Step Hybrid Motor. The standard stepper motor operates in the manner just described as a model, but it has a greater number of teeth on the rotor and stator, giving a smaller basic step size. The rotor is in two sections, as described previously, but has 50 teeth on each section. The half-tooth displacement between the two sections is retained. The stator has eight poles, each with five teeth, making a total of 40 teeth (Fig. 11).

Visualize that a tooth is placed in each of the gaps between the stator poles, in which case there would be a total of 48 teeth, two less than the number of rotor teeth. If rotor and stator teeth were aligned at 12 o'clock,

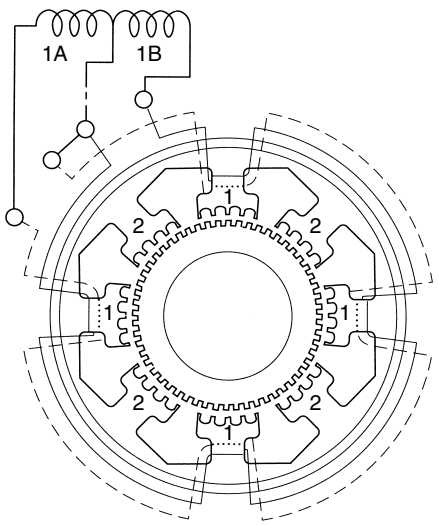

Fig. 11. 200-step hybrid motor. (*Parker-Hannifin, Compumotor Div.*)

they would also be aligned at 6 o'clock. But at 3 and 9 o'clock the teeth would be misaligned. However, due to the displacement between the sets of rotor teeth, alignment will occur at 3 o'clock and 9 o'clock at the other end of the rotor.

In practice, the windings are arranged in sets of four and wound such that diametrically opposite poles are the same. Thus, referring to Fig. 11, the north poles at 12 and 6 o'clock attract the south-pole teeth at the front of the rotor and the south poles at 3 and 9 o'clock attract the north-pole teeth at the back. By switching current to the second set of coils, the stator field pattern rotates through 45°, but to align with this new field, the rotor only has to turn through 1.8°. This is equivalent to one-quarter of a tooth pitch on the rotor, giving 200 full steps per revolution.

Note that there are as many detent positions as there are full steps per revolution, namely, 200. The detent positions correspond with rotor teeth being fully aligned with stator teeth. When power is applied to a stepper drive, it is usual for it to energize in the zero-phase state in which there is current in both sets of windings. The resulting rotor position does not correspond with a natural detent position, so an unloaded motor will always move by at least one-half step at power on. Of course, if the system were turned off other than in the zero-phase state, or the motor is moved in the meantime, a greater movement may be seen at power-up.

For a given current pattern in the windings there are as many stable positions as there are rotor teeth (50 for a 200-step motor). If a motor is desynchronized, the resulting position error will always be a whole number of rotor teeth, or a multiple of 7.2°. A motor cannot "miss" individual steps. Position errors of one or two steps may be due to noise, spurious step pulses, or a controller fault.

Bifilar Windings. Most motors are described as being bifilar wound, which means there are two identical sets of windings on each pole. Two lengths of wire are wound together as though they were a single coil. This produces two windings that are electrically and magnetically almost identical. If one coil were wound on top of the other, even with the same number of turns, the magnetic characteristics would be different.

The origin of the bifilar winding goes back to the unipolar drive. Rather than reversing the current in one winding, the field may be reversed by transferring current to a second coil wound in the opposite direction. (Although the two coils are wound the same way, interchanging the ends has the same effect.) Thus, with a bifilar-wound motor, the drive can be kept simple. However, this requirement has now largely disappeared with the widespread availability of the more efficient bipolar drive. Nevertheless, the two sets of windings do provide additional flexibility.

If all the coils in a bifilar-wound motor are brought out separately, there will be a total of eight leads (Fig. 12). This is becoming the most common configuration, since it gives the greatest flexibility. However, there are still a number of motors produced with only six leads, one lead serving as a

common connection to each winding in a bifilar pair. This arrangement limits the range of applications of the motor, since the windings cannot be connected in parallel. Some motors are made with only four leads. These are not bifilar-wound and cannot be used with a unipolar drive. There is obviously no alternative connection method with a four-lead motor, but in many applications this is not a drawback and the problem of insulating unused leads is avoided. Occasionally a five-lead motor may be encountered. These should be avoided inasmuch as they cannot be used with conventional bipolar drives requiring electrical isolation between the phases.

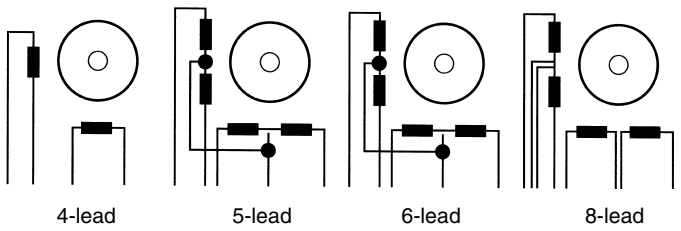

Fig. 12. Motor lead configurations.

Linear Stepper Motors

The linear stepper is essentially a conventional rotary stepper that has been "unwrapped" so that it operates in a straight line. The moving component is referred to as the forcer, and it travels along a fixed element, or platen. For operational purposes the platen is equivalent to the rotor in a normal stepper, although it is an entirely passive device and has no permanent magnet. The magnet is incorporated in the moving forcer together with the coils (Fig. 13).

The forcer is equipped with four pole pieces, each having three teeth. The teeth are staggered in pitch with respect to those on the platens so that switching the current in the coils will bring the next set of teeth into alignment. A complete switching cycle (four full steps) is equivalent to one tooth pitch on the platen. Like the rotary stepper, the linear motor can be driven from a microstep drive. In this case a typical linear resolution will be 12,500 steps per inch (4921 steps/cm).

The linear motor finds favor in applications involving a low mass to be moved at very high speed. In a lead-screw-driven system the predominant inertia usually is the lead screw rather than the load to be moved. Hence most of the motor torque goes to accelerate the lead screw, and this problem becomes more severe the longer the travel required. In using a linear motor, all the developed force is applied directly to the load and the performance achieved is independent of the length of the move. A screw-driven system can develop greater linear force and better stiffness. However, the maximum speed may be as much as 10 times higher with the equivalent linear motor.

With further reference to Fig. 13, the forcer consists of two electromagnets A and B and a strong rare-earth permanent magnet. The two pole faces of each electromagnet are toothed to concentrate the magnetic flux. Four sets of teeth on the forcer are spaced in quadrature so that only one set at a time can be aligned with the platen teeth.

The magnetic flux passing between the forcer and the platen gives rise to a very strong force of attraction between the two pieces. The attractive force can be up to 10 times the peak holding force of the motor, requiring a bearing arrangement to maintain precise clearance between the pole faces and the platen teeth. Either mechanical roller bearings or air bearings are used to maintain the required clearance.

When current is established in a field winding, the resulting magnetic field tends to reinforce permanent magnetic flux at one pole face and cancel it at the other. By reversing the current, the reinforcement and cancellation are exchanged. Removing current divides the permanent magnetic flux equally between the pole faces. By selectively applying current to phases A and B it is possible to concentrate the flux at any of the forcer's four pole faces. The face receiving the highest flux concentration will attempt to align its teeth with the platen. Fig. 14 shows the four primary states or full steps of the forcer. The four steps result in motion of one tooth interval to the right. Reversing the sequence moves the forcer to the left.

Repeating the sequence in the example will cause the forcer to continue its movement. When the sequence is stopped, the forcer stops, with the appropriate tooth set aligned. At rest, the forcer develops a holding force that opposes any attempt to displace it. As the resting motor is displaced from equilibrium, the restoring force increases until the displacement reaches one-quarter of a tooth interval (Fig. 15). Beyond this point the restoring force drops. If the motor is pushed over the crest of its holding force, it slips or jumps rather sharply and comes to rest at an integral number of tooth intervals away from its original location. If this occurs while the forcer is traveling along the platen, it is referred to as a stall condition.

Linear Step Motor Characteristics. These include velocity ripple, platen mounting, environment, life expectancy, yaw (plus pitch and roll), and accuracy. To summarize, the worstcase accuracy of a linear step motor can be given by

$$\text{Accuracy} = A + B + C + D + E + F$$

where A = cyclic error due to motor magnetics, which recurs once every pole pitch as measured on motor body
B = unidirectional repeatability — error measured by repeated moves to the same point from different distances in the same direction
C = hysteresis — backlash of motor when changing direction due to magnetic nonlinearity and mechanical friction
D = cumulative platen error — linear error of platen as measured on motor body

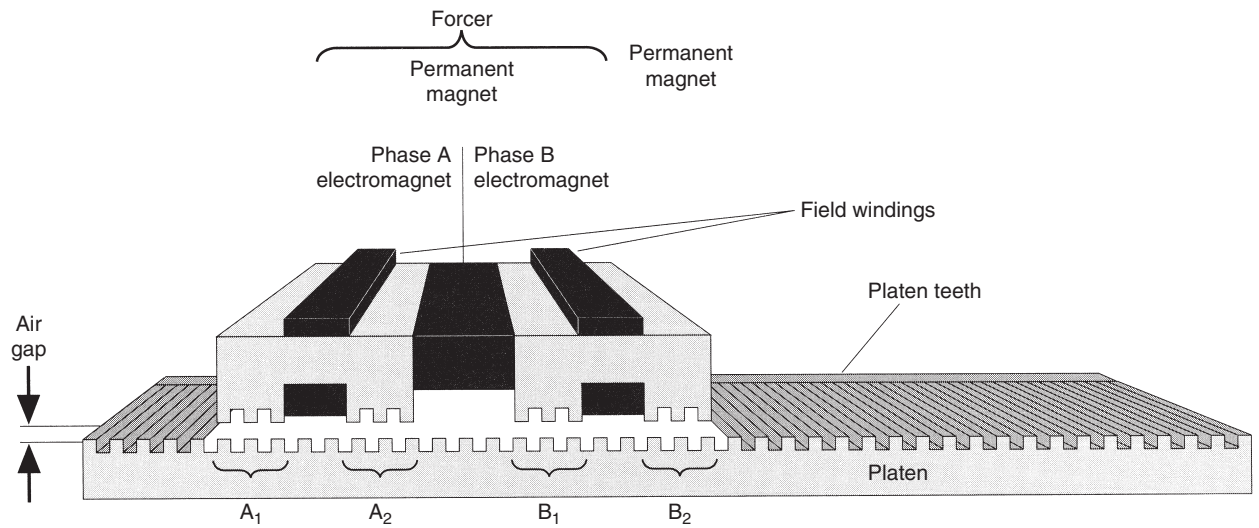

Fig. 13. Principle of linear stepping motor.

E = random platen error — nonlinear errors remaining in platen after linear error is disregarded
F = thermal expansion error — error caused by change in temperature, expanding or contracting the platen

STEP RESPONSE TIME. Of a system or an element, the time required for an output to make the change from an initial value to a large specified percentage of the final steady-state value, either before or in the absence of overshoot, as a result of a step change to the input. See figure that accompanies entry on **Response (Instrument)**. This time is usually stated for 90, 95 or 99% change.

Time Constant. The value T in an exponential response term $A \exp(-t/T)$ or in one of the transform factors $1 + sT$, $1 + j\omega T$, $1/(1 + sT)$, $1/(1 + j\omega T)$, where s = complex variable; t = time, seconds; T = time constant; $j = \sqrt{-1}$; ω = frequency, radian/second.

For the output of a first-order (lag or lead) system forced by a step or an impulse, T is the time required to complete 63.2% of the total rise or decay; at any instant during the process, T is the quotient of the instantaneous rate of change divided into the change to be completed. In higher-order systems, there is a time constant for each of the first-order components of the process. In a Bode diagram, breakpoints occur at $\omega = 1/T$.

STEPTOE. A hill or mountain whose top projects above a lava flow which has surrounded its lower flanks.

STERADIAN. The unit solid angle that cuts unit area from the surface of a sphere of unit radius centered at the vertex of the solid angle. There are 4π steradians in a sphere.

STEREO BROADCASTING. A system of radio broadcasting using frequency modulation in which the modulating signal contains information obtained from a stereo microphone which following its modulation, transmission, and reception can subsequently be reproduced by a stereo loudspeaker. The complete communication process involves generating electric signals that correspond to variations in sound intensity at two different points in the physical location where the program originates, transmitting a combination of these two signals by means of a frequency modulated radio transmitter, separating the signals in the listener's receiver and supplying the components to the loudspeaker system.

In the United States, transmission is in accordance with standards established by the Federal Communications Commission. The electrical signals obtained from the two microphones are arbitrarily designated Left (L) and Right (R) signals. They are combined to produce a sum signal (L + R) and difference signal (L − R). According to the standards, each of the audio signals may contain frequency components in the range of 50–15,000 Hz. A frequency translation of the L − R signal spectrum is effected by amplitude modulation on a subcarrier of 38 kHz which is then suppressed. To the combination of the L + R spectrum and the translated L − R spectrum is added a 19 kHz pilot signal, which is to be used to aid in the restoration of the L and R signals after demodulation of the transmitted signal in the listener's receiver. The distribution of the composite modulating signal, which is used for the frequency modulation of the transmitter, is depicted in Fig. 1. Radio transmission takes place in the frequency range 88.1 to 107.9 Hz.

Upon reception, after demodulation, which recovers the composite modulating signal, the signal requires processing to recover the L and R audio signals originally developed by the two microphones. The inverse of the frequency translation which occurred prior to the frequency modulation is now performed on the L − R signal. The composite signal is passed through a bandpass filter, which passes only frequencies in the range from

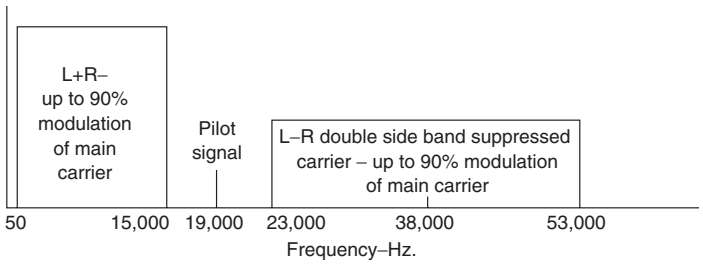

Fig. 1. Frequency distribution of composite modulating signal for stereo broadcasting.

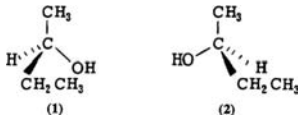
23 to 53 kHz. The 19 kHz pilot signal is also extracted using a filter and is then passed through a doubler-amplifier circuit from which a signal of 38 kHz is obtained. This signal and the output of the bandpass filter are applied to a detector in which *heterodyne* action occurs. The resultant output from the detector has the waveform of the L − R audio signal at the transmitter, together with some extraneous signals that were introduced by the modulation and demodulation processes. The L + R and L − R signals are now fed to a circuit which separates them into the L and R signals in a manner inverse to that in which they were obtained at the transmitter. After further amplification, the L and R signals are furnished to an appropriate stereophonic loudspeaker system. It should be noted that the L + R signal not only provides one portion of the stereo signal but also serves as the compatible monophonic signal for those listeners whose receivers are not equipped for stereo reception and reproduction.

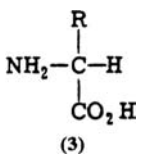
See also **Radio Communication**.

STEREOCHEMISTRY. Two molecules are said to be sterioisomers if they possess identical chemical formulas with the same atoms bonded one to another, but differ in the manner these atoms are arranged in space. Thus *sec*-butanol can exist in two forms, (**1**) and (**2**), which cannot be superimposed on each other.



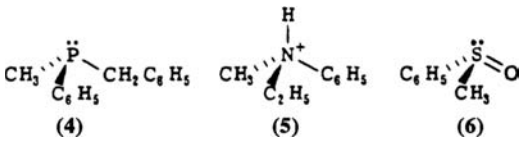
This particular example represents one class of stereoisomers known as *enantiomers*, which may be defined as two molecules that are mirror images but are nonetheless nonsuperimposable. Such molecules are said to possess opposite configuration. If these isomers are separated (*resolved*), the separate enantiomers have been found to rotate the plane of plane-polarized light. This phenomenon of *optical activity* has been known for well over a century. A 50–50 mixture of two enantiomers is optically inactive or *racemic*, since the rotation of light by one enantiomer is precisely compensated by the rotation of light in the opposite direction by the other enantiomer.

Physiological activity is closely related to configuration. Thus the left-rotating, or *levo*, form of adrenalin is over ten times more active in raising the blood pressure than is the right-rotating, or *dextro* form. Many organic chemicals essential to plants and animals are optically active. Enzymes, which catalyze chemical reactions in the body, are frequently programmed to accept only one enantiomer. All the essential amino acids, generally of the formula (3), are of the *levo* type, although important

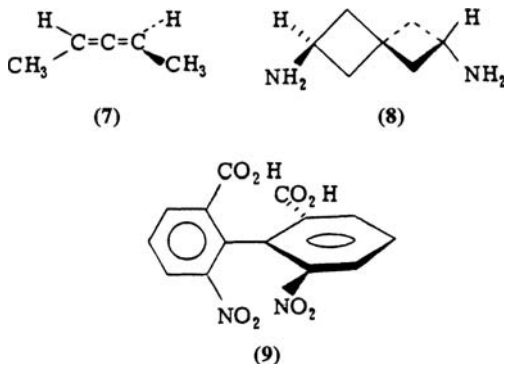


exceptions exist. Recently, several amino acids were found by NASA in a meteorite that presumably originated from the asteroid belt between Mars and Jupiter. The proof that the amino acids were extraterrestrial came from the fact that they were racemic. Any terrestrial contaminants from laboratory handling would have been optically active and *levo*.

Many examples of optically active molecules contain an asymmetric carbon atom, that is, one with four different groups attached, as in (**1**)–(**3**) A wide variety of other atoms may also be asymmetric (**4**–**6**). An asymmetric center is by no means



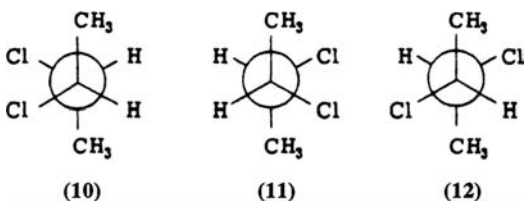
a necessary condition for enantiomerism. Well-known examples of non-superimposable mirror images without asymmetric atoms are allenes (**7**), spiranes (**8**), biphenyls (**9**), and various



inorganic complexes. Molecules that can support optical activity are said to be *chiral*, and to possess *chirality* (meaning *handedness*, since the human hand is chiral).

The process of converting optically active materials into equal amounts of the enantiomers is called *racemization*. Ordinarily this process requires breaking of bonds to form a symmetrical (*achiral*) intermediate, and reforming the bonds to generate the racemic material. For special cases such as phosphines (**4**) and sulfoxides (**6**), in which one "substituent," is a nonbonding electron pair, configurational inversion may occur without breaking any bonds. For such molecules the tetrahedral enantiomers may interconvert through a metastable planar intermediate.

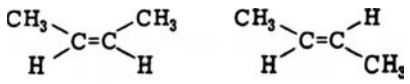
Stereoisomers that are not enantiomers are called *diastereoisomers*. Three classes may be distinguished: configurational, geometrical, and conformational isomers. Configurational diastereomers include molecules with more than one chiral center. Thus 2,3-dichlorobutane can exist in three configurationally



different forms, (**10**–**12**). Although forms (**10**) and (**11**) are enantiomers, (**12**) is a stereoisomer that is not a mirror image of (**10**) or (**11**). It is therefore termed a diastereomer of (**10**) and (**11**). Even though there are two asymmetric centers in (**12**), it is superimposable on its mirror image. The molecule is therefore achiral. The term *meso* is applied to molecules that contain chiral centers but are achiral as a whole. The molecules of nature frequently have many asymmetric centers. If a molecule has n centers, there can be 2^n stereoisomers, although this number may be reduced if some of the diastereoisomers are *meso* or if certain ring constraints are present. Glucose is one of the aldohexose sugars, which contain four chiral centers (disregarding the phenomenon known as anomerism). The

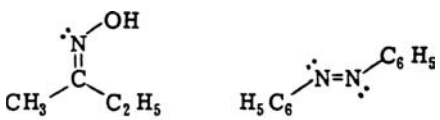
naturally occurring *dextro*-glucose is enantiomeric to *levo*-glucose, and diastereomeric to the other fourteen isomers.

Geometrical isomers differ in the arrangement of groups about certain bonds, rather than about a chiral center. 2-Butene may exist in *cis* (**13**) or *trans* (**14**) forms. In the former case the methyl groups lie on the same side of the double bond, and in the latter on opposite sides. Chirality is not important in geometrical isomerism. The isomers may be interconverted



(13) (14)

if the double bond is broken to leave a residual single bond about which rotation may occur, followed by reformation of the double bond. Geometrical isomerism may occur not only in alkenes (**13,14**), but also in oximes (**15**), azo compounds (**16**), and many other doubly bonded systems. More importantly, cyclic

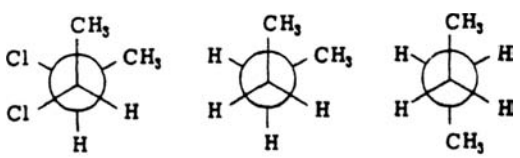


(15) (16)

molecules exhibit this type of isomerism; the average plane of the ring serves as the reference. Molecule (**17**) is therefore named *cis*-1,2-dimethylcyclopropane, and (**18**) is the *trans* isomer. Interconversion of (**17**) and (**18**) would require breaking and reforming a ring bond.

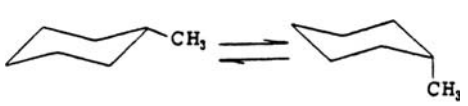
(17) (18)

Conformational isomers differ only in the arrangements of atoms obtainable by rotations about one or more single bonds. *meso*-2,3-Dichlorobutane can exist not only in the form (**12**), but also as the representation (**19**). To take a simpler case,



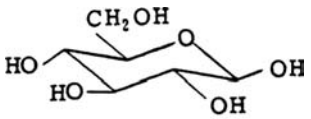
(19) (20) (21)

n-butane may exist in two conformational forms, known as the *gauche* (**20**) and the *anti* (**21**). These isomers may inter-convert by rotation about the C−C single bond, a process that requires an energy of only 3–5 kilocalories/mole. No bonds are broken, in contrast to the manner by which geometrical isomers are interconverted. In a more complicated but very common case, substituents on the six-membered cyclohexane ring may assume either the equatorial (**22**) or axial (**23**) positions. These isomers may interconvert by *ring reversal*, Eq. 1,



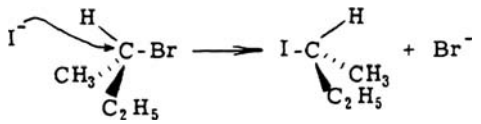
(22) (23) (1)

which consists of a sequence of single-bond rotations. β-D-(+)-Glucose has the specific conformation of (**24**) in which all the substituents are equatorial.



(24)

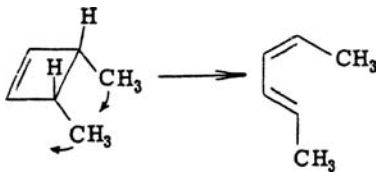
Stereochemistry is one of the most important characteristics of a reaction mechanism. In the nucleophilic displacement of iodide ion on *sec*-butyl bromide, Eq. 2, the reaction is known to occur with inversion. If one disregards the identity of the



(2)

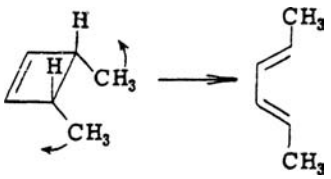
halogen, then the starting material and product have opposite configurations. Thus the iodide ion must attack the C−Br bond from the backside, thereby effecting an inversion of the chiral center.

Important mechanistic consequences may also derive from geometrical isomerism. *cis*-3,4-Dimethylcyclobutene may ring-open to form either *cis, trans*- or *trans,trans*-2,4-hexadiene. The methyl groups may rotate away from each other (disrotation, Eq. 3) to form the *trans, trans* isomer. Alternatively, they



(3)

may rotate in the same direction (conrotation, Eq. 4) to form the *cis,trans* isomer. An alternative disrotatory mode to form



(4)

a *cis,cis* isomer by rotation of the methyl groups toward each other need not be considered because the methyl groups cannot pass by each other. Recent experimental and theoretical consideration of this problem has demonstrated that only the conrotatory mode is permitted for this ring opening. Thus *cis*-dimethylcyclobutene always forms only *cis,trans*-hexene.

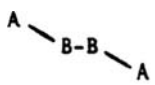
STEREOGRAPHIC PROJECTION. 1. The stereographic projection of a sphere on a plane is defined as follows: For a given point P, called the pole, on the surface of a sphere S, and for a given plane M not passing through P, and perpendicular to a diameter through P, the line joining P

with a variable point Q and M intersects S in a second point R. This mapping of the points R of the sphere S on the points Q of M is called a stereographic projection of S on M.

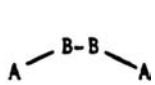
2. This type of map projection is used to some extent by navigators, but more commonly for maps of the celestial sphere, particularly in constructing the basic map for star finders. A stereographic projection has a valuable property in that circles on the sphere appear as circles on the projected map. Because of this property, several attempts have been made to use the projection for drawing lines of position obtained from celestial objects. In the proposed methods, the subastral point would be plotted on the chart and the circle of position drawn about this point with a radius equal to the observed zenith distance of the object. This method is proposed for use by aviators, where speed in drawing lines of position and obtaining a fix is particularly desirable, and where extreme accuracy is never possible because of errors inherent in measuring altitude with a bubble sextant in a moving plane.

STEREOISOMERISM. If one considers a molecular unit consisting of three unlike atoms A, B, and C which are connected (*bonded*) to each other to form a linear system, three arrangements are possible: A–B–C, A–C–B, and B–A–C. By employing the simple test of superimposability it is seen that these arrangements are nonidentical and are termed *structural isomers* (Gr. *isos*, equal). Structural isomers are thus chemical species that have the same molecular formula (the same number and types of atoms) but differ in the sequence in which the atoms are bonded. Of great significance is the fact that these isomers are separated by an energy barrier: in order to convert, for example, A–B–C into A–C–B an input of energy would be necessary to break the existing A–B and B–C bonds, followed by a rearrangement of the sequence of the atoms to yield A–C–B. The rearrangement process is termed an *isomerization* and the magnitude of the energy required (the barrier) for the conversion has important consequences regarding the number of arrangements that may exist for structural isomers.

Turning to a four-atom arrangement consisting of A_2B_2, four structural isomers are possible if linearity of the system is again assumed: A–A–B–B; A–B–A–B; A–B–B–A; B–A–A–B. Each arrangement can be characterized in terms of interatomic distances (A to B, B to B, and A to A) and such distances would be distinctive for each isomer. It is not mandatory, however, that any one of these A_2B_2 combinations exists in a linear form and the consequences of nonlinearity will be viewed. If (for the ABBA case) planarity of the unit still exists but the internuclear angles A–B–B are set at, say, 120°, two arrangements are apparent:



(**1**)



(**2**)

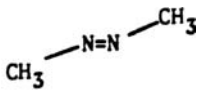
Arrangements (**1**) and (**2**) are clearly different forms of the same structural isomer and are called *stereoisomers* (Gr. *stereo*, solid or space). The relationship between (**1**) and (**2**) may be expressed in terms of the geometry of the molecule and hence these forms have also been called *geometrical isomers*. (Recalling the provisos set down for this system — planarity and angles — the difference between (**1**) and (**2**) is merely the location of one A with respect to the other in the unit.)

The statement made earlier about the energy requirement for the conversion of one structural isomer into another will now be examined. Conversion of (**2**) into (**1**) may be viewed in the simplest manner is involving a rotation of 180° about the B–B internuclear axis:

(**2**)

This operation involves no reshuffling of the atomic arrangement (or constitution) within the unit but does represent an isomerization. How readily such a conversion occurs then depends upon the size of the energy barrier to rotation. Looking at specific examples, the compound $CH_3-N=N-CH_3$, exists in two different and stable stereochemical arrangements (**3**, *cis* and **4**, *trans*) corresponding to (**1**) and (**2**) above:

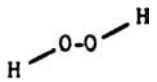
(**3**)



(**4**)

The C–N–N–C atoms are coplanar in each form and the interconversion of (**3**) and (**4**) requires a relatively high amount of energy. On the other hand, hydrogen peroxide (H_2O_2), which may be thought of as existing in similar *cis* and *trans* stereochemical arrangements (**5** and **6**), does *not* exhibit stereoisomerism

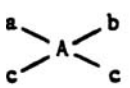
(**5**)



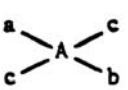
(**6**)

and only one isolable H_2O_2 is known. The difference in the two systems lies in the fact that rotation about the O–O single bond in H_2O_2 is relatively "free" (i.e., requires little energy) whereas the interconversion of (**3**)and (**4**) is a higher energy process that necessitates breaking a π bond before rotation may occur.

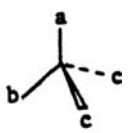
Now consider the case of four atoms (called *ligands*) that are attached to a center atom. If the general case consists of grouping A_{abcc}, square planar and tetrahedral structures, among others, may result:



(**7**)

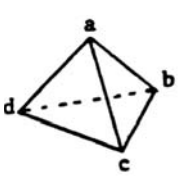


(**8**)

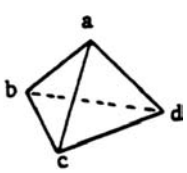


(**9**)

The square planar forms (**7**) and (**8**) are stereoisomers which are nonequivalent to the single nonplanar tetrahedral arrangement (**9**). Now of grouping A_{abcd} is examined one predicts three square planar stereoisomers and the following *two* tetrahedral stereoisomers (**10** and **11**):



(**10**)



(**11**)

The relationship of (**10**) to (**11**) is that of the right hand to the left hand and these nonsuperimposable stereoisomers are mirror images or *enantiomers* (Gr. *enantio-*, opposite). Thus, *chiral* (Gr. *cheir*, hand) molecules are those which possess mirror images and arise when appropriate conditions of geometry and number and types of ligands are present in a system.

A molecule that has a mirror image is also said to be dissymmetric while one that does not (an achiral molecule) have an enantiomer is nondissymmetric. The classification of a given structure as dissymmetric or nondissymmetric is based upon the presence (or lack) of symmetry elements (axes, planes) in the structure.

It is important to note that in either (**10**) or (**11**) the magnitude of any internuclear angle (e.g., a — A — c), or any bond length (e.g., A — b), or the distance between any two ligands is exactly the same. This is not true in the case of the achiral square planar isomers that may be written for the A_{abcd} system.

The single most important physical property that differentiates enantiomers is their ability to rotate the plane of plane polarized light. This property is called *optical activity* and is displayed only by chiral molecules. Thus, stereoisomers which are also chiral are known as *optical isomers*. Chiral molecules that rotate polarized light in a clockwise fashion are termed *dextrorotatory* (*d*) while those that rotate the beam counterclockwise are *levorotatory* (*l*). Enantiomers have optical rotations of the same magnitude but of different signs (*d* or *l*).

The structures (**10**) and (**11**) denoted above contain a single chiral center **A**, the atom to which the ligands are attached. If two different such centers, A and B, are in a molecule the number of optical isomers is increased to four:

A±	A± B±
one chiral center	two different chiral centers

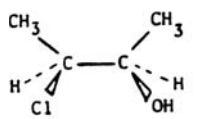
where + and − refer to the handedness or *configuration* at the chiral center. In the AB system, each optical isomer will have a mirror image whose configurations are opposite at the

A+ B+	A− B−	A+ B+	A− B−
mirror	images	mirror	images

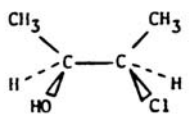
chiral centers. The relationship of A + B+ or A − B− to A + B− (or A − B+) cannot be an enantiomeric one for the obvious reason that a given optical isomer may have only one mirror image. Instead, the relationship is said to be *diastereomeric* (Gr. *dia*, apart). Any given AB optical isomer will therefore have one enantiomer and two diastereomers $CH_3CH(Cl)-CH(OH)CH_3$.

We again examine a specific case. In 3-chloro-2-butanol,

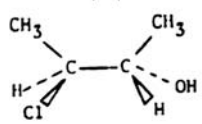
and A ± B ± situation — exists whose four isomers (**12**–**15**) are shown in three dimensions so that the mirror image relationship of (**12**) to (**13**) and (**14**) to (**15**) is readily apparent.



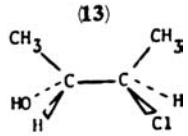
(**12**)



(**13**)

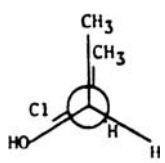


(**14**)



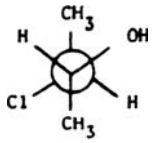
(**15**)

(The carbon atoms in the middle of the carbon chain are the chiral centers A and B.) Taking (**12**) (which is assumed to be the A + B+ combination) if one views down the bond axis of the chiral centers from the right a projection of the molecule results which shows the orientation of ligands to one another.



(**12**)

As noted earlier rotation may occur about single bonds in molecules and if a clockwise rotation of 180° is made about the bond axis of the chiral centers, a different form (*conformation*) (**16**), results.

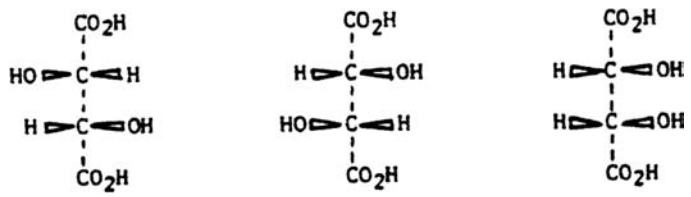


(**16**)

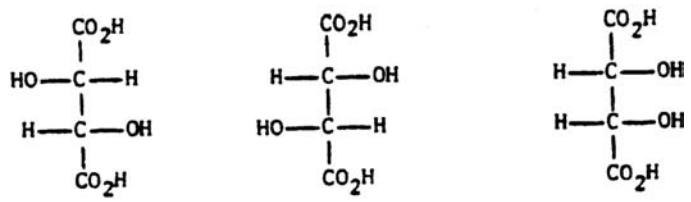
Conformations (**16**) and the *infinite number* of others that are obtained by rotation about the single bond in (**12**) are all nonidentical but the energy barrier separating them is small hence only one chiral compound having configurations ++ at the chiral centers may be isolated under normal conditions for (**12**).

If two *identical* chiral centers are present in a molecular unit the number of stereoisomers is reduced to three: A + A+ and A − A− represent a pair of enantiomers but A + A− and A−A+ are identical arrangements. The +− form is said to be a *meso* or optically inactive diastereomer of the active forms A + A+ and A−A.

The three tartaric acids may be used to illustrate the method employed in depicting three-dimensional molecules in two-dimension projections.



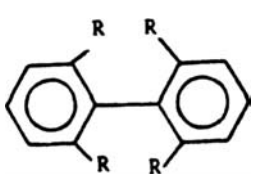
enantiomers meso



D enantiomers L meso

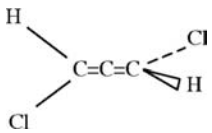
The top formulas show the three-dimensional relation of the groups along the main carbon chain (dashed groups lie below the plane of the paper, bold above) while the bottom formulas correspond to projections in two dimensions obtained by lifting the dashed substituents into the plane of reference and pushing the bold groups down into the plane. In this process a unique projection is obtained for each three-dimensional molecule. The symbols D and L under the formulas for the enantiomeric tartaric acids are notations used to relate the configuration at the bottom chiral center to that of a standard compound, glyceraldehyde.

The presence of a chiral center is a sufficient, but not a necessary condition, for the existence of chirality in a molecule. For example, numerous biphenyl derivatives may exist in chiral pairs

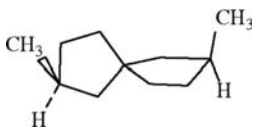


if the size of the R groups is large enough to restrict rotation about the single bond connecting the two rings. The restriction causes the rings to adopt a nonplanar orientation and raises the energy barrier to rotation about the connecting bond. No chiral center is present and the resulting enantiomers in the example following

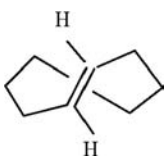
are said to possess a *chiral axis* (coinciding with the connecting bond). Axial chirality is also found in the compounds known as allenes



and in spiranes



while chiral structures such as *trans*-cyclooctene



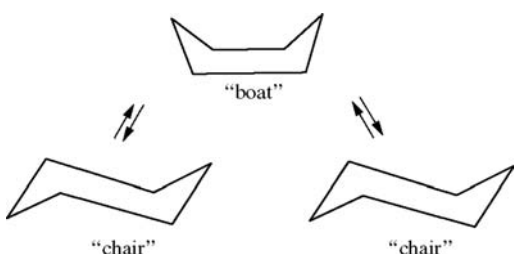
are said to possess a *chiral plane*. Each of the last three structures has a mirror image.

It is clear, then, that the number of chiral isomers that may exist for a given structural isomer is 2^n, where $n =$ the number of different chiral elements (centers, axes, or planes). When identical chiral elements are present, the 2^n formula does not hold.

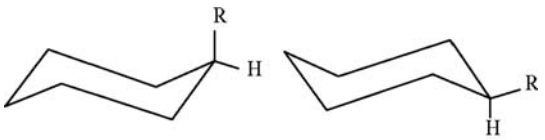
The examples used above to illustrate centers of chirality included carbon atoms which were attached to four unlike ligands, resulting in localized tetrahedral geometry. Numerous other atoms may serve as chiral centers, however, and these include the Group IVA elements silicon, germanium, and tin; the Group VA elements nitrogen, phosphorus, antimony, and arsenic; and the Group VIA elements sulfur, selenium, and tellurium. Under conditions of bonding to three or four dissimilar ligands, chiral molecules containing these atoms as chiral centers may be isolated. Also, the geometric form about the chiral center need not be tetrahedral, for octahedral complexes of the transition metals or their ions (Co^{3+}, Cr^{3+}, etc.) may be chiral when substituted by the proper number and type of ligands.

Conformations in Six-Membered Rings

The nonplanar ring compound, cyclohexane, which contains six contiguous $-CH_2-$ units, may exist in chair or boat forms (hydrogens are not shown):

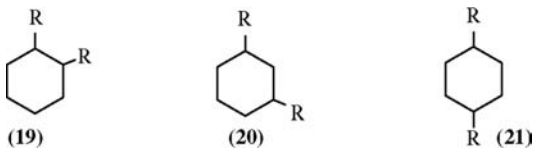


These forms are conformations of the C_6H_{12} structure and are separated by energy barriers which restrict, but do not prohibit, interconversion of the conformations. Substitution of a group on the ring yields a single nonchrial structure that exists in two main conformations, one with the substituent R *axial* and the other *equatorial* to the main plane of the ring.



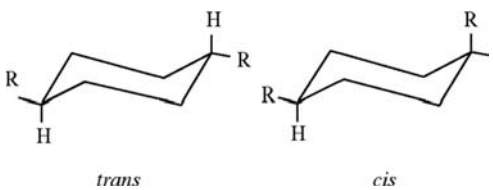
R *axial* (**17**) R *equatorial* (**18**)

Conformation (**18**) is in a lower energy state and predominates in the equilibrium mixture. The introduction of a second substituent into the ring gives rise to three structural isomers (shown here in projection):



(**19**) (**20**) (**21**)

In (**19**) and (**20**), both carbon atoms in the ring to which the R groups are bonded are identical chiral centers and hence one pair of enantiomers and one meso diastereomer exist for each structure. In (**21**) no chiral center is present but the isomers that are possible in this case (shown below in the preferred conformations)

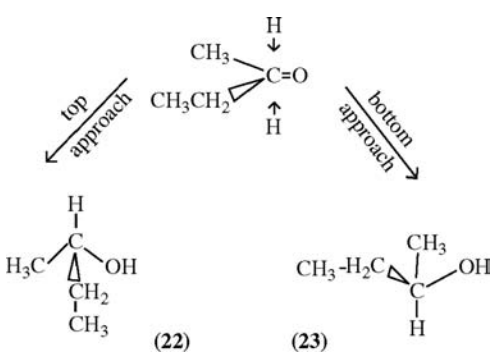


trans *cis*

may be viewed as having a diastereomeric relationship.

Consequences of Molecular Chirality. A mixture containing an equal number of molecules of enantiomers is known as a *racemic modification*. The preparation and reactions of these modifications (as well as the individual enantiomers themselves) represent important aspects of the study of stereochemistry.

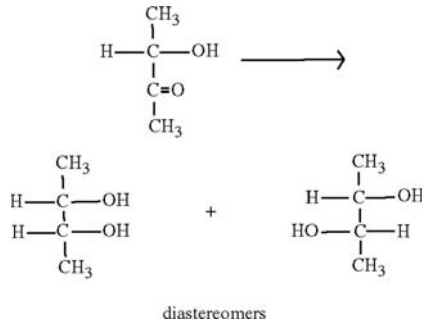
If a molecule  is converted into  by some achiral reagent (e.g., hydrogen gas and a catalyst) the chiral center in the product molecule may be considered as being generated by approach of a hydrogen from the top *or* bottom "face" of the planar  grouping in reactant molecule



(**22**) (**23**)

The molecule (**22**) produced by "top" approach is the enantiomer of that (**23**) resulting from "bottom" approach. In fact, the pathways leading to each are enantiomeric, hence are of equal energy. The overall result is thus the production of a racemic modification, since one approach is as probable as another.

Now if a similar reaction were conducted with a chiral substrate that has a preexisting chiral center (A+), the combinations of configurations at the centers in the product molecules would be A + B+ and A + B−. These are diastereomers, the pathways involving their information are diastereomeric (unequal energy!), and hence they are produced in unequal amounts. Such a case is illustrated as follows:



Diastereomeric reaction pathways may be obtained in numerous other ways. An interesting case is represented by the biological reduction of acetaldehyde-1-D, $CH_3—C(=O)—D$. The product is the chiral structure $CH_3—CH(—D)—OH$ and a racemic modification might be expected from the reduction. In fact, the transfer of a hydrogen during the enzymatic reduction (an enzyme is a large chiral molecule) to one face of the acetaldehyde is diastereomeric with the transfer to the opposite face, hence (very) unequal amounts of the enantiomers are formed. These interactions may be described as E + ··· A+ and E + ··· A−, where E + represents the chirality of the enzyme and A+ or A− represent the incipient chirality in the reduced acetaldehyde molecules.

The last example reflects in a modest way the importance of the study of stereoisomerism. Biological conversions represent a glorious array of diastereomeric reactions and interactions: a given chiral amino acid is metabolized but its enantiomer is not; a certain complex drug (often a chiral molecule) alleviates pain but its enantiomer is inactive; and subtle changes in structure alter a given chiral compound's action completely in the human body.

ALEX T. ROWLAND, Gettysburg College, Gettysburg, PA

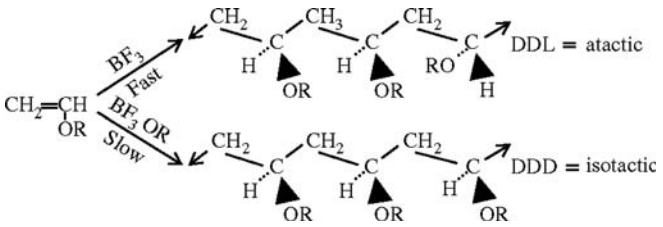
STEREO-POWER. For prism binoculars or similar stereo systems, the ratio of the distance between the objective axes to the distance between eyepiece axes multiplied by the magnifying power. A measure of the stereoscopic radius.

STEREOREGULAR POLYMERS. The properties of natural and synthetic high polymers and their applications in plastics, fibers, elastomers, adhesives and coatings are determined in large part by (a) their average molecular weights, (b) the forces between the long chain molecules and (c) geometrical considerations, especially the degree of regularity of repeating units. Molecular weight characteristics and forces have received attention for many years. In contrast, the importance of stereoregularity vs. irregularity of chemical substituents became fully appreciated only around 1950. In general, strong interchain forces and regularity promote normal crystallinity, along with high strength, high softening temperatures, hardness and insolubility in common solvents.

Some polymers have regular structure free of diastereoisomerism because of the symmetry of the monomers, such as vinylidene chloride, $CH_2=CCl_2$ and isobutene $CH_2=C(CH_3)_2$. However, the term stereoregular polymer is generally reserved for stereoregular polymer structures derived from unsymmetrical monomers which can be obtained by special ionic methods of polymerization (usually from heterogeneous systems). These polymerization processes often using complex catalysts such as Ziegler-Natta activated transition metal catalysts, e.g., from AlR_3 and polymeric $TiCl_3$, have been called stereoregulated, stereospecific or oriented polymerizations. In 1964 the writer suggested the word *stereopolymerization* to describe those special ionic polymerization systems for treating unsymmetrical ethylenic monomers to obtain either normally crystalline polymers with DDDDD regularity, permanently amorphous polymers with irregular DLDDL sequences or intermediate structures according to conditions chosen. Such control of polymer stereoisomerism was achieved first with vinyl alkyl ethers, but the first stereoregular polymers to become the basis of a major industry were the stereoregular or isotactic propylene polymers (heat-resistant molding plastics and fibers).

Crystallinity has been one of the principal effects by which stereoregularity or tacticity has been studied in polymers. However, as expected, not all stereoregular polymers are equally crystallizable. Differences in chemical reactivity, nuclear magnetic resonance and infrared have given useful information about stereoregularity. However, for comparing polymers from a given monomer x-ray diffraction and solubility data are most reliable for estimating tacticity.

Interest in controlling steric configurations and stereoisomerism in polymers by polymerization conditions developed only slowly. Staudinger and Schwalbach in 1931 suggested that invariable low crystallinity in polyvinyl acetate might be caused by diastereoisomerism, that is randomness in D and L positions of the acetate groups along the chain molecules[1]. Branching and deviations from head to tail addition were studied mean-while as types of isomerism. However not until 1948 were examples of stereoregulated polymerizations of a vinyl-type monomer disclosed by Schildknecht and coworkers. In both early types of stereopolymerizations vinyl isobutyl ether diluted by liquid propane could be treated at low temperatures. Addition of gaseous boron fluoride gave very rapid polymerizations to rubber-like substantially amorphous high polymers. Careful addition of cold boron fluoride etherate, immiscible with liquid propane at −78 °C or above produced a slow growth or proliferous polymerization to form normally crystalline polymers.



This suggested that it might be possible to prepare normally crystalline polymers from other unsymmetrical monomers of the type $CH_2=CHY$ in ionic heterogeneous systems.

The discovery of stereopolymerizations of 1-alkenes by use of Ziegler-Natta catalysts in heterogeneous systems in 1954, and subsequent studies of polymer structure, attracted world-wide attention to this field. Propylene and 1-butene, which are monoallylic compounds, had not been homopolymerized by conventional ionic or free radical conditions to give linear high polymers suitable as plastics or other synthetic materials. Short branches in polyethylenes had been shown to reduce crystallinity and hardness. Natta and coworkers demonstrated the ability of catalysts such as those from reaction of aluminum alkyls with titanium halides to form normally crystalline, surprisingly high softening polymers from propylene. A helix of three monomer units explained the regularity required for crystallization and the identity period observed from x-ray diffraction. Stereoregular isotactic polymers of crystal melting ranges shown in Table 1 were prepared by slow heterogeneous ionic polymerizations using special catalysts at moderate pressures and temperatures.

Stereoregular propylene polymer plastics have outstanding utility, for example, heat resistance superior to that of polyethylenes in sterilizable hospital devices. By copolymerization and control of the degree of stereoregularity brittleness at low temperatures can be avoided. Stereoregular 1-butene and isobutylethylene polymers are also manufactured, but the isotactic polymers from styrene and from methyl methacrylate are too brittle for much use. Crystallizable polystyrenes also have been prepared by heterogeneous anionic polymerizations (Lewis basic catalysts) and crystalline methyl methacrylate polymers can be prepared using Grignard catalysts.

Soluble catalysts derived from organoaluminum compounds and vanadium halides promote formation of atactic elastomeric propylene polymers and copolymers such as ethylene-propylenediene terpolymer rubbers

TABLE 1. CRYSTAL MELTING RANGES OF SOME STEREOREGULAR POLYMERS

Isotactic stereopolymers	Melting range	Stereopolymers	Approximate maximum melting point
Propylene	165–176 °C	Isotactic 1,2-butadiene	120 °C
1-Butylene	120–136	Syndiotactic 1,2-butadiene	154
1-Amylene	60–70	*Cis*-1,4-butadiene	+1
Isopropylethylene	300–310	*Trans*-1,4-butadiene	148
Isobutylethylene	235–250	*Cis*-1,4-isoprene	22
Isoamylethylene	about 110	*Trans*-1,4-isoprene	65
4,4-Dimethyl-1-pentene	>380	*Cis*-1,4-(2,3-dimethyl butadiene)	190
Styrene	230–250	*Trans*-1,4-(2,3-dimethyl butadiene)	260
Isobutyl vinyl ether	100–130		
Methyl methacrylate	160		

(EPDM). Amorphous adhesive propylene homopolymers have some commercial use. Syndiotactic or DLDL propylene polymers have been reported but their structures and properties have not been completely established.

Isomeric isoprene polymers are formed biologically as natural rubber (*cis*-1,4) and balata or gutta-percha (largely *trans*-1,4). Modified Ziegler-Natta type catalysts, colloidal lithium or lithium alkyls (in absence of ethers) were found to give predominantly *cis*-1,4 polymer rubbers from isoprene. *Cis*-1,4-polybutadiene, so-called synthetic natural rubbers, have become important in tires and in graft copolymerization with styrene for high-impact plastics. Different conditions of polymerization give rigid *trans*-1,4-diene polymers resembling balata.

Although precise mechanisms of the stereopolymerizations are yet uncertain, several characteristics become evident. The reactions are predominantly heterogeneous, ionic reactions at low or moderate temperatures. The more stereoregular polymers grow as a separate phase upon the solid or immiscible liquid catalyst. However, some monomers such as vinyl isobutyl ether can form somewhat isotactic polymer fractions even from homogeneous solutions of Lewis acid and monomer. In contrast, the polymers from vinyl isopropyl ether, which apparently are stereoregular when obtained by slow growth polymerization using boron fluoride etherate catalysts, nevertheless do not crystallize readily. BF_3 can be used to form isotactic vinyl isobutyl ether polymers if it is applied in a separate phase of methylene chloride immiscible with liquid propane. Relatively polar solvents which favor separation of gegen ions from their growing macroions generally impair stereospecificity.

Although the Ziegler-Natta catalyst systems for stereopolymerization of 1-olefins were regarded by Natta, Mark, and others as examples of anionic polymerizations, the writer considers them as a special type of cationic polymerization. A consistent system relating monomer structure to response to catalyst types is only possible if propylene containing an electron repelling methyl group attached to the ethylene nucleus polymerizes with Lewis acid catalysts (cationic polymerization). Propylene as an allyl compound lacks sufficient electron withdrawal from the ethylene group to homopolymerize by free radical initiation (peroxide, azo catalysts or ultraviolet light) and it also lacks sufficient electron donation (as in isobutene) for homopolymerization by conventional cationic system. Ziegler-Natta catalysts have been observed to homopolymerize some other monoallyl compounds. An intensive study of the literature by the writer and Mabel D. Reiner showed no well-characterized homopolymers of high molecular weight obtained from monoallyl compounds by free radical or conventional ionic catalyst systems.

Transition metal catalysts for polymerization of 1-alkenes similar to those of Ziegler were developed in DuPont laboratories and have been called coordination catalysts.

Outside of vinyl addition polymerizations some crystallizable stereoregular polymers also have been prepared. An example is isotactic polymer from propylene oxide  made by using ferric chloride complex catalysts for proliferous type reactions.

After the demonstrations of preparation of stereoregular polymers having novel properties by means of special ionic methods, the possibilities of free radical methods were examined extensively. It must be concluded that in free radical systems the structures of homopolymers and copolymers can be little influenced by specific catalysts and other reaction conditions, but are determined largely by monomer structure. This is consistent with the relative uniformity of comonomer reactivity ratios in radical copolymerizations. However, it has been found possible to obtain somewhat more syndiotactic structure, DLDL, than normally obtained by radical reactions, at low temperatures and by selecting solvents. Examples are polyvinyl chlorides of higher than usual crystallinity from polymerizations at low temperature e.g., −50 °C under ultraviolet light.

Although they do not crystallize, polyvinyl acetates prepared at low temperatures apparently are more syndiotactic since they yield more than usually crystalline polyvinyl alcohols by saponification. Monomers of high polarity such as vinyl trifluoracetate by radical polymerization can form relatively syndiotactic polymers from which more crystalline polyvinyl alcohols can be prepared by saponification.

C.E. SCHILDKNECHT, Gettysburg College, Gettysburg, PA

STEREOSCOPE. The sensation of depth in an object is due to binocular vision; that is, to the fact that two eyes do not each see exactly the same view. By taking two pictures with a camera moved a few inches — or with a double stereoscopic camera — two slightly different pictures are obtained. A stereoscope is a device by which each eye sees only one of these pictures, and the same sensation of depth is obtained as with direct binocular vision.

STEREOSPECTROGRAM. A method of representing spectral data in which the three variables, concentration of solute, optical density, and wavelength of light, are plotted in three dimensions to produce a three-dimensional figure; or else in two dimensions by choosing an oblique axis in addition to the customary x-axis and y-axis.

STEREO SYSTEM. An acoustical system in which a plurality of microphones (or other transducers), transmission channels and reproducers are arranged so as to provide a sensation of spatial distribution of the original sound sources to the listener.

STERIC EFFECTS. *Steric effects* arise from the fact that each atom within a molecule occupies a certain amount of space. If atoms are brought too close together, there is an associated cost in energy due to overlapping electron clouds (Pauli or Born repulsion), and this may affect the molecule's preferred shape (conformation) and reactivity.

Types of Steric Effects

Steric hindrance or Steric resistance occurs when the size of groups within a molecule prevents chemical reactions that are observed in related smaller molecules. Although steric hindrance is sometimes a problem, it can also be a very useful tool, and is often exploited by chemists to change the reactivity pattern of a molecule by stopping unwanted side-reactions (steric protection). Steric hindrance between adjacent groups can also restrict torsional bond angles.

Steric shielding occurs when a charged group on a molecule is seemingly weakened or spatially shielded by less charged (or oppositely charged) atoms, including counterions in solution (Debye shielding). In some cases, for an atom to interact with sterically shielded atoms, it would have to approach from a vicinity where there is less shielding,

thus controlling where and from what direction a molecular interaction can take place.

Steric attraction occurs when molecules have shapes or geometries that are optimized for interaction with one another. In these cases molecules will react with each other most often in specific arrangements.

Chain crossing Occurs since a random coil cannot change from one conformation to a closely related shape by a small displacement if it would require one polymer chain to pass through another, or through itself.

Understanding steric effects is critical to chemistry, biochemistry and pharmacology. In chemistry, steric effects are nearly universal and affect the rates and energies of most chemical reactions to varying degrees. In biochemistry, steric effects are often exploited in naturally occurring molecules such as enzymes, where the catalytic site may be buried within a large protein structure. In pharmacology, steric effects determine how and at what rate a drug will interact with its target biomolecules.

STERLING SILVER. Silver alloy, usually with copper, containing at least 92.5% silver.

STERN-GERLACH EXPERIMENT. An experimental test by O. Stern and W. Gerlach (Germany, 1924) of the magnetic moment of atoms. A stream of metallic atoms, issuing from a vaporizing furnace through a narrow slit, entered a strong magnetic field. The magnetic intensity was perpendicular to the atom stream, and had a strong gradient in its own direction. If magnetic moments of atoms are due to revolving electrons, the atoms should, according to classical theory, begin to precess at all angles about the field direction, and the atomic beam should simply broaden into a band. According to the quantum theory, they should precess at certain angles only, and the original stream should be divided into distinct streams. Since the beam was split into $2J + 1$ different beams, the experiment showed that in a magnetic field not all orientations to the field, but only $2J + 1$ discrete directions, are possible. See also **Magnetism**; and **Precession**.

STEROIDS. Organic compounds characterized from a structural standpoint by the cyclopentanophenanthrene nucleus as shown in Fig. 1. Biochemically, the steroids are closely related to the terpenes. Steroids occur widely in nature, both in animals and plants. Many steroids are hormones, such as estrogens and cortisone, which are produced by the body's endocrine system and which are of great importance in the regulation of numerous body processes, such as growth and metabolism. Similarly, steroid hormones are important to several physiological processes within plants. Auxin, for example, is a plant growth hormone that regulates longitudinal cell structure so as to permit bending of the stalk or stem in phototropic response. The most common animal steroid, a steroid alcohol (or *sterol*) is *cholesterol*, which is the precursor of bile acids, steroid hormones, and provitamin D3. It should be stressed, however, that not all steroids are hormones; and not all hormones are steroids.

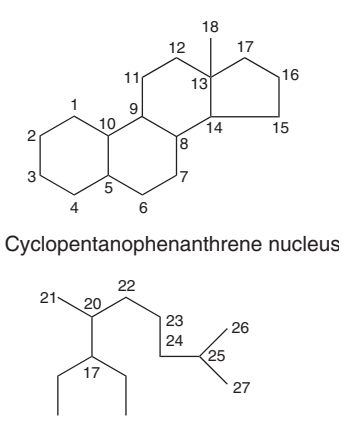


Fig. 1. Steroid molecule nucleus and side chain.

Over the last 35 to 40 years, steroid therapy, that is, the medical augmentation of steroid hormones that are insufficient in the body (as well as treating diseases and elements which result from an overabundance of certain steroid hormones in the body), is one of the major chapters in the history of medical progress. Similarly, the understanding of steroid chemistry has contributed markedly to plant biology, notably to plant breeding and the development of plant growth regulators. Commencing with the isolation of steroid hormones from natural sources, techniques were later developed to synthesize a number of hormones. Then, a further step involved the application of steroid hormones, developed by way of synthesis, but for which there are no known counterparts in nature. Some of the steroid hormones, including steroidal synthetics, of importance medically and to scientific investigations, are listed and described briefly in Table 1.

The early history of steroid chemistry commenced with the observations of Mauthner, Windlaus, Wieland, Jacobs, Diels, and other organic chemists and biologists in their early observations on the products of oxidation, aromatization, and other reactions of cholesterol, bile acids, and plant glycosides. The interrelationship between sterols and bile acids was recognized early during these investigations. Shortly after the steroid character of the female and male sex hormones had been established, x-ray crystallography demonstrated errors in early theories concerning molecular structure. Rosenheim and King, working with monomolecular layers and x-ray evidence gained by Bernal, formulated the concept of the cyclopentanophenanthrene nucleus.

Once the skeleton of the steroids was established, there remained the task of understanding the steric relationships of the molecules. With reference to Fig. 1, it will be noted that there are nine asymmetric carbon atoms in the steroid skeleton — C_5, C_{10}, C_9, C_8, C_{14}, and C_{13} in the ring system. There are also two asymmetric carbons in the side chain attached at C_{17}. These are C_{20} and C_{25}. With reference to Figs. 1 and 2, the relative configuration of C_5 and C_{10}, of C_9 and C_8, and of C_{14} and C_{13}, determines whether the junctions between rings a/b, b/c, and c/d, respectively, are *trans* or *cis*. According to an arbitrary convention, one designates the substituent groups α or β depending upon whether they are situated below the plane of the molecule, when depicted in a certain way. Usually, in a structural diagram of a steroid molecule, a dotted line connection will be used between atoms to designate an alpha position; a regular solid line for a beta position.

Figure 2 illustrates one of the two most important configurations of steroid skeletons, among 63 other possibilities, as they are found in nature. The side chain is usually attached in β-position to C_{17}. The configurations on C_{20} and C_{24} have likewise been determined and are known to produce steric isomerisms.

The sterols, from which the name of the entire group is derived, are monovalent alcohols with a secondary hydroxyl group on C_3 usually

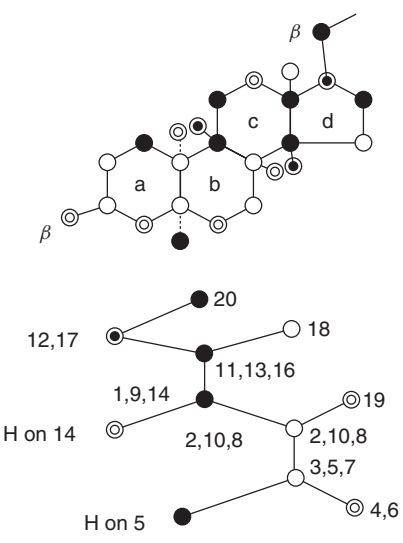

Fig. 2. Constellation of a saturated beta-sterol; • = atoms in bottom plane; ◉ = atoms in second plane; ○ = atoms in third plane; ◎ = atoms in top plane. Lateral view of molecule is shown at right.

TABLE 1. REPRESENTATIVE STEROID HORMONES AND STEROIDAL SYNTHETICS[1]

Antiinflammatory, Antiallergic, and Antirheumatic Agents (Adrenal Corticosteroids)

Betamethasone (9-fluoro-16β-methylprednisolone; 16β-methyl-11b,17α,21-trihydroxy-9α-fluoro-1,4-pregnadiene-3,20-dione). $C_{22}H_{29}O_5F$, mw = 329.5. Also, the *betamethasone acetate*, $C_{24}H_{31}O_6F$, mw = 434.5; and *betamethasone disodium phosphate*, $C_{22}H_{28}O_8FNa_2P$, mw = 516.4. Both of the latter compounds are used for treating carpal tunnel syndrome, the most common of the entrapment neuropathies. The median nerve is subjected to compression and possibly ischemia in the confined space between the carpal bones and the flexor retinaculum of the wrist.

Chloroprednisone acetate (6α-chloroprednisone acetate; 6α-chloro-$\Delta^{1,4}$-pregnidien-17β,21-diol-3,11,20-trione-21-acetate). Mw = 436.6. Multiple uses.

Corticosterone (11,21-dihydroxyprogesterone; Δ^4-pregnene-11β,21-diol-3,20-dione; 11β,21-dihydroxy-4-pregnene-3,20-dione). $C_{21}H_{30}O_4$, mw = 346.4. Multiple uses.

Cortisone (17-hydroxy-11-dehydrocorticosterone; 17α,21-dihydroxy-4-pregnene-3,11,20-trione; Δ^4-pregnene-17α,21-diol-3,11,20- trione; Kendall compound; Wintersteiner compound F). $C_{21}H_{28}O_5$, mw = 360.4. Multiple uses.

Desoxycorticosterone (deoxycorticosterone; 11-desoxycorticosterone; 21-hydroxyprogesterone; 4-pregnen-21-ol-3,20-dione; Kendall desoxy compound B; Reichstein substance Q). $C_{21}H_{30}O_3$, mw = 330.2. Also, the *desoxycorticosterone acetate* (DCA). $C_{23}H_{32}O_4$, mw = 372.4; and *desoxycorticosterone pivalate*, $C_{26}H_{38}O_4$, mw = 414.6. Multiple uses.

Dexamethasone (hexadecadrol; 9α-fluoro-16α-21-trihydroxy-16α-methyl-1,4-pregnadiene-3,20-dione). $C_{22}H_{29}FO_5$, mw = 392.4. Widely used in the treatment of benign intracranial hypertension, brain abscess, brain metastases, brain tumor, cerebral thrombosis, Cushing's syndrome, encephalitis, hypertensive encephalopathy, lumbar disk disease, meningococcal cerebral edema, shock, superior vena cava obstruction in cancer patients, ulcerative colitis.

Dichlorisone acetate (9α,11β-dichloro-1,4-pregnadiene-17α,21-diol-3,20-dione-21-acetate). $C_{23}H_{28}O_5Cl$, mw = 455.3.

Fluocinolone acetonide (6α,9α-difluoro-16α hydroxyprednisolone-16,17-acetonide). $C_{24}H_{30}O_6F_2$, mw = 452.50.

Fluorohydrocortisone (fluorocortisone; 9α-fluoro-11β,17α,21-trihydroxy-4-pregnene-3,20-dione). $C_{21}H_{29}O_5$, mw = 380.4. Used in treating Shy-Drager syndrome (parenchymatous degeneration of the central nervous system); also in treating orthostatic hypotension (a cause of temporary loss of consciousness when a person rises to an erect position). Also *fluorometholone* (9α-fluoro-11β,17α-dihydroxy-6α-methyl-1,4-pregnadiene-3,20-dione). $C_{22}H_{24}FO_4$, mw = 376.4; and *fluprednisolone* (6α-fluoroprednisolone), $C_{21}H_{27}FO_3$, mw = 378.4; and flurandrenolone (6-fluoro-16α-hydroxyhydrocortisone-16,17-acetonide), $C_{24}H_{33}O_6F$, mw = 436.5.

Hydrocortisone (cortisol; 11β,17α,21-trihydroxy-4-pregnene-3,20-dione), $C_{21}H_{30}O_5$, mw = 362.5. Used in treating adrenal insufficiency, notably in cancer patients, contact dermatitis, panhypopituitarism, psoriasis, shock, and urticaria. Also *hydrocortisone acetate* (cortisol acetate), $C_{23}H_{32}O_6$, mw = 404.5, used in treating rheumatoid arthritis; and *hydrocortisone sodium succinate* (11β,17α,21-trihydroxy-4-pregnene-3,20-dione-21-hydrogen succinate, sodium salt), $C_{25}H_{33}O_8Na$, mw = 484.5. The latter compound is used in treating ulcerative colitis.

Methylprednisolone (D1-6a-methylhydrocortisone). $C_{22}H_{30}O_5$, mw = 374.5. Used in treating thrombocytopenia with intracranial hemorrhage, Gram-negative bacteremia, posttransfusion purpura, and shock. Also *methylprednisolone sodium succinate*, $C_{26}H_{33}O_8Na$, mw = 496.5.

Paramethasone (6α-fluoro-16α-methylprednisolone). $C_{22}H_{30}O_5$, mw = 392.45. Also *paramethasone acetate*, $C_{24}H_{31}O_6F$, mw = 434.5.

Prednisolone (methacortandralone; 1,4-pregnadiene-3,20-dione-11β,17α,21-triol). $C_{21}H_{28}O_5$, mw = 360.4. Also *prednisolone phosphate sodium* (disodium prednisolone-21-phosphate), $C_{21}H_{27}Na_2O_8P$, mw = 484.4, used in treating ulcerative colitis. Also *prednisolone pivalate* (prednisolone trimethylacetate), $C_{26}H_{36}O_6$, mw = 444.6.

Prednisone (metacortandricin; 17α,21-dihydroxy-1,4-pregnadiene-3,11,20-trione). $C_{21}H_{26}O_5$, mw = 358.4. Used in the treatment of scores of ailments and diseases. To mention a few: acute erythroleukemia, acute gouty arthritis, acute pericarditis, aspiration pneumonitis, autoimmune hemolytic anemia, breast cancer, bronchial asthma, chronic hepatitis, dermatomyositis, desquamative interstitial pneumonia, Hodgkin's disease, hypercalcemia, immune neutropenia, lymphocytic leukemia, osteoporosis, hemoglobinuria, prostate cancer, psoriasis, radiation enteritis, rheumatoid arthritis, trichinosis, ulcerative colitis, usual interstitial pneumonia, viral anthropathies.

Triamcinolone (9α-fluoro-16α-hydroxyprednisolone). $C_{21}H_{27}FO_6$, mw = 394.4. Used in treating acute gouty arthritis and uremic pericarditis. Also *triamcinolone acetonide* (9α-fluoro-11β,21-dihydroxy-16α,17α-isopropylidenedioxy-1,4-pregnadiene-3,20-dione), $C_{24}H_{31}FO_6$, mw = 434.4. Used in treating acne vulgaris. Also *triamcinolone diacetate* (9α-fluoro-16α-hydroxyprednisolone-16,21-diacetate), $C_{25}H_{31}FO_8$, mw = 478.49.

Androgens and Anabolic Agents

Androsterone (3α-hydroxy-17-androstenone). $C_{19}H_{30}2$, mw = 290.4. Also *fluoxymesterone* (9α-fluoro-11β, 17β-dihydroxy-17α-methyl-4-androsten-3-one), $C_{20}H_{29}FO_3$, mw = 336.4. Used in treating paroxysmal nocturnal hemoglobinuria. Also *aldosterone* (electrocortin; 18-formyl-11β,21-dihydroxy-4-pregnene-3,20-dione) $C_{21}H_{28}O_5$, mw = 360.4.

Androgens and Anabolic Agents

Hydroxydione sodium (21-hydroxypregnane-3,20-dione-21-sodium hemisuccinate). $C_{25}H_{35}O_6Na$, mw = 454.5.

Spironolactone (3-(30-oxo-7α-acethylthio-17β-hydroxy-4-androsten-17α-yl)-propionic acid γ-lactone), $C_{24}H_{32}O_4S$, mw = 416.5. Used in treating congestive heart failure, hypertension, hypokalemia.

Methandrostenolone (17α-methyl-17β-hydroxy-1,4-androstadien-3-one). $C_{20}H_{28}O_2$, mw = 300.4.

Methylandrostenediol (MAD; methandriol; 17α-methyl-5-androsten-3β,17β-diol). $C_{20}H_{32}O_2$, mw = 304.4.

Methyl testosterone (17α-methyl-Δ^4-androsten-17-β-0 1-3-one). $C_{20}H_{30}O_2$, mw = 302.4.

Norethandrolone (17α-ethyl-19-nortestosterone). $C_{20}H_{30}O2$, mw = 302.4. Also *oxandroline* (17β-hydroxy-17α-methyl-2-oxa-5α-androstane-3-one), $C_{19}H_{30}O_3$, mw = 306.4.

Oxymetholone (2-hydroxymethylene-17-α-methyldihydrotestosterone). $C_{21}H_{32}O_3$, mw = 332.4. Used in treating agnogenic myeloid metaplasia and hereditary angioedema. Also *prometholone* (2α-methyl-dihydro-testosterone propionate), mw = 360.5.

Testosterone (trans-testosterone; 17β-hydroxy-4-androsten-3-one). $C_{19}H_{28}O_2$, mw = 288.4. Used in treating acne vulgaris, impotence, polycystic ovary syndrome, male hypogonadism. Also *testosterone cypionate*, $C_{27}H_{40}O_3$, mw = 412.6; *testosterone enanthate*, $C_{26}H_{40}O_3$, mw = 400.6; *testosterone phenylacetate*, $C_{27}H_{34}O_3$, mw = 406.5; *testosterone propionate*, $C_{22}H_{32}O_3$, mw = 344.4.

Estrogens

Equilenin (1,3,5-10,6,8-estrapentaen-3-ol-17-one). $C_{18}H_{18}O_2$, mw = 266.3. Also *equilin* (1,3,5,7-estratetraen-3-ol-17-one), $C_{18}H_{20}O_2$, mw = 268.3.

Estradiol (β-estradiol; dihydrofolliculin, dihydroxyestrin; 3,17-ephidhydroxyestratriene). $C_{18}H_{24}O_2$, mw = 272.3. Also *estradiol benzoate*, $C_{25}H_{28}O_3$, mw = 376.4; *estradiol cypionate*, $C_{26}H_{36}O_2$, mw = 396.6; *estradiol diprionate*, $C_{24}H_{32}O_4$, mw = 384.5.

Estriol (trihydroxyestrin; 1,3,5-estratriene-3,16α,17β-triol). $C_{18}H_{24}O_3$, mw = 288.3.

Estrone (folliculin; ketohydroxyestrin; 1,3,5-estratriene-3-ol-17-one). $C_{18}H_{22}O_2$, mw = 270.3. Also *estrone benzoate*, $C_{25}H_{26}O_3$, mw = 374.4.

Ethynyl estradiol (17-ethinyl estradiol; 17α-ethynyl-1,3,5-estratriene-3,17β-diol). $C_{20}H_{24}O_2$, mw = 296.4. Used to treat acne vulgaris, osteoporosis.

Mestranol (ethylestradiol-3-methylether; 3-methoxy-19-nor-17α-pregnα-1,3,5-trien-20-yn-17-ol). $C_{21}H_{26}O_2$, mw = 310.4. Used in treating acne vulgaris.

TABLE 1. (*Continued*)

Progestogens and Progestins
Acetoxypregnenolone (21-acetoxypregnenolone; 3-hydroxy-21-acetoxy-5-pregnen-20-one). $C_{23}H_{34}O_4$, mw = 374.5.
Anagestone acetate (6α-methyl-4-pregnen-17α-ol-20-one). $C_{24}H_{36}O_3$, mw = 372.6.
Chlormadinone acetate (6-chloro-D4,6-pregnadiene-17α-ol-3,20-dione acetate). $C_{23}H_{29}ClO_4$, mw = 414.9.
Dimethisterone (17β-hydroxy-6α-methyl-17α-(prop-1-nyl)-androst-4-ene-3-one). $C_{23}H_{32}O_2{\cdot}H_2O$, mw = 358.5. Also *ethisterone*, $C_{21}H_{28}O_2$, mw = 312.4.
Ethynodiol diacetate (19-nor-17α-pregn-4-en-20-yne-3β,17-diol diacetate). $C_{24}H_{32}O_4$, mw = 384.5. Used in treating acne vulgaris.
Flurogestone acetate (17α-acetoxy-9α-fluoro-11β-hydroxy-4-pregnene-3,20-dione). $C_{23}H_{31}O_5F$, mw = 406.5.
Hydroxymethylprogesterone (medroxyprogesterone; 17α-hydroxy-6α-methyl-4-pregnene-3,20-dione). $C_{22}H_{23}O_3$, mw = 344.5. Used for treating menopausal symptoms, secondary amenorrhea. Also *hydroxymethylprogesterone acetate*, $C_{24}H_{24}O_3$, mw = 386.5. Used in treating hypogonadal females. Also *hydroxyprogesterone* (4-pregen-17α-ol-3,20-dione), $C_{21}H_{30}O_3$, mw = 330.4. Also *hydroxyprogesterone caproate* (17α-hydroxy-4-pregnene-3,20-dione caproate), $C_{27}H_{40}O_4$, mw = 428.6.
Melengestrol acetate (MGA; 6-dehydro-17-hydroxy-6-methyl-16-methylene-progesterone acetate), $C_{25}H_{32}O_4$, mw = 396.51.
Norethindrone (norethisterone; 17α-ethynyl-17-hydroxy-19-nor-17α-4-en-20-yn-3-one). $C_{20}H_{26}O_2$, mw = 298.4. Used in treating acne vulgaris. Also *norethindrone acetate*, $C_{22}H_{28}O_3$, mw = 340.4. Also *norethynodrel*, $C_{20}H_{26}O_2$, mw = 298.4. Also *normethisterone*, $C_{19}H_{28}O_2$, mw = 288.4.
Pregnenolone (D5-pregnen-3β-ol-20-one). $C_{21}H_{32}O_2$, mw = 308.4. Important in the synthesis of adrenal hormones.
Progesterone (progestin; progestone; Δ^4-pregnene-3,20-dione). $C_{21}H_{30}O_2$, mw = 314.4. Used in treating excessive uterine bleeding, hypogonadal females, menopausal symptoms, polycystic ovary syndrome, secondary amenorrhea.
Diuretic, Antiduretic and Anesthetic Agents
Aldosterone and spironolactone are described earlier in this list.
Hydroxydione sodium (21-hydroxypregnane-3,20-dione-21-sodium hemisuccinate). $C_{25}H_{35}O_6Na$, mw = 454.5

[1]This is an abridged list of steroid hormones. Some are much more important and widely used than others. Some are relatively recent to steroid therapy; others have been used more widely in the past than presently. See also **Hormones**.

in β-position. The best known representative is *cholesterol*. See Fig. 3. This compound forms esters with a great variety of acids. Both the free and esterified sterols accompany the neutral fat and the phosphatides in most animal and plant fat. Upon alkaline hydrolysis, the other lipid constituents form fatty acid soaps; the fraction which remains insoluble in aqueous alkaline solution is called "unsaponifiable" and consists primarily of sterols. The variations in the cholesterol content of blood of animals, particularly in humans, are of significance for the diagnosis of various diseases. See also **Cholesterol**. Cholesterol is the principal sterol of all vertebrate animals. It is also found in some mollusks and in crustaceans, where it may be of alimentary origin.

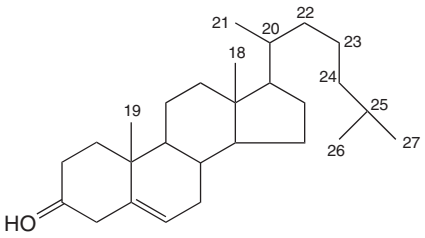

Fig. 3. Cholesterol.

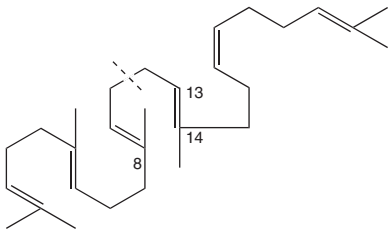

Fig. 4. Squalene.

Sterol Biogenesis. The finding that ingestion of radioactively labeled acetic acid leads to the synthesis of radioactive cholesterol was the first step in the elucidation of sterol biosynthesis. A growth factor for *Lactobacilli*, replaceable by acetic acid, was found to have the structure $HOCH_2{\cdot}CH_2{\cdot}C(CH_3)(OH){\cdot}CH_2{\cdot}CO_2H$. This compound was termed *mevalonic acid*. Its close relationship to a trimer of acetic acid is evident. Six molecules of the C_6 acid polymerize, losing their carboxyl groups, to the linear isoprenol *squalene*, a hydrocarbon occurring in nature. Twelve of the carbon atoms shown as circles in Fig. 4, originate from the carboxy groups of the original acetic acid, the remaining 18 from the methyl groups. Squalene folds in the manner indicated in the formula and yields (with a two-step rearrangement of the methyl group from C_8 and C_{13}) *lanosterol*, a "protosterol" found in wool and fat. This protosterol loses three methyl groups in positions 4, 4, and 14 in the course of biosynthesis, yielding *zymosterol*, found in yeast, which is convertible to cholesterol. The gradual oxidative degradation of the side chain in cholesterol to bile acids and subsequently to the various steroid hormones in animals is well established and has been confirmed by C-14 tracer studies. Many of the enzymes operative during these hormone syntheses in the insertion of hydroxyl groups on individual carbon atoms have been separated and localized in various cell constituents. Major steps in sterol biogenesis are shown in Fig. 5.

Classification of Medically Important and Useful Steroid Hormones

In addition to the medical uses of steroid hormones for alleviating conditions brought about by insufficiencies or overabundance of any particular hormone of this class within the body, and thus returning the desirable hormone balance, numerous therapies do not fall directly into these two categories. Rather, steroid hormones are used in connection with some ailments and diseases because of positive clinical results even though much remains to be learned concerning the details of their function.

Steroid hormones are difficult to classify because some of them serve large numbers of uses. The conventional approach places them into four categories.

Androgens and Anabolic Agents. Androgen is the male sex hormone. The androgenic hormones are synthesized in the body by the testis, the cortex of the adrenal gland, and, to a slight extent, by the ovary. The androgens have a number of sexually related functions. Androgens also serve as anabolic agents, i.e., in nutrition of muscle and bone in both male and female persons. A number of androgens have been synthesized. Some of these reduce or eliminate the production of male secondary sex characteristics when administered to females (growth of facial hair, lowering of the voice, etc.)

Estrogens. Estrogen is a general term for female sex hormones. They are responsible for the development of the female secondary sex characteristics, such as the deposition of fat and the development of the breasts. Estrogens are produced by the ovary, and, to a lesser degree, by the adrenal cortex and testis. Some synthetic *nonsteroid* compounds, such as diethylstilbestrol and hexestrol, have estrogenic activity.

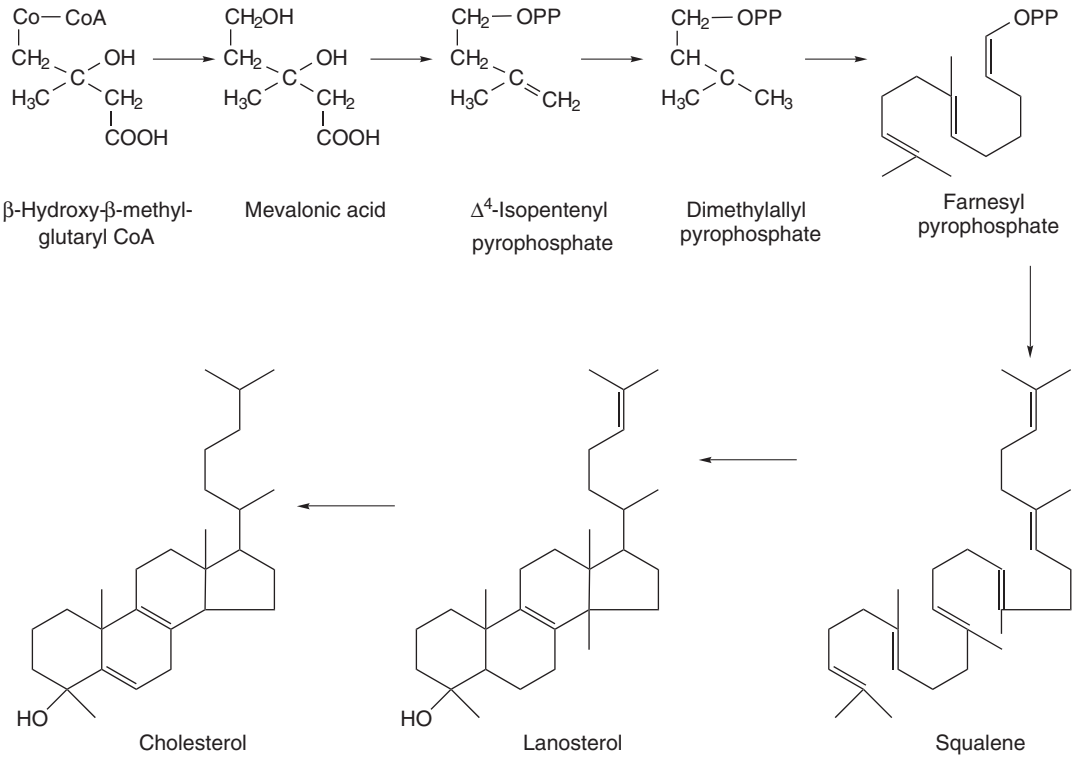

Fig. 5. Structures of key compounds involved in biogenesis of sterols.

Progestogens and Progestins. Progesterone (Δ^4-pregnene-3,20-dione), $C_{21}H_{30}O_2$, is the female sex hormone secreted in the body by the corpus luteum, by the adrenal cortex, or by the placenta during pregnancy. It is important in the preparation of the uterus for pregnancy, and for the maintenance of pregnancy. Progesterone is believed to be the precursor of the adrenal steroid hormones.

Adrenal Corticosteroids. Among these hormones are compounds which have been found to be antiinflammatory, antiallergic, and antirheumatic agents and consequently are very important in steroid therapy. Cortisone was first applied in 1949 and became a major drug for treating rheumatoid arthritis, among other ailments, soon thereafter. Hydrocortisone followed and a bit later several synthetic analogues (not found in the body) were developed. Well known among these is prednisone, found particularly effective in cases of diseases of collagen tissue. But its use is much more widespread. Several examples are given in the accompanying table. See also **Hormones**. Steroid therapy throughout the years has had to cope with production of numerous side effects. Problems like this provide an incentive to continued vigorous research for new compounds.

In addition to the foregoing four major classifications (by application), there are also steroid hormones which are effective diuretic, antiduretic, and local anesthetic agents. Among these are aldosterone, spironolactone, and hydroxydione sodium.

Bile Acids

The bile acids are monocarboxylic acids of the steroid group with 24 carbon atoms and 1–3 secondary hydroxyl groups. They occur in the bile of all vertebrates from the teleosts upward, mostly in peptidic conjugation with glycine and taurine. The bile acids are described in the entry on **Bile**.

STETHOSCOPE. An instrument for listening to sounds originating within the body, especially of the heart and lungs. The stethoscope is a low-pass filter the exact acoustical characteristics of which vary significantly from one manufacturer to another. Electronic stethoscopes are available.

STEVENS REARRANGEMENT. Migration of an alkyl group from a quaternary ammonium salt to an adjacent carbanionic center on treatment with strong base. The product is a rearranged tertiary amine, sulfonium, or sulfide.

STEVIOSIDE. See **Sweeteners**.

STIBNITE. The mineral stibnite, antimony sulfide, [CAS: 1345-04-6] Sb_2S_3, is found in radiated groups of acicular orthorhombic crystals or in other sorts of aggregates, as well as blades, also as columnar or granular masses. It shows a highly perfect pinacoidal cleavage; conchoidal fracture; hardness, 2; specific gravity, 4.63–4.66; luster, metallic and very brilliant on cleavage faces or freshly fractured surfaces. Its color is a steely gray; the streak very similar in color, may be covered with a black, sometimes iridescent tarnish. See also **Antimony**.

Stibnite is the most common antimony mineral known and is the chief ore of that metal. It is a primary ore mineral and occurs with other antimony minerals and galena, sphalerite, and silver ores. Small deposits of Stibnite are common, large ones are rare. It occurs in Canada, Mexico, Peru,

Japan, China, Germany, Romania, Italy, France, England, Algeria, and Kalimantan, Borneo. In the United States it is found in Arkansas, Idaho, Nevada, California, and Alaska.

The name stibnite is derived from the Latin word for antimony, *stibium*.

STIFFNESS. In general, the ability of a system to resist a prescribed deviation. In the case of a deformable elastic medium, stiffness is the ratio of a steady force to the elastic displacement produced by it, e.g., for a spring the force required to produce unit stretch. The term is applied most often to an elastic system vibrating about a position of equilibrium. Acoustic stiffness is the quantity which, when divided by 2π times the frequency, gives the acoustic reactance associated with the potential energy of the medium or its boundaries. The unit commonly used is dyne/centimeter. Mechanical stiffness is expressed in terms of the various elastic constants and moduli.

STIGMA. 1. A secondary sexual mark of insects. In many species of butterflies, it consists of a patch on the wing of the male bearing modified scales on a more or less modified area of the wing membrane. 2. A term used by some entomologists in place of spiracle. 3. A pigmented spot or "eye spot" sensitive to light in some flagellate protozoa.

STIGMATIC. Two uses of this term in optics are: (1) For a bundle of rays, homocentric. (2) For an optical system, having equal focal power in all meridians.

STILBITE. The mineral stilbite, $NaCa_2(Al_5Si_{13})O_{36}\cdot 14H_2O$, is a zeolite, the compound monoclinic crystals of which are usually grouped in approximately parallel positions, forming sheaf-like aggregates, which have a soft pearly luster, whence the name stilbite from the Greek, meaning luster. The less commonly used term desmine is likewise from the Greek, meaning a bundle. Stilbite has one perfect cleavage; uneven fracture; is brittle; hardness, 3.5–4; specific gravity, 2–2.2; luster, vitreous to pearly; color, usually white but may be brownish, yellowish, red or pink. Its streak is white, and it is transparent to translucent. Like the other zeolites stilbite occurs in cavities in basalts and traps, rarely in granites and gneisses. Of the many localities may be mentioned Trentino, Italy; the Harz Mountains; Valais, Switzerland; Arendal, Norway; the Ghats Mountains of India; and Mexico. The Triassic traps of New Jersey and Pennsylvania furnish specimens as do also rocks of the same age in Nova Scotia. This mineral sometimes is called *desmine*.

STIMULUS (Nerve). Physical agent used to set up a nerve impulse. Since the nerve fiber is excitable by electric currents, a common stimulus is a brief current pulse whose amplitude and duration and rate of delivery can be controlled with precision. Other physical agents can be used, depending upon the input under examination, e.g., sudden stretch in the case of stretch receptor, sound wave for auditory input, and light in the case of the eye.

STINK BUG *(Insecta, Hemiptera)*. A flattened bug of generally ovate form, in many species with an angular outline. Most species are moderately large, reaching a length of about half an inch. The many species, constituting the family *Pentatomidae*, are also characterized by the fetid odor of the secretion discharged from glands opening on the lower surface of the body.

One species, the harlequin cabbage bug or calico-back, is a troublesome pest. It is best controlled by clean cultivation of fields, hand picking of bugs and their eggs, and the use of trap crops, planted early to attract the insects.

Some members of the group eat other insects and are probably beneficial in destroying pests, but unfortunately even the harmless species may contaminate berries with their unpleasant odors.

ST LOUIS ENCEPHALITIS VIRUS (SLEV). See **Arthropod-borne Viruses**.

STOCHASTIC. The adjective "stochastic" implies the presence of a random variable; e.g., stochastic variation is variation in which at least one of the elements is a random variable, and a stochastic process is one wherein the system incorporates an element of randomness as opposed to a deterministic system.

The word derives from Greek $\sigma\tau\acute{o}\chi o\varsigma$, a target, and a stochastiches was a person who forecast a future event in the sense of aiming at the truth. In this sense it occurs in sixteenth-century English writings. Bernoulli in the *Ars Conjectandi* (1719) refers to the "ars conjectandi sive stochastice." The word passed out of usage until revived in the twentieth century.

STOCHASTIC PROCESS. A family of variates (x_t) where t assumes values in a certain range T. In most practical cases x_t is the observation at time t and T is a time-range, but t may also refer to distribution in space and may be considered for discontinuous or continuous values.

A stochastic process (x_t) is said to be stochastically continuous if, for values t, $t + h_1$, $t = h_2, \ldots$ with h_n tending to zero as n tends to infinity

$$\lim_{n\to\infty} x_t + h_n$$

exists in the sense of stochastic convergence and is equal to x. Likewise, if

$$\lim \frac{x_{t+h_n} - x_t}{h_n}$$

exists in the sense of stochastic convergence, the process is said to be stochastically differentiable. And if the process exists in $a \le t \le b$ and the Riemann integral

$$\int_b^a x_t\, dt$$

exists in the sense of stochastic convergence, the process is said to be stochastically integrable.

STOICHIOMETRY. The mathematics of chemical reactions and processes. It relates to all the quantitative aspects of chemical changes, both mass and energy. Stoichiometry is based on the absolute laws of conversion of mass and of energy and on the chemical law of combining weights. This basis makes stoichiometry as exact as any other branch of mathematics.

The law of conservation of mass dictates that, regardless of the nature of the changes undergone in a physical or chemical process, the total mass of all the materials in the system remains the same, even though the physical states and chemical compositions of the materials may change. Likewise, the law of conservation of energy is based upon the fact that the total energy in a reacting system remains constant even though the level or form of the energy may change. In radioactive transformations, however, a slight correction must be applied to the law of the conservation of mass. Mass and energy have been found to be interconvertible, so that in general the total energy of the system remains constant even though there may be small mass changes.

The above concepts form the basis for weight and heat balance calculations. Such calculations are of great significance in engineering practice for the purpose of evaluating performance of existing operations or designing new manufacturing facilities and equipment.

The basic laws of conservation specifically state that matter or energy in a given system cannot be created or destroyed, and accordingly this requires that the following equality holds true:

$$\text{Input} = \text{output} + \text{accumulation}$$

For continuous, steady flow systems the change in in-process inventory is zero during any interval of time. In this case, therefore, the above expression reduces to the simplified form of input = output.

In making material weight balances the above relation may be applied to a single unit of the operation, or to the over-all operation with reference to the separate elements and/or the total mass entering and leaving the system. This method of analysis can best be exemplified by means of a synthetic problem: Let it be assumed that consideration is being given to a continuous, steady flow system, to which X pounds of material is fed per minute and from which Y pounds of useful product are analyzed to contain $a\%$ and $b\%$ by weight of a certain constituent, respectively. It is desired to determine the extent of unmeasured loss, Z pounds per minute, incurred

from the system and the average concentration, c, of the said constituent in the waste stream.

First, it may be written that input = output. By dividing each side of this equality by an element of time, this relationship can then be transformed into the following expression:

$$\text{Rate of input} = \text{rate of output}$$

Then, a total weight balance can be written to express this statement of equality in terms of the quantities specified in the problem:

$$X = Y + Z \tag{1}$$

A similar balance may also be written in terms of the constituent in question:

$$\frac{a}{100}X = \frac{b}{100}Y + \frac{c}{100}Z \tag{2}$$

Finally, by algebraic solution of the two simultaneous equations it follows that

$$Z = X - Y \tag{3}$$

and

$$c = \frac{aX - bY}{X - Y} \tag{4}$$

The above example is only a simple illustration of a weight balance. Similarly, the reaction between elements and compounds may be symbolically expressed to portray the principle of conservation of matter. For example, if hydrogen is completely burned to water, the reaction between it and oxygen can be represented as follows:

$$\text{(Hydrogen)} + \text{(Oxygen)} \longrightarrow \text{(Water)}$$

$$H_2 + \frac{1}{2}O_2 \longrightarrow H_2O$$

$$\text{(2.02Wgt. units)} + \text{(16.00Wgt. units)} \longrightarrow \text{(18.02Wgt. units)}$$

It would be found that these materials would always react in the same relative proportions to form water in an amount equal to the total weight of reactants. The relative weights indicated are equal to the molecular weights of the materials in question. Even if a reaction does not go to completion, the quantities which did react would be proportional to the combining weights expressed in the balanced chemical equation.

Since the element of time is usually involved as the basis of a stoichiometric calculation, proper quantitative deductions often depend on adequate knowledge of other laws or principles, such as those governing rates of reaction and those pertaining to chemical equilibria. When materials in the gaseous state are involved, the general gas laws are of great utility.

Another independent relation for a system is obtainable by applying the law of conservation of energy, which requires that energy input equals energy output. A valid equality of this type must include all forms of energy such as potential energy, kinetic energy, internal energy, flow work, electrical energy, etc. This type of equality results in the so-called "total energy balance." Another very useful but similar expression is the Bernoulli mechanical energy balance for steady mass flow of fluids. However, heat energy is very frequently the only primary effect in a process so that, in such cases, the total energy balance can be simplified to the very advantageous expression of heat input equals heat output. This constitutes the basis for heat balances which, together with weight balances, are the most useful tools in any stoichiometric calculations.

Since chemical reactions involve combination of atoms or molecules to form new compounds or decomposition of compounds to form simpler ones, it is most convenient in stoichiometric calculations to employ molecular units rather than weight units. This particular kind of unit is called a "mole" and represents the quantity of substance numerically equal to its molecular weight. This weight quantity may be based on any system of weight units desired, and it is thus necessary to designate this basis by referring to pound moles, gram moles, etc.

A particular chemical reaction may be written to embody both laws of conservation of mass and energy as demonstrated below:

$$FeS + \frac{7}{4}O_2 \longrightarrow \frac{1}{2}Fe_2O_3 + SO_2 + 268,000\text{Btu}$$

This equation states that 1 pound mole of ferrous sulfide reacts with 7/4 moles of oxygen to form $\frac{1}{2}$ mole of ferric oxide and 1 mole of sulfur dioxide, accompanied by a release of heat amounting to 268,000 Btu. However, to assign a specific meaning to the numerical value for this heat release, it is customary to specify a reference temperature and pressure for the reaction, these being 25 °C and 1 atmosphere in the example cited. In making heat balance calculations, it is then convenient to choose these conditions as the datum level and then calculate the heat input and heat output quantities above or below the reference state.

WALTER C. LAPPLE, Alliance, Ohio

STOKES FLOW. Flow of a viscous fluid at a very small Reynolds number when inertial, acceleration forces are negligible and the Navier-Stokes equations reduce to

$$\mu\nabla^2\mathbf{v} - \text{ grad } p = 0$$

The approximation may not be possible in all parts of the flow even at very low speeds.

STOKES LAW FOR VISCOSITY. A solid sphere moving with velocity V through a fluid of viscosity μ experiences a resistance to motion

$$F = 6\pi\mu a\text{V}$$

where a is the radius of the sphere. The law is accurate only if the flow Reynolds number $\rho aV/\mu$ is less than 0.1.

STOKES THEOREM. The surface integral of the curl of a vector function equals the line-integral of that function around a closed curve bounding the surface.

$$\int_S \nabla \times \nabla \cdot d\mathbf{S} = \mathbf{V} \cdot d\mathbf{S}$$

If the components of $\mathbf{V}$ in rectangular Cartesian coordinates are u, v, w and the direction cosines of the normal to $d\mathbf{S}$ are λ, μ, v the theorem may also be given as

$$\int_S \left[\lambda\left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}\right) + \mu\left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}\right) + v\left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right)\right] dS = \int_C (u\,dx + v\,dy + w\,dz)$$

See also **Curl**; and **Vector**.

STOLON. 1. In botany, a branch that grows out horizontally from the base of the stem, takes root, and gives rise to a new plant at the nodes or at the tip.

2. In zoology, a shoot growing from the base of an animal or a colony, from which other individuals arise by budding.

STOMATE (or Stoma). Stomates or stomata (singular: stomate or stoma) are structures on the surfaces of plant leaves that allow gas exchange (transpiration, i.e., loss of water vapor, uptake of CO_2, and emission or uptake of O_2) between the interior of a leaf and the atmosphere. Plant leaves are covered by a waxy layer, the *cuticle*, which prevents water loss from cells on the leaf surface, or *epidermis*. The cuticle does not completely cover the leaves, however; it is interrupted by microscopic pores, surrounded by pairs of specialized *guard cells* (Fig. 1a). The size and shape of the guard cells varies considerably from one species to another. Unlike other epidermal cells the *guard cells* contain chloroplasts

TABLE 1. OCCURRENCE AND DIMENSIONS OF STOMATA FOR SEVERAL REPRESENTATIVE SPECIES

			Stomatal Density, Pores/mm^2		Guard Cell Dimensions, μm, for each Leaf Surface				Dimensions of Stomatal Pore, Abaxial, μm	
					Adaxial		Abaxial			
Plant Type	Representative Species	Common Name	Upper	Lower	Length	Width	Length	Width	Length	Depth
Moss	*Polytrichum commune*	Hair cap moss	16	16	46	15	46	15	15	12
Fern	*Osmunda regalis*	Royal fern	0	67			56	19	30	15
Conifer	*Pinus silvestris*	Scotch pine	120	120	28	7	28	7	20	6
Dicot tree	*Tilia europea*	European linden	0	370			25	9	10	8
Dicot herb	*Helianthus annuus*	Sunflower	120	175	35	13	32	14	17	
Dicot herb (xerophyte)	*Sedum spectabilis*	Autumn joy	35	56	32	10	33	10	20	18
Monocot herb	*Allium cepa*	Onion	175	175	42	19	42	19	24	18
Monocot C_3 grass	*Avena sativa*	Oats	50	45	52	15	56	13	20	10
Monocot C_4 grass	*Zea mays*	Corn	98	108	38	10	43	12	20	10

(photosynthesizing organelles containing chlorophyll). In some plants, there are also additional, specialized subsidiary cells that differ in shape from regular epidermal cells and participate in the osmotic changes that drive guard cell movement. In many species of plants stomates occur in both the upper and lower epidermis of the leaf. In many other species, especially of woody plants, stomates occur only in the lower epidermis. Even in those species in which the stomates are present in both epidermises there are commonly, although not invariably, more per unit area in the lower epidermis. In floating leaves, such as those of the water lily, stomates are present only in the upper epidermis. In many kinds of plants, the stomates are restricted to grooves or furrows in the leaf.

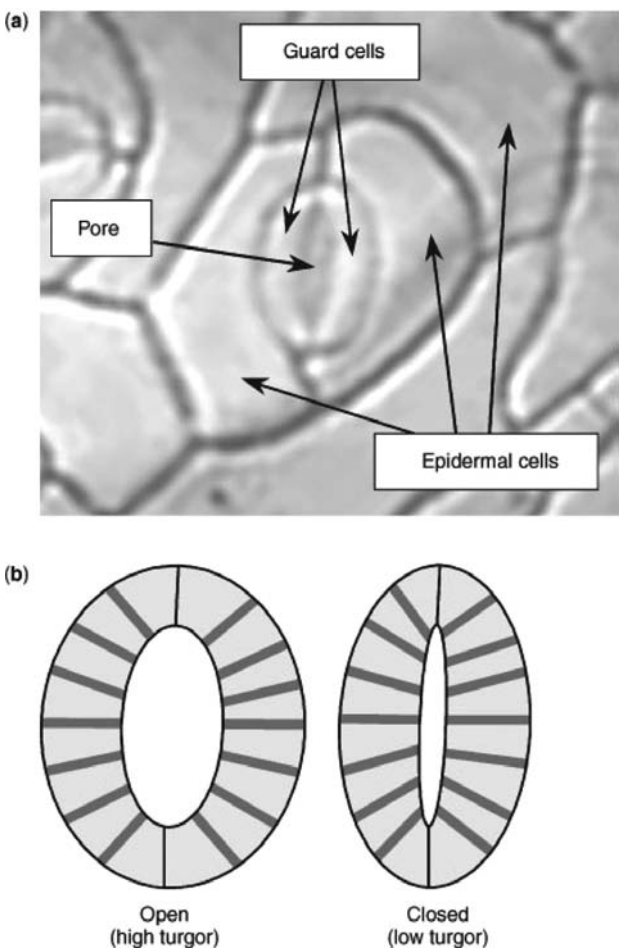

Fig. 1. (**a**) Micrograph of a peanut (*Arachis hypogaea* L.) epidermis, showing the guard cells, the stomatal pore, and epidermal cells: (**b**) Diagram of open and closed stomata, showing cellulose microfibrils.

The number of stomates per unit area is called the *stomatal density*. This figure may vary when plants are grown under different environmental conditions such as atmospheric CO_2 concentration. The range is from a few thousand to about a hundred thousand per square centimeter of leaf surface. A single corn plant has been estimated to bear from 140 to 240 million stomates and the number on a large tree could be represented only by a figure of astronomical dimensions. The size of the individual stomates also varies greatly from species to species, (Table 1), their dimensions being expressed in microns. In some species the fully open stomates may be as large as 8 to 10×30 to 40 micromillimeters, as measured along the two axes of the elliptical pore, but in most species they are smaller. Species in which the stomates are relatively small usually have more per unit area than those which have relatively large stomates.

The structure of the cell wall of a guard cell is quite complex, varying considerably in thickness and elasticity from one part of the cell to another. This wall structure is such that when the guard cells increase in turgidity their inner walls — those bounding the pore — bow away from each other causing a widening of the stomate. In general, therefore, when the guard cells are turgid the stomate is open; when the guard cells are flaccid the stomach is closed.

Shifts in the turgidity of the guard cells causing opening and closing of stomates are conditioned by a number of factors among which the most important are light, temperature, and the internal water supply of the leaf. In general stomates are open in the light and closed in the dark although there are many exceptions to this statement. In general, low temperatures are unfavorable to stomatal opening, and when the temperature falls below the optimum for stomatal opening for a given species, the stomates will remain closed or open only incompletely, even if light conditions and water supply are favorable. Similarly, drought conditions, by resulting in a reduction in the water content of the leaves, are usually unfavorable to stomatal opening even if light and temperature conditions are favorable. During prolonged droughts, the stomates of many species remain nearly or completely closed most of the time. Night opening of the stomates is of regular occurrence in some species such as certain cacti, in which they are not usually open in the daytime, and may occur in some other species under certain conditions.

When the stomates are open they serve as the principal pathways through which gases diffuse into or out of the leaf; when the stomates are closed all gaseous exchanges between a leaf and its environment are greatly retarded. The gases of greatest physiological importance which enter or depart from a leaf principally through the stomates are oxygen, carbon dioxide, and water vapor. Loss of water vapor in the process of transpiration occurs principally through the stomates. Similarly the inward diffusion of carbon dioxide and outward diffusion of oxygen, the gaseous exchanges accompanying photosynthesis, occur principally through the stomates.

STONE AGE. An archeological term to designate a cultural level that is characterized by the use of stone implements. Classically it is divided into the Eolithic, Paleolithic, and Neolithic Periods. The Stone Age is the first of the so-called three-age system (Bronze Age and Iron Age following).

STONE ROLLER *(Osteichthyes)*. Of the group *Cypriniformes*, family *Cyprinidae*, the stone roller is a bottom-feeding fish of moderate size found in small streams from Wyoming to New York and south to the Gulf. It is herbivorous.

STOOPING. A mirage in which the angular height of the image is less than that of the object. As the width is unaffected (the angular width of image width remains that of the object because the refractive index gradient is vertical), the aspect ratio is altered and distant images appear vertically squashed. Stooping often accompanies *looming*: Distant features appear lifted and squashed. See also **Looming**; **Mirage**; **Sinking**; and **Towering**.

STOPPING POWER. A measure of the effect of a substance upon the kinetic energy of a charged particle passing through it. The linear stopping power S_l is the energy loss per unit distance and is given by $S_l = -dE/dx$, where E is the kinetic energy of the particle and x is the distance traversed in the medium. The *mass stopping power* S_m is the energy loss per unit surface density traversed, and is given by $S_m = S_l/\rho$, where ρ is the density of the substance. The *atomic stopping power* S_a of an element is the energy loss per atom, per unit area normal to the particle's motion, and is given by $S_a = S_l/n = S_m A/N$, where n is the number of atoms per unit volume, N is the Avogadro number, and A is the atomic weight. The *molecular stopping power* of a compound is similarly defined in terms of molecules; it is very nearly if not exactly equal to the sum of the atomic stopping powers of the constituent atoms. The *relative stopping power* is the ratio of the stopping power of a given substance to that of a standard substance, commonly aluminum, oxygen or air. The *stopping equivalent* for a given thickness of a substance is that thickness of a standard substance capable of producing the same energy loss. The *air equivalent* is the stopping equivalent in terms of air at 15 °C and 1 atmosphere as the standard substance. The term equivalent stopping power is not clearly defined, but sometimes is used synonymously with relative stopping power and sometimes with stopping equivalent.

STOPWATCH. See **Clocks**.

STORAGE AREA NETWORKS (SANS). A SAN (*storage area network*) is a networked high-speed infrastructure (subnetwork) that establishes direct access by servers to an interconnected group of heterogeneous storage devices such as optical disks, RAID arrays, and tape backups, which are effective for storing large amounts of information and backing up data online in e-commerce, online transaction processing, electronic vaulting, data warehousing, data mining, multimedia Internet/intranet browsing, and enterprise database managing applications. SANs provide additional capabilities (fault tolerance, remote management, clustering, and topological flexibility) to mission-critical, data-intensive applications. A SAN is typically a part of an enterprise network of computing resources [Sachdev & Arunkundram, 2002]. A simple model of the storage area network as a networked high-speed infrastructure is shown in Figure 1.

A SAN can be considered as an extended and shared storage bus within a data center, consisting of various storage devices and specific interfaces (e.g., fiber channel, ESCON, HIPPI, SCSI, or SSA) rather than the Ethernet [Peterson, 1998]. In order to be connected to the enterprise network, the SAN utilizes technologies similar to those of LANs and WANs: switches, routers, gateways, and hubs (see Figure 1). Wide area network carrier technologies, such as asynchronous transfer mode (ATM) or synchronous optical networks can be used for remote archival data storing and backup. As an important element of modern distributed networking architectures of storage-centric enterprise information processing, SAN technology represents a significant step toward a fully networked secure data storage infrastructure that is radically different from traditional server-attached storage [Clark, 1999]. In addition, SANs provide improved options for network storages, such as a creation of remote or local, dedicated or shared data storage networks with access capability faster than *network attached storage* (NAS).

SANs are based on the storage-centric information-processing paradigm, which enables any-to-any connectivity of computers (servers) and storage devices over a high-speed enterprise network of interconnected fiber channel switches that form the SAN fabric. The incidence of unconnected

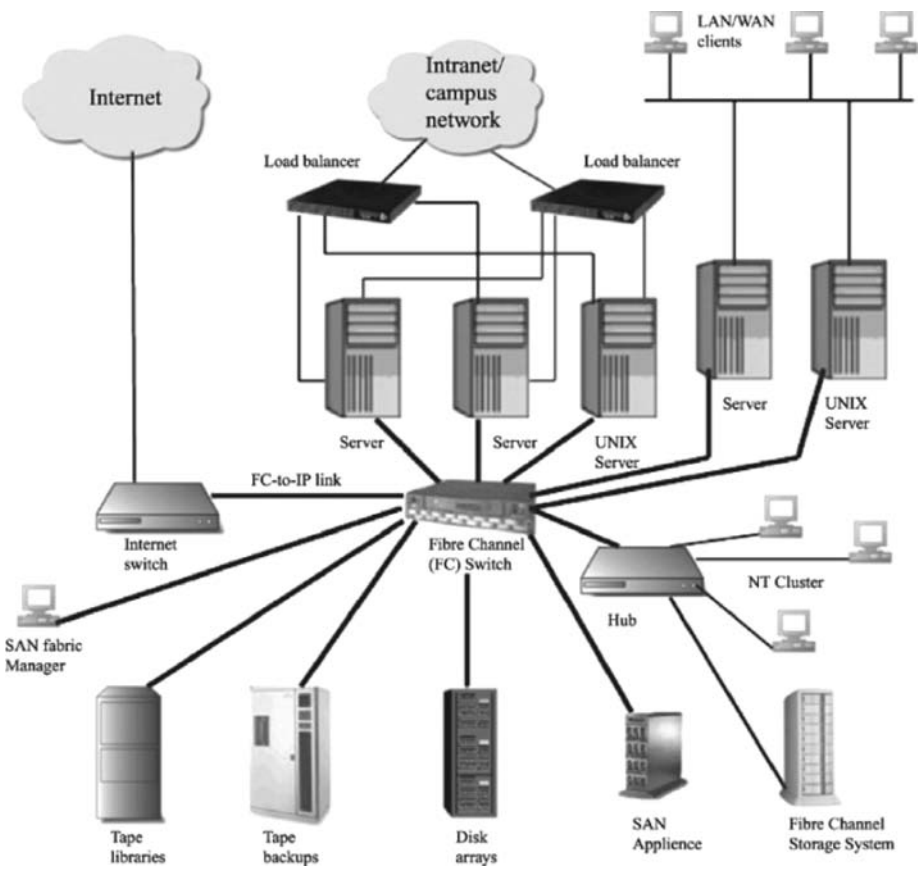

Fig. 1. Storage area network as a networked high-speed enterprise infrastructure.

clusters of information is eliminated or significantly reduced by SANs. According to this concept, a SAN resides behind the server and provides any users or devices on the enterprise network ("clients") with fast access to an array of data storage devices. It can be viewed as multihost connected-and-shared enterprise storage. Adding new storage devices and server elements resolves traditional network-bottlenecks and small-scale problems of interfaces, such as the small computer systems interface (SCSI) and network attached storage (NAS), and can easily expand the scale of the SAN [Thornburgh & Schoenborn, 2001]. Another advantage of SAN technology is that backups can be made over the SAN fibre channel subnet, and, in this case, backup traffic is totally removed from the enterprise network.

The SAN represents a new segment of the information services industry called storage solution providers (SSP). However, isolated SANs cannot realize SSPs' services, such as real-time data replication, failover, storage hosting, and remote vaulting.

Benefits of SANs. A SAN makes physical storage capacity a single, scalable resource and allows the flexible allocation of virtualized storage volumes (e.g., RAIDs, JBODs, and EMC, SUN, and DELL storage devices). The SAN can manage backup tasks that were a huge administrative and computer-resource burden under old storage architectures. The storage management cost savings can be higher than 80%. A cost-effective, scalable SAN enhances overall system performance. It can integrate legacy SCSI devices, which allows increasing their system-wide effective usable capacity by up to 30%. See also **InfraStor Technology Corp.: http://www.infrastor.com/solutions/index.htm.**

SANs are an integral part of a large financial services enterprise, ISP, government organization, research laboratory, electronic publisher, digital video production group, TV-broadcasting station moving to digital services, or educational institution, or any organization with increasing data storage needs.

There are several key reasons for implementing a SAN. The first three concern business issues of return on the investment in data storage, as well as the protection of existing investments:

- SANs are cost-effective (reduced cost of storage management, including backup and recovery; increased user productivity; cost-effective implementations of high availability disaster protection, using remote clusters and remote mirrored arrays);
- SANs reduce business risk (faster disaster recovery; reduced revenue loss from down-time; reduced lost-opportunity costs);
- Legacy investments are protected (SANs can be implemented without abandoning existing storage infrastructures such as devices using SCSI connections).

The next four address critical technical issues that face data-center managers at a time when the volume of data to be managed and made available in many organizations is increasing at a 60% annual rate:

- SANs provide scalability (add servers and storage independently);
- SANs allow flexibility (reconfigure storage and servers dynamically without interrupting their services; load sharing and redistribution);
- SANs enhance overall system performance (more effective use of existing server compute cycles; real-time backup without impacting LAN/WAN; multiple server-to-storage paths; networked storage arrays that can outperform bus-attached storage; compatibility with parallelized database applications);
- SANs are an integral part of any high-availability plan (facilitation of shared on-line spares and remote backup or mirroring; reduced down-time requirements; storage independent of the application and accessible through alternate data paths such as found in clustered systems).

The implementation of a SAN can realize significant overall cost savings in data-center operations and can increase user productivity. The opportunity to avoid escalating costs depends on decentralization of data and applications. A key element in the consolidation of data storage must include the implementation of a basic SAN infrastructure in order to provide the following:

- Bandwidth to service clients;
- Maintenance of data availability without impacting LAN bandwidth;
- Scalability for long term, rapid growth with protection of legacy investments;
- Flexibility to provide optimum balance of server and storage capacity;
- Manageability for ease of installation and maintainability;
- Shared access to data resources for real-time backup and recovery.

Distributed environments require high-cost maintenance in terms of staff resources. The consolidation of distributed NT-based storages to a virtualized SAN-based resource can save 80% or more of the costs of management. See also InfraStor Technologies Corp.: http://www.infrastor.com/.

SAN Applications. SAN applications cover the following areas of data transfer [Peterson, 1998]: (1) the externalization of data storage out of the server-SAN-attached-storage (SAS) and NAS-with-SAN-interconnects network architectures; (2) clustering, a redundant process that provides failover, high availability, performance, and scalability through the use of multiple servers as a data pipe and allows data storage resources to be shared; (3) data protection solutions for backup, remote clustering, file mirroring, and replicating and journaling file systems by creating data storage redundancy on a dynamic basis; (4) data vaulting, which is the process of transferring archived data to less expensive media; (5) data interchange from one storage system to another or between different environments; and (6) disaster recovery, which is similar to data interchange, moving copies of data offsite, and is built on remote vaulting (backup) processes or on remote array mirroring or clustering. Several new applications benefit from 2 Gb/s fiber channel SANs; multimedia audio/video servers that provide the ability to stream higher resolution files, medical imaging, prepress that speeds up design and file preparation, and video editing of uncompressed HDTV data.

The first effective application of SANs has been serverless backup, which provides enterprises with full-time information availability. All backup-related tasks have been relegated to the SAN. Large enterprises can store and manage huge amounts of information (several terabytes or more) in the SAN high-performance environment. Enterprise servers are connected to storage devices (e.g., RAID arrays) via a high-speed interconnection, such as fiber channel. The SAN any-to-any communication principle provides the ability to share storage resources and alternative paths from server to data storage device. A SAN is also able to share the resources among several consolidated servers.

A cluster of interconnected servers may be connected to common storage devices in the SAN environment and be accessible to all clients. Modern enterprises employ this clustering technology to resolve several challenging application problems [Barker & Massiglia, 2001, p. 244], i.e., providing customers, partners, and employees with *continuous* application service, even if the enterprise systems fail, and supporting application performance growth as demand grows, without service disruption to customers. Clusters provide load balancing, high availability, and fault tolerance and support application scaling. In some implementations, the clustered servers can be managed from a single console. Clustering methodology is effectively used in e-commerce, online transaction processing, and other Web applications, which handle a high volume of requests.

SAN methodology has its roots in two low-cost technologies: SCSI-based storage and the NAS-based concept. They both successfully implement storage-network links, but are limited to a low volume of data flows and rates. SCSI still remains the most popular "bus-attached" server–storage connection in SAN-attached storage (SAS) systems, especially at the stage of transition from SCSI bus devices to fiber–channel switches using the SCSI-fiber protocol converter in a new enterprise storage ("data center") environment. In the network attached storage (NAS) system, storage elements (i.e., a disk array) are attached directly to any type of network via a LAN interface (e.g., Ethernet) and provide file access services to computer systems. If the NAS elements are connected to SANs, they can be considered as members of the SAN-attached storage (SAS) system. The stored data may be accessed by a host computer system using file access protocols such as *NFS* or *CIFS*.

SANs provide high-bandwidth block storage access over long distance via extended fiber channel links. However, such links are generally restricted to connections between data centers. NAS access is less restricted by physical distance because communications are via TCP/IP. See also **Transmission Control Protocol (TCP)/Internet Protocol (IP) Suite**. NAS controls simple access to files via a standard TCP/IP link. A SAN

TABLE 1. THREE GENERATIONS OF SANS

	Fabric	Main Characteristics	Applications
First-Generation SANs	1Gb Loop	FC-AL protocol; 1Gb speed; enabled first SANs	SCSI replacement
Second-Generation SANs	1Gb Proprietary; Legacy Fabric	FC-SW protocol; 1Gb speed; proprietary switch-to-switch connections; expensive	LAN-free backup; HA clustering
Third-Generation SANs	2Gb Open Fabric	Open FC-SW-2 protocol; 2Gb speed; standards-based switch-to-switch connections; competition-driven price reductions price reductions	Serverless backup; heterogeneous storage consolidation; high-definition video; data; virtualization

provides storage access to client devices, but does not impose any inherent restrictions on the operating system or file system that may be used. For this reason, SANs are well suited to high-bandwidth storage access by transaction-processing and DBMS applications that manage storage access by themselves. NAS, which has the inherent ability to provide shared file-level access to multiple OS environments, is well suited for such requirements as Web file services, CAD file access by combined WinNT/2000, UNIX, and LINUX devices, and wide-area streaming video distribution. A balanced combination of these approaches will dominate in the future.

SAN Architecture. The SANs architectures have been changed evolutionarily, adapting to new application demands and expanding capacities. The original fiber-channel-based SANs were simple loop configurations based on the fiber channel arbitrated loop (FC-AP) standard. Requirements of scalability and new functionality had transformed SANs into fabric-based switching systems. Numerous vendors offered different solutions of problems based on fabric switching. As a result, immature standards created various interoperability problems. Homogeneous high-cost SANs were developed. The latest architectural approach is associated with a standards-based "Open" 2Gb fabric switch that provides all the benefits of fabric switching, but based on new industry standards (FC-SW-2) and interoperability architecture that runs at twice the speed of legacy fabric. The standards-based switches provide heterogeneous capability. The latest feature reduces prices of the SAN's components and management costs of running a SAN. Characteristics of three generations of SANs are summarized in Table 1.

The Open 2Gb fibre channel allows doubled SAN speeds, enables greater flexibility in configuring SANs for a wide range of applications, and is especially useful for managing 1.5-Gb high-definition video data. In the HDTV applications, a single fibre can carry a full high-definition video stream without having to cache, buffer, or compress the data. Other examples include storage service providers that must deliver block data from to users at the highest possible speeds and e-commerce companies that have to minimize transaction times. The 2-Gb fiber channel provides the high-speed backbone capability for fiber channel networks, which can be used to interconnect two SAN switches. This configuration increase overall data throughput across the SAN even if servers and disk subsystems continue to operate via 1-Gb channels.

A SAN system consists of software and hardware components that establish logical and physical paths between stored data and applications that request them [Sheldon, 2001]. The data transforms, which are located on the paths from storage device to application, are the four main abstract components [Barker & Massiglia, 2001, p. 128]: the *disks* (viewed through ESCON, FCP, HIPPI, SCSI, and SSA interfaces as abstract entities), *volumes* (logical/virtual disk-like storage entities that provide their clients with identified storage blocks of persistent/retrieved data), *file systems*, and application-independent *database management systems*. In a system with a storage area network, five different combinations [Barker & Massiglia, 2001] of these data transforms and corresponding transformation paths serve different applications and system architectures by various physical system elements. The disk abstraction is actually the physical disk drive. The abstract volume entity is realized as an external or embedded RAID controller, as an out-of-band or in-band SAN appliance, or as a volume manager serving a database or an application. Storage servers (such as NAS devices), database servers, and application servers may contain the abstract file systems. These devices and servers can be clustered to increase scaling and application availability. In that case, their volume file and management systems should be cluster-aware [Barker & Massiglia, 2001].

Any SAN-based client–server system consists of three architectural components: *interfaces*, *interconnects* or *network infrastructure components* (switches, hubs, routers bridges, gateways, multiplexors, extenders, and directors), and *fabrics*. The SAN interfaces are fibre channel, ESCON, HIPPI, SCSI, and SSA. The SAN interconnects link these storage interfaces together, making various network configurations. Routers and bridges perform protocol transformation in SANs. Switches increase the overall SAN bandwidth by connecting system elements for data transmission and allow advantages of the centralized storage repositories with the shared applications and central management. The most common SAN fabrics are switched fibre channel, switched SCSI, and switched SSA, all of which physically link the interconnects and determine the SAN's performance and scalability. Some fabrics embed operating systems that provide for SAN security, monitoring, and management. Hosts are connected to the fibre channel SAN through host bus adapters (HBAs), which consist of hardware and interface drivers. Fiber channel HBAs support negotiation with network-attached devices and switches and allow the host to minimize its CPU overhead.

SAN Operating System Software Components. The SAN software plays an important role in providing an environment for various business and management applications, called *system applications* [Barker & Massiglia, 2001, p. 13], such as clustering, data replication, and data copying. The *management applications* (zoning, device discovery, allocation, RAID subsystems, and others) manage the complex environment of distributed systems. These applications can significantly reduce the cost and improve the quality of enterprise information services.

STORAGE BATTERY. A secondary battery so called because the conversion of chemical to electrical energy is reversible and the battery is thus rechargeable. An automobile battery usually consists of 12–17 cells with plates (electrodes) made of sponge lead (negative plate or anode) and lead dioxide (positive plate or cathode) that is in the form of a paste. The electrolyte is sulfuric acid. The chemical reaction that yields electric current is $Pb + PbO_2 + 2H_2SO_4 \longleftrightarrow 2PbSO_4 + 2H_2O + 2e$. More complicated and expensive types have nickel–iron, nickel–cadmium, silver–zinc, and silver–cadmium as electrode materials. A sodium–liquid sulfur battery for high-temperature operation as well as a chlorine-zinc type using titanium electrodes have also been developed.

As part of the U.S. effort to replace gasoline with another form of energy, DOE is supporting short-and long-term research on batteries for electric vehicles at Argonne National Laboratories. These types intended to deliver 20–30 kwh are in the short-term program: improved lead–acid, nickel–zinc and nickel–iron. The long-term program includes lithium–metal sulfide, sodium–sulfur (β-battery), zinc–chlorine, and metal–air. Independent research indicates that a zinc-nickel oxide system has encouraging possibilities. A lead–acid battery for storing energy from solar cells has been reported to have a life of 5–7 years. See also **Battery**.

STORAGE (Computer). Any medium capable of storing information. As generally defined, however, a storage unit is a device on or in which data can be stored, read, and erased. The major classifications of storage devices associated with computer systems are: (1) *immediate-access*; (2) *random-access*; and (3) *sequential-access*. As a general rule, the cost per bit of information is greater for immediate-access storage devices, but the access time is considerably faster than for the other two types.

The various physical means to effect storage are described under **Memory (Electronic)**.

Immediate-Access Storage. In these devices, information can be read in a microsecond or less. Usually an array of storage elements can be directly addressed and thus all information in the array requires the same amount of time to be read. Specific storage configurations in this class include core storage, and monolithic storage.

Random-Access Storage. Storage devices in which the time required to obtain information is independent of the location of the information most recently obtained. This strict definition must be qualified by the observation that what is meant is *relatively* random. Thus, magnetic drums are relatively nonrandom access when compared with monolithic storage, but are relatively random access when compared with magnetic tapes for file storage. Disk-storage and drum-storage units usually are referred to as random-access storage devices. The time required to read or write information on these units generally is in the 10- to 200-millisecond range. This time is dependent upon where the information is recorded, with respect to the read/write head at the time the data are addressed.

Sequential-Access Storage. Storage devices in which the items of information stored become available only in a one-after-the-other sequence, whether or not all the information or only some of it is desired. Storage on magnetic tape is an example.

Some other computer storage configurations are defined by:

Auxiliary Storage. A storage device in addition to the main storage of a computer; e.g., magnetic tape, disk, diskette, or magnetic drum. Auxiliary storage usually holds much larger amounts of information than the main storage, and the information is accessible less rapidly.

Buffer Storage. (1) A synchronizing element between two different forms of storage, usually between internal and external. (2) An input device in which information is assembled from external or secondary storage and stored ready for transfer to internal storage. (3) An output device into which information is copied from internal storage and held for transfer to secondary or external storage. Computation continues while transfers between buffer storage and secondary or internal storage or vice versa take place. (4) Any device that stores information temporarily during data transfers.

Circulating Storage. A device or unit which stores information in a train or pattern of pulses, where the pattern of pulses issuing at the final end are sensed, amplified, reshaped and reinserted into the device at the beginning end.

External Storage. (1) The storage of data on a device that is not an integral part of a computer, but in a form prescribed for use by the computer. (2) A facility or device, not an integral part of a computer, on which data usable by a computer is stored such as off-line magnetic tape units, or punch card devices.

Internal Storage. (1) The storage of data on a device which is an integral part of a computer. (2) The storage facilities forming an integral physical part of the computer and directly controlled by the computer. In such facilities, all data are automatically accessible to the computer; e.g., magnetic core, and magnetic tape on-line.

Main Storage. Usually the fastest storage device of a computer and the one from which instructions are executed.

Program Storage. A portion of the internal storage reserved for the storage of programs, routines, and subroutines. In many systems protection devices are used to prevent inadvertent alteration of the contents of the program storage.

Serial Storage. A storage technique in which time is one of the factors used to locate any given bit, character, word, or groups of words appearing one after the other in time sequence, and in which access time includes a variable latency or waiting time of from zero to many word times. A storage is said to be serial by word when the individual bits comprising a word appear serially in time; or a storage is serial by character when the characters representing coded decimal or other nonbinary numbers appear serially in time; e.g., magnetic drums are usually serial by word but may be serial by bit, or parallel by bit, or serial by character and parallel by bit.

Working Storage. A portion of the internal storage reserved for the data upon which operations are being performed. Synonymous with working space and temporary storage and contrasted with program storage.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

STORKS *(Aves, Ciconniformes)*. Large birds of the Old World and South America. They range from Argentina northward to Mexico, but not into the United States. They are found widely in Europe; Asia, Africa, and in parts of Australia. Their size ranges from about 42 to 60 inches (107 to 152 centimeters) tall when standing and ranges from 4 to 6.5 feet (1.2 to 2 meters) in length. The color varies with species, ranging from white through dull gray, sometimes having a somewhat greenish sheen. There are numerous species, of which at least 28 tropical species are known. Most storks are migrating birds, flying with their neck stretched and legs slanted backward in a V-shape. The migration pattern is from colder to warmer areas in the fall and returning to the colder climates for spring and summer. Some species prefer chimney tops as nesting locations, while other species like marshes near water and in tall grasses. There are usually 3 to 5 blunt, oval, white eggs, the eggs being laid at intervals of about 2 days. Both parents incubate the eggs for 30 to 38 days. Some species fly in large flocks, particularly those migrating from Africa to Europe and Asia in early spring. The return flight is usually made some time in August. Numerous bird-watching groups have banded the legs of the baby storks to keep track of these migrations. After banding, a baby will often "play dead" for quite a period. The young storks are called siblings.

The common white stork of Europe, *Ciconia alba*, which nests on the tops of chimneys is probably the best-known species. See Fig. 1. The jabiru (*Jabiru mycteria*) is a white stork with green head and green coloring on the partly-naked neck. The upper portion of the neck also may have dark blue and orange coloring. This bird may achieve a length of some 55 inches (140 centimeters) and is one of the larger flying birds. Nesting preference is pine trees. Eggs are light-green in color. This stork is known to prey on grass fires, catching small animals as they are flushed out by the heat. Other dietary items include small fish and a variety of insects. Some varieties of

Fig. 1. Storks. (*A.M. Winchester.*)

jabiru have a bronze coloration on their wings and a bit of green color in the tail — with coral color legs.

Adjutant is a name applied to stork-like birds of several species. These birds occur in Africa and the Oriental region where they are valuable as scavengers. From at least one species (*Leptoptilus crumenifer*) the soft downy feathers known as marabou are secured. Birds as tall as 6–7 feet (1.8–2.1 meters) have been reported in India. These birds feed on frogs, carrion, and fish. They are known for their success in chasing vultures away from carrion.

The name stork sometimes is confused with that of the related herons, as in the case of the whale-headed or shoe-billed species of the White Nile. This species, called both heron and stork, has an enormous and powerful beak, both broad and deep and provided with a strong hook at the tip. See also **Ciconiiformes**.

STORM. Any disturbed state of the atmosphere, especially as affecting the earth's surface, implying inclement and possibly destructive weather. There are at least three somewhat different viewpoints of storms. 1) In synoptic meteorology, a storm is a complete individual disturbance identified on synoptic charts as a complex of pressure, wind, clouds, precipitation, etc., or identified by such mesometeorological means as radar or sferics. Thus, storms range in scale from tornadoes and thunderstorms, through tropical cyclones, to widespread extratropical cyclones. 2) From a local and special interest viewpoint, a storm is a transient occurrence identified by its most destructive or spectacular aspect(s). In this manner we speak of rainstorms, windstorms, hailstorms, snowstorms, etc. Notable special cases are blizzards, ice storms, sandstorms, and duststorms. 3) To a hydrologist, "storm" alludes primarily to the space- and time-distribution of rainfall over a given region. See also **Fronts and Storms**.

STORM-RELATIVE ENVIRONMENTAL HELICITY. See **Helicity**.

STORM SURGE. A rise and onshore surge of seawater as the result primarily of the winds of a storm, and secondarily of the surface pressure drop near the storm center. Also called *storm tide, storm wave,* and *hurricane tide*. The magnitude of the surge depends on the size, intensity, and movement of the storm; the shape of the coastline; nearshore underwater topography; and the state of the astronomical tides. The storm surge is responsible for most loss of life in tropical cyclones worldwide. See also **Fronts and Storms**.

STORM WARNING. See **Meteorology**.

STRABISMUS (Cross-Eyes). Strabismus is a functional defect where the eyes are misaligned and point in different directions. The brain's ability to see three-dimensional objects depends on proper alignment of the eyes. When both eyes are properly aligned and aimed at the same target, the visual portion of the brain fuses the forms into a single image. When one eye turns inward, outward, upward, or downward, two different pictures are sent to the brain. This causes loss of depth perception and binocular vision. The turned eye may be straight at times, and the misalignment may come and go. Strabismus occurs in about 4% of all children in the United States, equally in males and females, and is sometimes hereditary. The condition can also develop later in life.

There are two forms of strabismus, esotropia and exotropia. In esotropia, one eye deviates inward toward the nose. In exotropia, one eye deviates outward away from the nose. Esotropia is the most common type of strabismus in infants. Exotropia often begins between the ages of 2 and 4.

In young children with any form of strabismus, the brain may learn to ignore the misaligned eye's image and see only the image from the best-seeing eye. This is called *amblyopia*, or lazy eye, and results in a loss of depth perception. When an adult develops strabismus, double vision sometimes occurs because the brain has already been trained to receive images from both eyes and cannot ignore the image from the turned eye.

The causes of strabismus are not fully understood. There are six muscles that control eye movement, four that move it up and down and two that move it side to side. All these muscles must be coordinated and working properly in order for the brain to see a single image. When one or more of these muscles does not work properly, some form of strabismus may occur. Strabismus is more common in children with disorders that affect the brain such as cerebral palsy, Down syndrome, hydrocephalus, and brain tumors.

The earliest sign of strabismus is usually a noticeable deviation of one eye. This symptom may at first be intermittent, occurring when a child is daydreaming, not feeling well, or tired. The deviation may also be more noticeable when the child looks at something in the distance. Frequent rubbing of the eyes is also common with strabismus. In bright light, children may squint or tilt their heads in order to use both eyes together. Few children ever complain about double vision, although they may close one eye to compensate for the problem.

The eyes of infants and small children can sometimes seem to be crossed when they have a wide, flat nose and a fold of skin at the inner eyelid. Called *false strabismus*, it usually disappears as the child grows. True strabismus will not be outgrown. An eye doctor can tell the difference between true and false strabismus.

To diagnose strabismus, an eye doctor will perform a comprehensive eye examination including an ocular motility (eye movement) evaluation and an evaluation of the internal ocular structures. The most reliable treatment for strabismus is usually eye muscle surgery, but this is often preceded by eye patching and/or eyeglass therapy, especially if amblyopia (lazy eye) is present. This therapy is designed to maximize the existing vision in the "bad" eye. In some children, this therapy may eliminate the need for surgery.

To correct strabismus, the eye surgeon makes a small incision in the tissue covering the eye and accesses the eye muscles. The appropriate muscles are then repositioned to allow the eye to move properly. The procedure is usually performed under general anesthesia. Recovery time is rapid, and most people are able to resume normal activities within a few days. Following surgery, corrective eyeglasses may be needed, and, in many cases, further surgery is required later to keep the eyes straight.

When a child requires surgery for strabismus, the procedure is usually performed before school age. This is easier for the child and gives the eyes a better chance to work together. As with all surgery, there are some risks. However, strabismus surgery is usually a safe and effective treatment. See also **Amblyopia**; **Estropia**; **Extropia**; and **Vision and the Eye**.

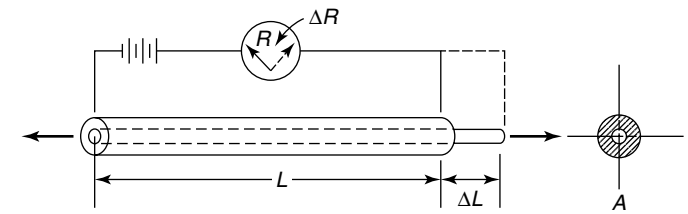
Vision Rx, Inc., Elmsford, NY

STRAIGHT EDGE. One of three surfaces, any two of which when placed together, coincide throughout their length. A straight-edge also is the name of a hand device in the form of a piece of material whose edge is "perfectly" straight and which is used for testing plane surfaces and drafting straight lines. A ruler is a straight-edge.

STRAIN ENERGY. A term that usually denotes the elastic energy stored in a stressed body that can be recovered as work upon unloading.

STRAIN GAGE. An instrumental device used to measure the dimensional change within or on the surface of a specimen. The electrical-type

strain gage may operate on the measurement of a capacitance, inductance, or a resistance change that is proportional to strain. The bonded resistance-type strain gage is the most widely used in many fields. The principle of operation was discovered in 1856 by Lord Kelvin. The fundamental relationships between resistance change and strain are shown by Fig. 1. When a conductor of length L and cross-sectional area A is elongated, the length increases and the area decreases by Poisson's effect to produce an increase in resistance. The resistance change $\Delta R/R$ then is related to the length change $\Delta L/L$, or strain ε by the strain sensitivity or gage factor. If the strain sensitivity were dependent upon dimensional change only, resulting from the usual Poisson ratio of 0.3, then all metallic conductors would have a theoretical value of 1.6 in the elastic range and 2.0 in the plastic range of the alloy used where the Poisson ratio becomes 0.5. However, the resistivity alters with strain in order to produce the gage-factor range of 2.0 to 4.5 experienced by the alloys most often used for metallic strain gages.



Legend:

$R = \rho \frac{L}{A}$ = Resistance, ohms
L = Conductor length
A = Cross section area
ρ = Resistivity constant

$S = \frac{\Delta R/R}{\Delta L/L}$ = Strain sensitivity (gage factor when applied to a specific gage)
$\Delta R/R$ = Resistance change
$\Delta L/L$ = Strain

Fig. 1. Basic relationships between resistance change and strain in resistance-type strain gage.

Early bonded strain gages were developed in the 1930s by Dr. Arthur C. Ruge at the Massachusetts Institute of Technology. The gage was made from fine strain-sensitive wire attached to a thin paper carrier with nitrocellulose cement for dimensional stability and to provide electrical isolation from a metal specimen. The carrier was bonded to the specimen with the same cement so that the specimen surface strain would be reliably transmitted into the fine-wire grid. The grid shape was designed to provide maximum gage resistance in the smallest possible gage length and width. Foil also can be used as the strain element. In addition to material variations, a large number of grid shapes is available in modern strain gages, particularly in the foil construction to meet the needs of specific applications. Gage lengths range from 6 to $\frac{1}{64}$th inch and resistance values from 1,000 to 60 ohms.

Strain gage sensing element materials most commonly used are: (1) *Constantan* (copper-nickel alloy) used mainly for static strain measurement because of low and controllable temperature coefficient; (2) *Nichrome V* (nickel-chrome alloy) frequently used for high-temperature static and dynamic strain measurements; (3) *Dynaloy* and *IsoElastic* (nickel-iron alloy plus other proprietary ingredients), used for dynamic tests where the larger temperature coefficients of these materials are of no consequence; (4) *Stabiloy* and *Karma* (nickel-chrome alloys) containing other ingredients which provide wider temperature compensation range; and (5) platinum alloy (usually tungsten) which shows unusual stability and fatigue life at elevated temperatures. Additionally, semiconductor strain gages are used. These are similar to conventional metallic gages, the principal difference being the greater response of semiconductor gages to both strain and temperature. They have large and nonlinear resistance versus strain, arising primarily to the piezoresistive effect. They have found their main use in development of high-output transducers, such as load cells and pressure cells.

The application of strain gages breaks down into two main areas: (1) applications where the gage measures strain as the primary objective of measurement (stress analysis of various structures — bridges, boat hulls, etc.); and (2) uses where the measurement of strain, in turn, is a measure of another variable, such as pressure, impact, acceleration, and other force-associated variables, i.e., the strain gage becomes a transducer. Because strain gages, when properly compensated for temperature effects, can achieve overall accuracies of plus-or-minus 0.10% or better and because of their great flexibility, relatively low cost, and availability of numerous configurations, they are widely used in numerous kinds of transducers. A few representative strain gage configurations are illustrated in Fig. 2.

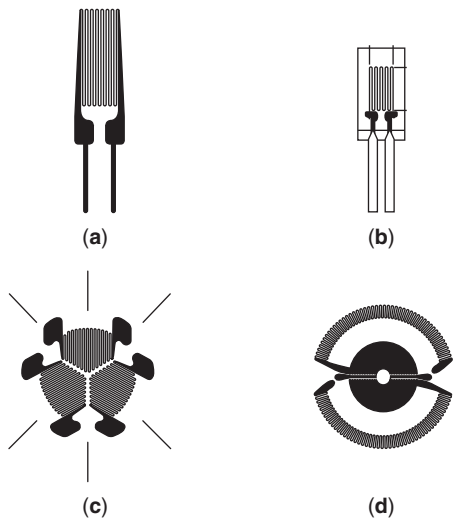


Fig. 2. Representative configurations of strain gages: (**a**) Uniaxial strain gage, wire type; (**b**) uniaxial strain gage, foil type; (**c**) rosette gage (3-element foil) rosette, 60 degrees planar; and (**d**) 4-element "diaphragm" gage which takes advantage of the tangential tensile strains developed at the center of the diaphragm and the compressive radial strains present at the edge.

STRAIN HARDENING EXPONENT. A measure of the rate of hardening with strain as in a tensile test, as expressed by the constant "n" in the equation $\sigma = \sigma_0 \delta^n$, where σ is the true stress, σ_0 the true stress at unit strain, and δ the true strain.

STRAIN THEORY. A theory first proposed by von Baeyer to explain the relative stability of various carbon compounds. It may be stated in the form: The regular tetrahedral-symmetric position is the most stable of all possible positions of neighboring carbon compounds; variations from this position produces increased energy content, and hence strain. Since the angle at the vertex of a regular tetrahedron is 109°28; this theory ascribes minimum strain to cyclopentane, of the polymethylenes. The theory is borne out by the lesser stability of cyclobutane and cyclopropane, but not to the degree that might be expected by the stability of some of the higher-membered rings. In that case, the lesser strain is often due to a spatial or three-dimensional structure.

Extensions of the strain theory have been made, with varying success, to other hydrocarbon ring structures, saturated and unsaturated, to ring compounds in which the hydrogen atoms have been variously substituted, and to rings containing atoms other than carbon, as well as to bicyclic and polycyclic systems.

STRATH. 1. In geography, a broad alluviated valley. 2. In geomorphology, a valley or confluent valleys which represent a local base level of erosion or a local and incipient peneplain.

STRATIFICATION (Ecology). As described under **Ecology**, the primary classification of ecological communities is by the broad nature of the environment — fresh-water, salt-water, terrestrial, etc. communities. Vertical stratification also occurs in many of these communities as, for example, certain fishes that prefer shallow water, others that inhabit deep water; or in a tropical forest, animals and birds that prefer the tree tops, others that prefer any one of several intervening levels between the surface and the top canopy. Further, some organisms prefer an underground habitat.

STRATIGRAPHY. The study of the origin and chronological successions of the observable rocks of the lithosphere, in which each lithologic unit is considered to be a formation. The term formation is usually confined to bedded or stratified rocks, including lava flows and volcanic ashes. The major principles involved in the correlation (dating) of formations are: (1) The law of superposition, or that the chronological sequence of any stratigraphic section depends upon the original order in which the formations were laid down; thus the fundamental basis of stratigraphy is structural geology. (2) Index fossils, or those species of fossils whose stratigraphic age are already known. (3) lithology. Igneous rocks may be dated by the age of the sedimentary rocks which they intrude, or overlie; or by radioactive minerals. See also **Paleontology**; **Structural Geology**; and **Radioactivity**.

STRATOSPHERE. The region of the atmosphere extending from the top of the troposphere (the tropopause), at heights of roughly 10–17 kilometers (6–10.5 miles), to the base of the mesosphere (the stratopause), at a height of roughly 50 kilometers (31 miles). The stratosphere is characterized by constant or increasing temperatures with increasing height and marked vertical stability. It owes its existence to heating of ozone by solar ultraviolet radiation, and its temperature varies from $-85\,^{\circ}$C ($-121\,^{\circ}$F) or less near the tropical tropopause to roughly $0\,^{\circ}$C ($32\,^{\circ}$F) at the stratopause. While the major constituents of the stratosphere are molecular nitrogen and oxygen, just as in the troposphere, the stratosphere contains a number of minor chemical species that result from photochemical reactions in the intense ultraviolet radiation environment. Chief among these is ozone, the presence of which shelters the underlying atmosphere and the earth's surface from exposure to potentially dangerous ultraviolet radiation. See also **Atmosphere (Earth)**.

STRATOSPHERIC OZONE. The stratosphere extends from ~10 to 50 km (6 to 31 miles). Ozone is a minor, but important constituent of the stratosphere. Its maximum concentration of about 10 ppmv occurs at ~35 km (~21.75 miles). The temperature ranges from ~215 K (~$-72.67\,^{\circ}$F) at 15 km (9 miles) to ~270 K (~$26.33\,^{\circ}$F) at 50 km (31 miles). Light absorption by the atmosphere is responsible for shielding the Earth's surface from solar radiation below ~300 nm. Oxygen is the main absorber at ~200 nm, whereas ozone is the main absorber in the 230–320 nm range. The warm layer at 45–55 km (28–34 miles) is due to absorption of solar radiation by ozone and heat liberated in ozone formation and destruction, which helps to maintain thermal equilibrium on earth.

Ozone Formation

Ozone is formed rapidly in the stratosphere (15–50 km (9–31 miles) by the action of short-wave ultraviolet solar radiation (<240 nm) on molecular oxygen, $O_2 + h\nu \rightarrow 2O$. At wavelengths above 175 nm, only ground-state (^{3}P) atoms are formed; whereas at wavelengths below 175 nm, one ground-state and one excited (^{1}D) atom are formed. Ground-state atoms also can be formed by the pre-dissociation of electronically excited O_2. The oxygen atoms can react with molecular oxygen to yield ozone: $O + O_2 + M \rightarrow O_3 + M$. Ozone also can form from vibrationally excited O_2:$O_2(X^3\Sigma_g^-) + O_2 \rightarrow O_3 + O$. [Miller and co-workers,1994].

Ozone Destruction

Ozone can be destroyed photochemically: $O_3 + h\nu \rightarrow O + O_2$. In addition, ozone can be destroyed by reaction with oxygen atoms ($O + O_3 \rightarrow 2O_2$) as well as with excited O_2 molecules ($^1\Delta_g$, $^1\Sigma_g^+$) and $^3\Sigma_g^-$ and other free radicals. Since the early 1960s, it has been recognized that radicals such as NO, OH, Cl, and Br affect the abundance and distribution of ozone in the stratosphere. The so-called ozone deficit problem has arisen because earlier studies simulating stratospheric chemistry concluded that ozone formation is significantly less than its destruction.

Ozone Concentration

Most ozone is formed near the equator, where solar radiation is greatest, and transported toward the poles by normal circulation patterns in the stratosphere. Consequently, the concentration is minimum at the equator and maximum for most of the year at the north pole and about 60°S latitude. The equilibrium ozone concentration also varies with altitude; the maximum occurs at about 25 km (15.5miles) at the equator and 15–20 km (9–12.4 miles) at or near the poles. It also varies seasonally, daily, as well as interannually.

Effect of Various Compounds in Ozone Depletion

Nitric Oxide. Nitrous oxide is injected into the atmosphere primarily by bacterial denitrification of nitrogen compounds (augmented by nitrogen fertilizers) in the soil. While this process mainly forms N_2, ~7% results in formation of N_2O. While N_2O is stable in the troposphere, it is degraded in the stratosphere (into which it is transported via Brewer–Dobson Circulation) where most is photolyzed to nitrogen ($N_2O + h\nu \rightarrow N_2 + O$), but ~3% is converted to nitric oxide [$N_2O + O(^1D) \rightarrow 2NO$], which in turn can catalyze the destruction of ozone.

The aircraft campaign via The Stratospheric Photochemistry, Aerosols and Dynamics Expedition (SPADE), http://cloud1.arc.nasa.gov/spade/, investigated the photochemistry of the atmosphere up to 21 km (13 miles) between 15 and 60°N latitude in the spring of 1993. It showed that cycles 1 and 2 account for <20% of the total ozone loss observed during spring in the lower stratosphere at mid-north latitudes [Wennberg and co-workers,1994]. Data from satellite measurements (the Halogen Occultation Experiment, HALOE, aboard the Upper Atmosphere Research Satellite, UARS) for 1993 show that NO_x (ie, $NO + NO_2$) catalyzed ozone destruction becomes more important at higher altitudes and latitudes [Crutzen, and Brühl, 2001].

During night time, NO_2 and NO_3 reform equilibrium amounts of N_2O_5. Nitrogen pentoxide can react on the surface of sulfuric acid aerosols releasing gaseous nitric acid. Reaction of NO_2 with HO radicals also forms HNO_3. Nitric acid and N_2O_5 photolyze slowly in the gas phase and regenerate NO_2 radicals. Nitric acid is slowly transported from the lower stratosphere into the troposphere where it is removed in rain.

Hydroxyl Radicals. Hydroxyl radicals, formed by reaction of (^{1}D) oxygen atoms with water vapor or CH_4 are involved in several catalytic cycles, which result from whether HO and the intermediate HO_2 react with O atoms or ozone. Above 40 km (25 miles), reaction of HO with O atoms is favored, whereas below 40 km, reaction with ozone is favored. Above 30 km (19 miles) the intermediate HO_2 reacts with O atoms, whereas <30 km (<19 miles) reaction with ozone is favored. Below 30 km (19 miles), where the O atom concentration is low, both HO and HO_2 react with ozone [Atkinson and co-workers,1997 and 2000 Ref.].

This cycle accounts for 30–50% of the total photochemical ozone loss observed during spring in the lower stratosphere at mid-north latitudes based on observed HO_2 concentrations [Wennberg, and co-workers, 1994].

Halogen Radicals. Halogen radicals capable of destroying ozone are formed by photolysis of chemical compounds from anthropogenic and natural sources.

Sources. The release of chlorofluorocarbons (CFCs) from industrial production of aerosol sprays, coolants for refrigerators and air conditioners, blowing agents for foams, cleaners for electronic parts, and Halons (bromofluorocarbons) from fire extinguishing agents, has created conditions for the depletion of O_3 in the stratosphere [Molina, and Rowland 1974, and Zuer, 1993-94 Refs.]. In addition to the main CFCs, $CFCl_3$ (CFC-11), and CF_2Cl_2 (CFC-12), other sources of chlorine are $CHFCl_2$ (CFC-22), $C_2F_3Cl_3$ (CFC-113), CCl_4, CH_3CCl_3, and CH_3Cl released from the oceans and from the burning of biomass. The main Halons are CF_3Br (H 1301) and CF_2ClBr (H 1211). Methyl bromide is another important source of bromine, released into the atmosphere by marine plankton, through the burning of biomass, or by its use as a soil fumigant. See also **Ozone Depletion (Science of)**.

Activation of Halogen Sources. Although inert in the lower atmosphere (troposphere), the fully halogenated CFCs and Halons diffuse into the upper stratosphere where they are photodissociated by the intense ultraviolet radiation.

The C−F bonds also are cleaved, resulting ultimately in the formation of HF, a stable fluorine reservoir. Hydrogen-containing molecules are degraded by HO radicals in the troposphere, limiting the fraction that reaches the stratosphere. The small natural source of active chlorine comes from photolysis of methyl chloride and via HO radical initiated degradation. Small amounts of chlorinated hydrocarbons (eg, CCl_4) also diffuse into the stratosphere from anthrpogenic sources and are photolyzed to Cl radicals. Methyl bromide, from natural and anthropogenic sources, undergoes photodissociation like methyl chloride forming Br atoms.

Ozone Destruction by Halogen Radicals. The Cl (or Br) atoms formed by photodecomposition of CFCs can convert ozone to oxygen catalytically; indeed, one chlorine atom is capable of destroying thousands of ozone molecules. Although much less abundant in the stratosphere than chlorine, bromine is considerably more reactive in some reactions, thus accounting for a significant fraction of ozone destruction in certain catalytic cycles. Satellite and airborne observations have shown significant decreases in total column ozone since 1978, ranging from zero near the equator to 6–8% at high latitudes [Gleason and co-workers,1993]. The most dramatic ozone decrease occurs every year in spring at the Antarctic ozone hole. In 1992 and 1993, the ozone levels were ∼50% less than in 1979.

Formation of Chlorine Reservoirs. Other reactions, eg, $ClO + NO_2 + M \rightarrow ClONO_2 + M$, $Cl + CH_4 \rightarrow HCl + CH_3$, and $ClO + HO_2 \rightarrow HOCl + O_2$ also are important and result in formation of temporary inert chlorine reservoirs and retard ozone depletion. Hydrogen chloride is the longest lived with a lifetime of weeks, whereas HOCl is the shortest with a lifetime of hours because it is quickly photolyzed in sunlight. The relative abundance varies as follows: $ClONO_2 > HCl > HOCl$. They are the most abundant chlorine species at lower latitudes before winter. The HCl is slowly transported from the lower stratosphere into the troposphere where it is removed in rain.

Formation of Bromine Reservoirs. By contrast with chlorine, bromine does not form significant reservoirs because $BrONO_2$ and HOBr are readily photolyzed and HBr formation is not favorable.

Denoxification. The slow photolysis of $ClONO_2$($ClONO_2 + h\nu \rightarrow Cl + NO_3$) yields chlorine atoms capable of decomposing ozone and accounts for 10–15% of halogen-controlled losses. Nitrogen trioxide can photolyze to O_2 and NO, which can react with ozone forming NO_2. It also can react with NO_2 forming N_2O_5, which can hydrolyze on sulfate aerosols forming HNO_3, reducing the availability of NO_2. This allows higher free ClO concentrations, shifting ozone catalytic decomposition from NO_x to ClO_x and HO_x [Fahey and co-workers, 1993]. With the exception of NO_2, all radicals are produced photolytically each day and their concentrations fall to zero during the night.

Effect of Antarctic Polar Stratospheric Clouds. Although relatively unreactive in the gas phase, chlorine nitrate and HCl can react on the surface of frozen particles in polar stratospheric clouds (PSCs), which form at altitudes of 10–25 km (6–16 miles) when air trapped within the polar vortex (a circular wind pattern) that circles the Antarctic in winter is cooled to low temperatures during the polar night, thus preventing replenishment by fresh ozone [Solomon and co-workers,1986]. Type I PSCs form at 193 K and type II (ice) at 187 K. Type I PSCs, originally thought to consist of nitric acid trihydrate, are now thought to consist of nitric and sulfuric acids and water.

Were the subscripts g and s denote, PSC chemistry produces an atmosphere rich in reactive chlorine species but depleted in NO_2. These reactions are the key to the formation of the Antarctic hole, and continue until the break-up of the polar vortex and warming of the stratosphere in the spring. Type II PSC particles can grow sufficiently large to sediment out of the stratosphere. This denitrification process removes HNO_3 as a source of NO_2 [Santee and co-workers, 1995]. The volatilized gaseous chlorine and HOCl are photolyzed to chlorine atoms when sunlight returns in the spring:$Cl_2 + h\nu \rightarrow 2Cl$ and $HOCl + h\nu \rightarrow HO + Cl$. The chlorine atoms reenter ozone catalytic destruction cycles.

The ClO dimer (ClOOCl) has been observed in the stratosphere by direct measurement via a NASA ER-2 aircraft during the joint SOLVE/THESEO-2000 mission over the Arctic in the winter of 1999–2000, http://www.agu.org/pubs/crossref/2002/2001JD001303.shtml.

Effect of Sulfate Clouds. Similar heterogeneous reactions also can occur, but somewhat less efficiently, in the lower stratosphere on global sulfate clouds (ie, aerosols of sulfuric acid), which are formed by oxidation of SO_2 and COS from volcanic and biological activity, respectively. The effect is most pronounced in the colder regions of the stratosphere at high latitudes. Indeed, the sulfate aerosols resulting from eruptions of El Chicon in 1982 and Mt. Pinatubo in 1991 have been implicated in subsequent reduced ozone concentrations [Wilson and co-workers, 1993].

Effect of Arctic Polar Stratospheric Clouds. Arctic polar stratospheric clouds (mostly type I) form sporadically because only rarely are temperatures sufficiently low. Nevertheless, the northern polar vortex contains enhanced ClO levels, similar to the Antarctic, that contribute to significant ozone loss in late winter. This may indicate that crucial heterogeneous chemistry on sulfate aerosols is occurring, although no hole has been observed. This is attributed to the relatively short period of significant loss and to the fact that the warmer, less stable Arctic vortex dissipates by late winter. In addition, there is a lack of denitrification, ie, removal of nitric acid via sedimentation of PSCs, observed in the Antarctic. Thus, the presence of HNO_3 throughout the arctic winter moderates ozone destruction by providing a source of NO_2 to quench ClO. Nevertheless, record-low ozone levels, up to 40% below normal and approaching those in the recurring Antarctic ozone hole, were observed in the winter of 1995 due to exceptionally low temperatures in the Arctic vortex.

STRATOSPHERIC SULFATE LAYER. A region in the lower stratosphere (approximately 15–25 kilometers (9–15.5 miles) in altitude and worldwide) where submicrometer-sized particles composed of aqueous sulfuric acid are present. Also called *Junge aerosol layer*.

Oxidation of sulfur compounds (primarily carbonyl sulfide [CAS: 463-58-1], OCS, and sulfur dioxide [CAS: 7446-09-5], SO_2) is believed to be the source of sulfuric acid [CAS: 7664-93-9] (H_2SO_4). Volcanic eruptions directly inject large quantities of H_2S or SO_2 into the stratosphere, causing large increases in the amount of particulate sulfuric acid. The particles undergo a slow falling-out process (timescale of years) into the lower atmosphere. Because these sulfuric acid particles are present in

the ozone layer, heterogeneous chemical reactions that occur on them can have a significant effect on ozone by influencing the abundance of trace species that affect ozone concentrations. See also **Ozone** and **Stratospheric Ozone**.

STREAK LIGHTNING. See **Lightning**.

STREAM FUNCTION. 1. A parameter of two-dimensional, nondivergent flow, with a value that is constant along each streamline. For flow in the (x,y) plane, the streamfunction ψ is related to the respective coordinate velocities u and v by the equations

$$u = -\frac{\partial \psi}{\partial y} \text{ and } v = \frac{\partial \psi}{\partial \chi}.$$

In meteorology the most common application of the streamfunction is in the assumption of geostrophic equilibrium. If variations in the Coriolis parameter f are ignored, the streamfunction in a constant-pressure surface is proportional to the geopotential gz, that is, $\psi = gz/f$; in an isentropic surface, it is $\psi = (gz + c_pT)/f$, called the Montgomery streamfunction, where c_p is the specific heat at constant pressure and T the Kelvin temperature.

2. Stokes's streamfunction (also called *current function*): If the flow is three-dimensional but is axisymmetric (i.e., the same in every plane containing the axis of symmetry), a Stokes's streamfunction ψ will exist such that

$$v_s = -\frac{1}{r}\frac{\partial \psi}{\partial n},$$

where v_s is the speed in an arbitrary direction s, r is the distance from the axis of symmetry, and n is normal to the direction s, increasing to the left.

Note that Stokes's streamfunction has dimensions of volume per time. Streamfunctions can also be defined for more complex three-dimensional flows.

AMS

STREAMING (Molecular). Application of kinetic theory to the flow of gas through a tube at low pressures, such that the mean free path is large compared with the diameter of the tube. In this case, the streaming of the gas is due to the random motion of the molecules, and to the density gradient down the tube, so that the numbers of molecules traversing a given cross section in opposite directions is different. For a tube of circular cross section, the mass flowing per second is proportional to the pressure difference and the cube of the radius.

STRESS RELIEVING. A heat treatment to relieve residual stresses.

STRESS-RUPTURE TEST. A form of short time creep test in which a tensile specimen is deformed to rupture (fracture) under constant load and temperature.

STRESS-STRAIN CURVE. A graphical representation of the relation between unit stress and unit deformation in a stressed body as a gradually increasing load is applied.

STRESS (Structural). A quantitative expression of a condition within an elastic material due to deformation, or strain, brought about by external forces, inequalities of temperature, or otherwise. Its measure is always the ratio of a force to an area. By some, stress is interpreted as a force distributed over an area, and the above ratio is called the "unit stress." Central, torsional and bending loads cause stress. The total resisting force acting at any section of the body divided by the area of the section is the average stress, commonly expressed in pounds per square inch. The unit stress is the resisting force on a unit of area. The component of a stress that acts at right angles to a surface is known as the normal stress. If this stress is produced by a load whose resultant passes through the center of gravity of the area, it is called an axial or direct stress. A normal resisting force that causes the fibers to increase in length is a tensile stress, while one which shortens the fibers is a compressive stress. The latter is often called a bearing stress. The component of any stress that lies in the plane of the area is a shearing stress. See also **Elasticity**.

The "conventional stress" as applied to tension or compression tests is the instantaneous value of the load divided by the original cross-section area. This type of stress is used by engineers for design purposes since their primary concern is how large a load or stress a structure is capable of carrying, as measured in terms of the structures' original dimensions. Frequently, however, for scientific purposes, it is important to know the true stress determined by dividing the force at a given instant by the area existing at that time.

Direct tensile or compressive stresses are known as primary stresses. The bending stress, resulting from deflection, is called a secondary stress. The stresses developed in a column due to the lateral deflections are of a secondary nature. The rigidity of the riveted or welded joints of a truss that has deflected due to the axial deformation of its members causes bending stresses in the members which are classified as secondary stresses. The resistance offered by a body to a combination of direct and bending loads is frequently called a combined stress. A normal stress which occurs at a point in a plane on which the shearing stress is zero is known as a principal stress. If this normal stress is tensile, it is often called a diagonal tension stress; if compressive it is known as a diagonal compression stress.

The internal resisting force that arises in a restrained body due to temperature changes is a thermal stress. The adhesive resistance developed in the concrete surrounding the steel reinforcing rods when a reinforced concrete member is subjected to load is known as bond stress. Safe unit resisting forces used in design are called working stresses. These are usually taken as a percentage of the ultimate stress or the elastic limit of the material.

The stress developed in bridge members as a result of traction between the wheels of the live load and the supporting surface is called a traction stress. The effect of these stresses is usually neglected in highway bridge design but must be considered in railway bridges.

STRESS TEST. See **Coronary Artery Disease (CAD)**.

STRIATION. Three uses of this term are: 1. A striped appearance of the positive column of a Crookes tube. 2. A defect of optical materials, such as optical glass, having the appearance of streaks through the material, and seriously affecting the material for use as lenses or windows. 3. The scratches on bedrock or on pebbles and boulders which are the result of glaciation. These are called glacial striae to distinguish them from the striae which occur on the surfaces of fault planes.

STRICKING CLOCK. See **Clocks**.

STRIGIFORMES *(Aves).* This order of birds is distinctly set off from other bird kinds. In physical structure they are remarkably homogeneous. They are recognized immediately by their large heads, their forward-directed eyes, the seeming absence of a neck, and their soft plumage. Their length is 15–80 centimeters (6–31 inches) and the weight is 55–4200 grams (2 ounces to 9 pounds). They have 11 primaries and 12 (rarely 10) tail feathers. The fourth toe is abducted and reversed diagonally. The beak is drawn down steeply, making it appear small. The upper mandible is hooked. The plumage is particularly well suited for nocturnal activity: gray, brown, black, and white shades arranged in patches, stripes, bands, and streaks effect a muted coloration. See accompanying illustration. They possess calls, mostly sounding an "oo" or an "ee," that serve to find and to keep contact with their conspecifics during their nocturnal activities. Their clutch consists of 1–12 white, roundish eggs. The 2 families are: 1. Barn Owls (*Tytonidae*); and 2. Owls in the narrower sense (*Strigidae*). Altogether there are 28 genera and 144 species.

Owls are to be distinguished from raptors not only by both external and internal morphology, but quite notably by their behavior. Owl young,

unlike those of raptors, are born blind. Most owls are active at dusk or during the night, and some during the day. They feed chiefly on smaller vertebrates, especially rodents, but also on insects and worms. Some, such as the fishing owls, are adapted for a specialized diet. Some smaller species prefer to consume insects. Indigestible parts of the prey (fur, feathers, bones, and chitin) are regurgitated.

The notion that owls cannot see well in daylight is still widespread, but untrue. Owls are indeed far-sighted, yet their vision is excellent in daylight; in complete darkness, they are just as helpless as humans. The particular structure of their eyes, however, enables them to orient themselves adequately in very dim light. The number of light-sensitive cells in the retina (rods) is greatly multiplied in those owls which are active at night, such as the tawny owl (*Strix aluco*). See Fig. 1. On the other hand, such species have very limited color discrimination, while owls that are active at twilight or during the day do recognize colors. The retina possesses not only the rods, but also more cones than that of nocturnal species. The owl's eyes, which are usually very large, are immovable, forcing the bird to turn its head for a change of visual field.

Fig. 1. Face of tawny owl (*Strix aluco*.)

The bony ring supporting the sclera (the dense, fibrous, opaque white outer coat of the eyeball), which is peculiar to a bird's eye, has developed into a regular cylinder in owls; it unites the dioptric apparatus (lens, cornea, and iris) with the relatively restricted retina. This results in an eye whose shape is strongly reminiscent of the "telescopic eyes" of some deep sea fish and some nocturnal mammals. Such "telescopic eyes" are adjusted to seeing in the dimmest of lights. The angle of the corneal fenestra is very wide (approximately 160 degrees), and the light gathered from a large field of vision is reduced to a small image on the retina.

The sense of hearing is superbly developed in owls. The margins of the auditory meatus are remodeled into feathered flaps, which can close over the ear completely and so protect the sensitive inner parts. When erected, the flaps become wide, movable sound-funnels, which enable the owl to pick up the faintest sounds from various directions. The feathery tufts on the head of various owl species are not ears, but decoration.

All owls lay pure white, more or less round eggs, which, as a rule, are incubated only by the female. During that period, it is usually the male alone that takes care of the feeding; they often pile up a store of food near the brooding ground. Both parents share in the rearing of the young.

No owl builds a genuine nest. The closest to it is a more or less thick layer of usually dry plant material put together by the short-eared owl, which is a ground-brooder. Other species dig a hollow at their brooding place and tear up boluses or food leftovers to use as a kind of nest bedding. In most cases, however, the eggs are deposited directly on the ground of the chosen brood site, sometimes in an abandoned crow's nest or in the aerie of a predator.

When young owls hatch, they are blind and covered with a whitish down, and their eyes are closed. Often the several young of one brood hatch at intervals of several days, for the eggs are laid in intervals and most species begin incubation after the first egg is laid. After one week, on the average, the ears and eyes open and gradually the young begin to get a second dress which in some species is downy and in others resembles the dress of the adult birds.

The family of the barn owls (*Tytonidae*) stands well removed based on recent studies, phylogenetically, from the true owls. The facial veil is more or less heart-shaped; the talon of the middle toe has a "comb;" and the posterior edge of the sternum has either two notches or none at all. There are 2 genera with a total of 11 species: (1) Barn Owls (*Tyto*), with 9 species; and (2) Bay Owls (*Pholidus*), with 2 species.

The 9 species of barn owls (*Tyto*) are as follows: 1. The Barn Owl (*Tyto alba*) reaches a length of 34 centimeters (13 inches), with a wingspread of 95 centimeters (37 inches), and weighs about 300 grams ($10\frac{1}{2}$ ounces). The facial veil is heart-shaped. The eyes are relatively small and black-brown; the wings are long and rather pointed. Since the intertarsal joints are close to each other when the bird is perching, it gives a knock-kneed impression. 2. The Cape Grass Owl (*Tyto capensis*) is found in southern Africa; it is a ground-breeding bird. 3. The Grass Owl (*Tyto longimembris*) occurs in the grasslands of India and southern China, some of the Sunda Islands, and Australia. 4. The Celebes Barn Owl (*Tyto rosenbergii*) inhabits the rain forests of Celebes. 5. The Minnahassa Barn Owl (*Tyto inexpectata*) inhabits northern Celebes. 6. The Madagascar Grass Owl (*Tyto soumagnei*) is relatively small, has long wings, and inhabits woodland glades in the rain forests of Madagascar; it feeds mainly on amphibia. 7. The Masked Owl (*Tyto novaehollandiae*) is found in the jungles of Australia and some Sunda Islands. 8. The Sooty Owl (*Tyto tenebricosa*) is the only species without yellow-brown or yellow-orange shades in its plumage. Its habitat is humid parts of the jungle and rain forests in New Guinea and Australia. 9. The New Britain Barn Owl (*Tyto aurantia*) occurs only in New Pomerani (New Britain).

The 2 species of bay owls (*Pholidus*) are as follows: 1. The Bay Owl (*Pholidus badius*) reaches a length of 30 centimeters (12 inches). 2. The Congo Bay Owl (*Pholidus prigoginei*) was discovered only in 1951, in the highlands northwest of Lake Tanganyika.

Bays owls are strictly nocturnally active birds, inhabiting the jungle. Wide, natural cavities serve as brood sites; the 3–5 purely white, roundish eggs are deposited directly on the floor, which is usually covered with a layer of decayed wood. The exact breeding season is not known. Bay owls feed on small vertebrates, such as small mammals, birds, reptiles, and amphibia, and possibly also on fish, for they like to hunt near the water. They are known by a hollow-sounding "hoo."

The family Owls (*Strigidae*) comprises 24 genera with 133 species. The claw of the middle toe has no pecten (comb). The 2 subfamilies are: (1) True Owls (*Buboninae)* and (2) Long-Eared Owls and Disk-Eyed Owls (*Striginae*).

The 18 genera which comprise the subfamily *Buboninae* are as follows: 1. The Scops Owls (*Otus*); 2. *Jubula* (Maned Owl, *Jubula lettii*); 3. *Lophostrix* (Crested Owl, *Lophostrix cristata*); 4. the Eagle Owls (*Bubo*); 5. the Fish Owls (*Ketupa*); 6. the Fishing Owls (*Scotopelia*); 7. the Spectacled Owls (*Pulsatrix*); 8. *Nyctea* (Snowy Owl, *Nyctea scandiaca*); 9. *Surnia* (Hawk Owl, *Surnia ulula*); 10. the Pygmy Owl (*Glaucidium*); 11. *Micrathene* (Elf Owl, *Micrathene whitneyi*); 12. *Uroglaux* (New Guinea Hawk Owl, *Uroglaux dimorpha*); 13. the Hawk Owls (*Ninox*); 14. *Gymnoglaux* (Bare-legged Owl, *Gymnoglaux lawrencii*); 15. *Sceloglaux* (Laughing Owl, *Sceloglaux albifacies*); 16. *Athene* (Little Owl, *Athene noctua*); 17. *Speotyto* (Burrowing Owl, *Speotyto cunicularia*); 18. the Tropical Tawny Owls (*Ciccaba*).

The 6 genera which comprise the subfamily of Long-eared Owls and Disk-eyed Owls (*Striginae*) are as follows: 1. The Disk-eyed Owls (*Strix*); 2. *Rhinoptynx* (*Rhinoptynx clamator*); 3. the Long-eared Owls (*Asio*); 4. *Pseudoscops* (Jamaican Owl, *Pseudoscops grammicus*); 5. *Nesasio* (Fearful Owl, *Nesasio solomonensis*); 6. the Tengmalm's Owls (*Aegolius*). See also **Owls**.

STRINGER. 1. A configuration of nonmetallic inclusions in wrought metals that is elongated in the direction of working. In steels, stringers are usually formed of oxides or sulfides. 2. One of the longitudinal beams in the floor system of a bridge.

STRIPPING. In nuclear reactions, an effect observed primarily in bombardment with deuterons, whereby only part of the incident particle merges with the target nucleus, and the remainder proceeds with most of its original momentum in a direction determined solely by its electromagnetic interactions with the target nucleus. The effect is strongly marked in deuteron bombardment, and in this case typically leads to directional neutron and proton beams that emerge from the target (if the latter is sufficiently thin) predominantly in the forward direction. The angular divergence of the beams decreases with increasing energy of the incident deuterons. Subsidiary peaks are sometimes observed at rather small angles relative to the forward direction. When the (d, p) type of stripping occurs with deuterons having energies smaller than or comparable with the Coulomb barrier of the target nucleus, it is often called the Oppenheimer-Phillips process.

For the use of the term stripping in chemical technology, see also **Distillation**.

STROBOSCOPE. An instrument that permits intermittent observations of a cyclically moving object in such a way as to produce an optical illusion of stopped or slowed motion. This phenomenon is readily apparent, for example, when rewinding a tape at many revolutions per minute when the tape deck is located under a 60-Hz incandescent lamp. Patterns on the reel tend to slow and then appear to stop before reversing their direction. Of course, stroboscopic effects have been known for decades,[1] one of the first scientific applications being found in very high-speed photography. Intermittency of observation can be provided by mechanical interruption of the line of sight (as with a motion picture camera) or by intermittent illumination of the object being viewed. The industrial stroboscope basically is a lamp plus the electronic circuits required to turn the lamp on and off very rapidly, at rates as high as 150,000 flashes per minute and higher.

The schematic diagram of an electronic stroboscope is shown in Fig. 1. The device includes a strobotron tube with its associated discharge capacitors, a triggering tube to fire the strobotron, an oscillator to determine the flashing rate, and a power supply. With the use of harmonic techniques, speeds up to 1 million r/min can be measured. Accuracy is nominally $\pm 1\%$ of the dial reading after calibration.

To serve as a tachometer, a stroboscope must have its own flashing-rate control circuits and calibrated dial. Stroboscope tachometer test disks are available. These disks can be cut out and mounted on light cardboard or metal. The center must be carefully located and fitted onto the drive shaft. Although more automatic means are available to measure belt slippage, this was commonly accomplished by stroboscopes in earlier times.

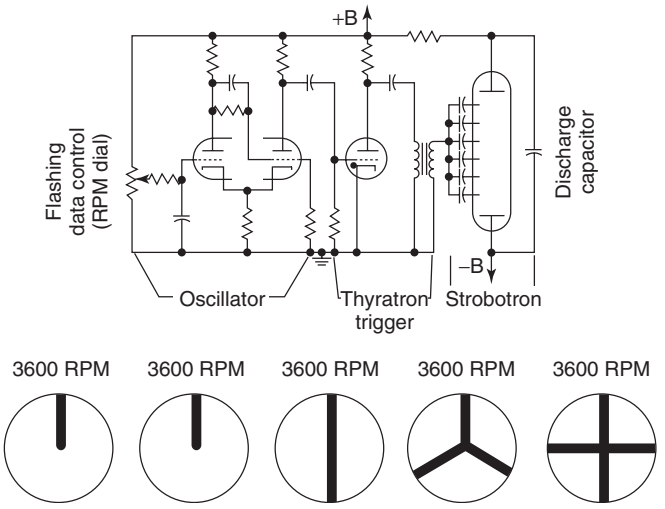

Fig. 1. Electronic stroboscope, (*a*) Schematic representation of circuit. (*b*) Images obtained at harmonic and subharmonic flashing rates of a stroboscope. Even with an asymmetrical object, the correct fundamental image is repeated when the stroboscope is flashing at one-half, one-third, and so on, the speed of the object. The proper setting for a fundamental speed measurement is the highest setting at which a single stationary image can be achieved. This does not hold, however, if the fundamental is beyond the flashing rate of the stroboscope. There are several ways to distinguish fundamental from submultiple images. The flashing rate can be decreased until another single image appears. If this occurs at half the first reading, the first reading was the actual speed of the device. If it occurs at some other value, then the first reading was a submultiple. Or the user can double the flashing rate and check for a double image. Or the user can flip the range switch to the next higher range. Because of the 6:1 relationship between ranges, a 6:1 pattern should appear. The 6:1 relationship between ranges also makes it convenient to convert speed readings from revolutions per minute into cycles per second. One simply flips to the next lower range and divides the new reading by 10.

Because of their portability and easy setup, stroboscopes find a variety of applications, principally in machine and vehicle research, development, and testing. (*GenRad.*)

STROKE. A stroke, or "brain attack," occurs when blood circulation to the brain fails. Brain cells can die from decreased blood flow and the resulting lack of oxygen. There are two broad categories of stroke: those caused by a blockage of blood flow and those caused by bleeding. While not usually fatal, a blockage of a blood vessel in the brain or neck, called an ischemic stroke, is the most frequent cause of stroke and is responsible for about 80 percent of strokes. These blockages stem from three conditions: the formation of a clot within a blood vessel of the brain or neck, called thrombosis; the movement of a clot from another part of the body such as the heart to the neck or brain, called embolism; or a severe narrowing of an artery in or leading to the brain, called stenosis. Bleeding into the brain or the spaces surrounding the brain causes the second type of stroke, called hemorrhagic stroke.

Generally there are three treatment stages for stroke: prevention, therapy immediately after the stroke, and post-stroke rehabilitation. Therapies to prevent a first or recurrent stroke are based on treating an individual's underlying risk factors for stroke, such as hypertension, atrial fibrillation, and diabetes. Acute stroke therapies try to stop a stroke while it is happening by quickly dissolving the blood clot causing an ischemic stroke or by stopping the bleeding of a hemorrhagic stroke. Post-stroke rehabilitation helps individuals overcome disabilities that result from stroke damage. Medication or drug therapy is the most common treatment for stroke. The most popular classes of drugs used to prevent or treat stroke are antithrombotics (antiplatelet agents and anticoagulants) and thrombolytics.

Although stroke is a disease of the brain, it can affect the entire body. A common disability that results from stroke is complete paralysis on one side of the body, called *hemiplegia*. A related disability that is not as debilitating as paralysis is one-sided weakness or *hemiparesis*. Stroke may cause problems with thinking, awareness, attention, learning, judgment, and memory. Stroke survivors often have problems understanding or forming speech. A stroke can lead to emotional problems. Stroke patients may have difficulty controlling their emotions or may express inappropriate emotions. Many stroke patients experience depression. Stroke survivors may also have numbness or strange sensations. The pain is often worse in the hands and feet and is made worse by movement and temperature changes, especially cold temperatures. Recurrent stroke is frequent; about 25 percent of people who recover from their first stroke will have another stroke within 5 years.

Each year in the United States, there are more than 700,000 strokes. Stroke is the third leading cause of death in the country. And stroke causes more serious long-term disabilities than any other disease. Nearly three-quarters of all strokes occur in people over the age of 65 and the risk of having a stroke more than doubles each decade after the age of 55. See also **Cerebrovascular Diseases**.

Two key steps you can take will lower your risk of death or disability from stroke: know stroke's warning signs and control stroke's risk factors.

[1] Invented independently by Stampfer of Vienna and Plateau of Ghent in 1832. Stampfer chose the name "stroboscope," which is derived from the Greek words meaning "whirling watcher."

Scientific research conducted by the NINDS has identified warning signs and a large number of risk factors.

Warning Signs of a Stroke

Warning signs are clues your body sends that your brain is not receiving enough oxygen. If you observe one or more of these signs of a stroke or "brain attack," don't wait, call a doctor or 911 right away!

- Sudden numbness or weakness of face, arm or leg, especially on one side of the body
- Sudden confusion, trouble speaking or understanding
- Sudden trouble seeing in one or both eyes
- Sudden trouble walking, dizziness, loss of balance or coordination
- Sudden severe headache with no known cause

Other danger signs that may occur include double vision, drowsiness, and nausea or vomiting. Sometimes the warning signs may last only a few moments and then disappear. These brief episodes, known as transient ischemic attacks or TIAs, are sometimes called "mini-strokes." Although brief, they identify an underlying serious condition that isn't going away without medical help. Unfortunately, since they clear up, many people ignore them. Don't. Heeding them can save your life.

Risk Factors for a Stroke

A risk factor is a condition or behavior that occurs more frequently in those who have, or are at greater risk of getting, a disease than in those who do not. Having a risk factor for stroke does not mean one will have a stroke. On the other hand, not having a risk factor does not mean one will avoid a stroke. But the risk of stroke grows as the number and severity of risk factors increases.

Stroke occurs in all age groups, in both sexes, and in all races in every country. It can even occur before birth, when the fetus is still in the womb. In African-Americans, stroke is more common and more deadly — even in young and middle-aged adults — than for any ethnic or other racial group in the United States. Scientists have found more and more severe risk factors in some minority groups and continue to look for patterns of stroke in these groups.

Treatable Risk Factors

Some of the most important treatable risk factors for stroke are.

High Blood Pressure. Also called hypertension, this is by far the most potent risk factor for stroke. If your blood pressure is high, you and your doctor need to work out an individual strategy to bring it down to the normal range. Some ways that work: Maintain proper weight. Avoid drugs known to raise blood pressure. Cut down on salt. Eat fruits and vegetables to increase potassium in your diet. Exercise more. Your doctor may prescribe medicines that help lower blood pressure. Controlling blood pressure will also help you avoid heart disease, diabetes, and kidney failure. See also **Hypertension (High Blood Pressure)**.

Cigarette Smoking. Cigarette smoking has been linked to the buildup of fatty substances in the carotid artery, the main neck artery supplying blood to the brain. Blockage of this artery is the leading cause of stroke in Americans. Also, nicotine raises blood pressure; carbon monoxide reduces the amount of oxygen your blood can carry to the brain; and cigarette smoke makes your blood thicker and more likely to clot. Your doctor can recommend programs and medications that may help you quit smoking. By quitting, at any age, you also reduce your risk of lung disease, heart disease, and a number of cancers including lung cancer.

Heart Disease. Common heart disorders such as coronary artery disease, valve defects, irregular heart beat, and enlargement of one of the heart's chambers can result in blood clots that may break loose and block vessels in or leading to the brain. The most common blood vessel disease, caused by the buildup of fatty deposits in the arteries, is called atherosclerosis. Your doctor will treat your heart disease and may also prescribe medication, such as aspirin, to help prevent the formation of clots. Your doctor may recommend surgery to clean out a clogged neck artery if you match a particular risk profile. If you are over 50, NINDS scientists believe you and your doctor should make a decision about aspirin therapy. A doctor can evaluate your risk factors and help you decide if you will benefit from aspirin or other blood-thinning therapy. See also **Heart and Circulatory System (Physiology)**.

Diabetes. You may think this disorder affects only the body's ability to use sugar, or glucose. But it also causes destructive changes in the blood vessels throughout the body, including the brain. Also, if blood glucose levels are high at the time of a stroke, then brain damage is usually more severe and extensive than when blood glucose is well-controlled. Treating diabetes can delay the onset of complications that increase the risk of stroke. See also **Diabetes Mellitus**.

Stroke Rehabilitation

Stroke is the third leading cause of death and the leading cause of long-term disability in the U.S. There are approximately 4 million Americans living with the effects of stroke. In addition, there are millions of husbands, wives, children and friends who care for stroke survivors and whose own lives are personally affected.

According to the National Stroke Association:

- 10% of stroke survivors recover almost completely
- 25% recover with minor impairments
- 40% experience moderate to severe impairments that require special care
- 10% require care in a nursing home or other long-term facility
- 15% die shortly after the stroke
- Approximately 14% of stroke survivors experience a second stroke in the first year following a stroke.

Successful rehabilitation depends on:

- Amount of damage to the brain
- Skill on the part of the rehabilitation team
- Cooperation of family and friends. Caring family/friends can be one of the most important factors in rehabilitation
- Timing of rehabilitation — the earlier it begins the more likely survivors are to regain lost abilities and skills

The goal of rehabilitation is to enable an individual who has experienced a stroke to reach the highest possible level of independence and be as productive as possible. Because stroke survivors often have complex rehabilitation needs, progress and recovery are unique for each person. Although a majority of functional abilities may be restored soon after a stroke, recovery is an ongoing process.

Effects of a Stroke. (1) Weakness (hemiparesis) or paralysis (hemiplegia) on one side of the body that may affect the whole side or just the arm or leg. The weakness or paralysis is on the side of the body opposite the side of the brain affected by the stroke. (2) Spasticity, stiffness in muscles, painful muscle spasms. (3) Problems with balance and/or coordination. (4) Problems using language, including having difficulty understanding speech or writing (aphasia); and knowing the right words but having trouble saying them clearly (dysarthria). (5) Being unaware of or ignoring sensations on one side of the body (bodily neglect or inattention). (6) Pain, numbness or odd sensations. (7) Problems with memory, thinking, attention or learning. (8) Being unaware of the effects of a stroke. (9) Trouble swallowing (dysphagia). (10) Problems with bowel or bladder control. (11) Fatigue. (12) Difficulty controlling emotions (emotional lability). (13) Depression, and (14) Difficulties with daily tasks.

Types of Rehabilitation Programs. (1) Hospital programs: in an acute care facility or a rehabilitation hospital. (2) Long-term care facility with therapy and skilled nursing care. (3) Outpatient programs, and (4) Home-based programs.

STROMATOLITE. A term that has been generally applied to variously shaped (often domal), laminated, calcareous sedimentary structures formed in a shallow-water environment under the influence of a mat or assemblage of sediment-binding blue-green algae that trap fine (silty) detritus and precipitate calcium carbonate and that commonly develop colonies or irregular accumulations of a constant shape, but with little or no microstructure. It has a variety of gross forms, from near-horizontal to markedly convex, columnar, and subspherical. Stromatolites were originally considered animal fossils, and although they are still regarded as fossils because they are the products of organic growth, they are not fossils of any specific organism, but rather consist of associations of different genera and species of organisms that can no longer be recognized and named or that are without organic structures. An excellent treatise on stromatolites is *Stromatolites* (M.R. Walter, editor), Elsevier, New York, 1976.

STROMATOLITH. A term proposed by Foye, in 1916, for banded gneisses composed of alternate layers of igneous and metamorphic (schistose) rocks.

STRONTIANITE. The mineral strontianite is strontium carbonate, [CAS: 1633-05-2], $SrCO_3$, usually occurring in whitish-yellow or whitish-green masses of radiated acicular crystals, or in fibrous or granular form. When distinctly crystallized it is obviously orthorhombic, but such crystals are rare. It has a nearly perfect prismatic cleavage; uneven fracture; brittle; hardness, 3.5; specific gravity, 3.785; luster, vitreous; color, as above, also green, gray and colorless; streak, white; transparent to translucent. Strontianite occurs in veins, chiefly in limestones, occasionally in the crystalline rocks, and it is usually associated with calcite and celestite. It is found in the metalliferous veins in the Harz Mountains and Saxony. It is commercially important in Westphalia where it is mined for use in the beet sugar industry. In the United States, crystalline masses and gorges of strontianite are found in Schoharie County, New York, long a famous locality for this mineral.

STRONTIUM. [CAS: 7440-24-6], Chemical element, symbol Sr, at. no. 38, at. wt. 87.62, periodic table group 2, mp 769 °C (1,416 °F), bp 1,384 °C (2,523 °F), density 2.54 g/cm^3 (20 °C (68 °F). Below 215 °C (419 °F), elemental strontium has a face-centered cubic crystal structure; between 215–605 °C (419–1,121 °F), a hexagonal close-packed crystal structure; and above 605 °C (1,121 °F), a body-centered cubic crystal structure.

Strontium is a silver-white metal, soft as lead, malleable, ductile, oxidizes rapidly on exposure to air, burns when heated in air emitting a brilliant light and forming oxide and nitride, reacts with water [CAS: 7732-18-5] H_2O yielding strontium hydroxide [CAS: 18480-07-4] H_2O_2Sr and hydrogen gas. Discovered by the Scottish chemist and physician Thomas Charles in 1793, and isolated by English chemist Humphry Davy in 1808. See also **Chemical Elements: The History of the Origin**.

There are four stable isotopes, ^{84}Sr and ^{86}Sr through ^{88}Sr, and seven known radioactive isotopes, ^{82}Sr, ^{83}Sr, ^{85}Sr, and ^{89}Sr through ^{92}Sr, all with relatively short half-lives measurable in hours or days except ^{90}Sr which has a half-life of about 26 years. The latter isotope represents a hazard from nuclear blasting activities because of its long half-life, tendency to contaminate food products, such as milk, and retention in the body. See also **Radioactivity**. In terms of abundance, strontium is 21st among the elements occurring in the rocks of the earth's crust. In terms of the content of sea water, the element ranks 11th, with an estimated 38,000 tons of strontium per cubic mile (9120 tons/cubic kilometer) of seawater. First ionization potential 5.692 eV; second, 10.98 eV. Oxidation potentials $Sr \rightarrow Sr^{2+} + 2e^-$, 2.89 V; $Sr + 2OH^- + 8H_2O \rightarrow Sr(OH)_2 \cdot 8H_2O + 2e^-$, 2.99 V. Other important physical properties of strontium are given under **Chemical Elements**.

Occurrence and Characteristics. Strontium occurs chiefly as sulfate (celestite, [CAS: 7759-02-6] $SrSO_4$) and carbonate (strontianite, [CAS: 1633-05-2] $SrCO_3$) although widely distributed in small concentration. The commercially exploited deposits are mainly in England. The sulfate or carbonate is transformed into chloride, and the electrolysis of the fused chloride yields strontium metal.

As is to be expected from its high oxidation potential (2.89 V) strontium, like calcium [7440-70-2] and barium [CAS: 7440-39-2], reacts readily with all halogens, oxygen and sulfur to form halides, oxide and sulfide. See also **Celestite**; and **Strontianite**. In all its compounds it is divalent. It reacts vigorously with H_2O to form the hydroxide, displacing hydrogen and it forms a hydride with hydrogen. Strontium hydroxide [CAS: 18480-07-4] SrH_2O_2, forms a peroxide on treatment with H_2O_2 [CAS: 7722084-1] in the cold. Strontium exhibits little tendency to form complexes; the ammines formed with NH_3 are unstable, the β-diketones and alcoholates are not well characterized, and the chelates formed with ethylenediamine and related compounds are the only representatives of the type. Common compounds of strontium are the following:

Chemistry and Compounds

Strontium acetate, [CAS: 543-94-2], $Sr(C_2H_3O_2)_2$, white crystals, soluble, formed by reaction of strontium carbonate or hydroxide and acetic acid.

Strontium carbide (acetylide), SrC_2, black solid, formed by reaction of strontium oxide and carbon at electric furnace temperature; the carbide reacts with water yielding acetylene gas and strontium hydroxide.

Strontium carbonate, [CAS: 1633-05-2], $SrCO_3$, white solid, insoluble ($K_{sp} = 9.4 \times 10^{-10}$), formed (1) by reaction of strontium salt solution and sodium carbonate or bicarbonate solution, (2) by reaction of strontium hydroxide solution and CO_2. Strontium carbonate decomposes at 1,200 °C (2,192 °F) to form strontium oxide and CO_2, and is dissolved by excess CO_2, forming strontium bicarbonate, $Sr(HCO_3)_2$, solution.

Strontium chloride, [CAS: 10476-85-4], $SrCl_2$ is a salt of strontium and chlorine. It is ionic and water-soluble. It is less toxic than barium chloride [CAS: 10361-37-2] $BaCl_2$, though more toxic than calcium chloride [CAS: 10043-52-4] $CaCl_2$. It emits a bright red color when heated in a flame. Strontium chloride can be prepared from strontium hydroxide or strontium carbonate reacting with hydrochloric acid. It can also be prepared by the union of the elements, strontium and chlorine.

There are no major uses for strontium chloride, though it can be used to prepare less common compounds of strontium, and may be useful in reducing gum sensitivity, and is known as Elecol for this purpose. Certain toothpastes such as Sensodyne are called "strontium chloride toothpastes," although most now use potassium nitrate instead (with the exception of Sensodyne original). Like barium chloride it can be used to test for sulfate ion, though not at such low concentration, since strontium sulfate is more soluble than barium sulfate. Strontium chloride is occasionally used as a flame coloring agent (red) in pyrotechnics, and in small quantities in glass making and metallurgy. It is added to some toothpastes to reduce periodontal disease, and is used in homeopathic medicine under the name of *strontium chlorii*.

Strontium chromate, [CAS: 7789-06-2], $SrCrO_4$, yellow precipitate ($K_{sp} = 3.75 \times 10^{-5}$) formed by reaction of strontium salt solution and potassium chromate solution.

Strontium cyanamide, $SrCN_2$, formed with the cyanide, $Sr(CN)_2$, by heating strontium carbide at 1,200 °C (2,192 °F) with nitrogen.

Strontium fluoride, [CAS: 7783-48-4], SrF_2, also called *strontium difluoride* and *strontium(II) fluoride*, is a fluoride of strontium. It is a stable brittle white crystalline solid, mp. 1,477 °C (2,691 °F) and bp 2,460 °C (4,460 °F). It forms face-centered cubic crystals, with structure of calcium fluoride. It is almost insoluble in water. Strontium fluoride is prepared by reaction of strontium chloride with fluorine gas, by action of hydrofluoric acid on strontium carbonate, or by addition of potassium chloride to strontium chloride solution. It irritates eyes and skin, and is harmful when inhaled or ingested.

Strontium fluoride is used as an optical material transparent from vacuum ultraviolet (150 nm) to infrared (11 μm) for a small range of special applications. Its optical properties are intermediate to calcium fluoride and barium fluoride. It is also used as an optical coating on lenses.

Strontium hydride, SrH_2, white solid, formed by heating strontium metal or amalgam in hydrogen gas at 250 °C [482 °F). Is reactive with H_2O, yielding strontium hydroxide and hydrogen gas.

Strontium nitrate, [CAS: 10042-76-9], $Sr(NO_3)_2$, white crystals, soluble, formed by reaction of strontium carbonate or hydroxide and HNO_3.

Strontium oxide or strontia, [CAS: 1314-11-0], SrO, white solid, mp about 2,400 °C (4,352 °F), reactive with H_2O to form strontium hydroxide ($K_{sp} = 3.2 \times 10^{-4}$); strontium peroxide, $SrO_2 \cdot 8H_2O$, white precipitate, by reaction of strontium salt solution and hydrogen or sodium peroxide, yields anhydrous strontium peroxide SrO_2, upon heating at 130 °C (266 °F) in a current of dry air. It also forms from the decomposition of strontium carbonate $SrCO_3$. It is a strongly basic oxide. Strontium oxide is used as a flux in the making of glass for television tubes in place of barium oxide [CAS: 1304-28-5] BaO.

Strontium oxalate, [CAS: 814-95-9], SrC_2O_4, white precipitate ($K_{sp} = 5.6 \times 10^{-8}$) formed by reaction of strontium salt solution and ammonium oxalate solution.

Strontium sulfate, [CAS: 7759-02-6], $SrSO_4$, white precipitate ($K_{sp} = 3.2 \times 10^{-7}$), formed by reaction of strontium salt solution and H_2SO_4 or sodium sulfate solution, insoluble in acids. On heating with carbon strontium sulfate yields strontium sulfide, SrS, while on boiling with sodium carbonate solution, $SrSO_4$ yields strontium carbonate.

Strontium sulfide, SrS, [CAS: 1314-96-1], grayish-white solid (thermodynamic K_{sp} 500) reactive with water to form strontium hydrosulfide, $Sr(SH)_2$, solution. Strontium hydrosulfide is formed (1) by reaction of strontium sulfide and H_2O, (2) by saturation of strontium hydroxide solution with H_2S. Strontium polysulfides are formed by boiling strontium hydrosulfide with sulfur.

Health and Safety. Strontium compounds that are water-insoluble can become water-soluble, as a result of chemical reactions. The water-soluble compounds are a greater threat to human health than the water-insoluble ones. Therefore, water-soluble forms of strontium have the opportunity to pollute drinking water.

People can be exposed to small levels of (radioactive) strontium by breathing air or dust, eating food, drinking water, or by contact with soil that contains strontium. Strontium concentrations in food contribute to the strontium concentrations in the human body. Foodstuffs that contain significantly high concentrations of strontium are grains, leafy vegetables and dairy products.

For most people, strontium uptake will be moderate. The only strontium compound that is considered a danger to human health, even in small quantities, is strontium chromate. The toxic chromium that it contains mainly causes this. Strontium chromate is known to cause lung cancer, but the risks of exposure have been greatly reduced by safety procedures in companies, so that it is no longer an important health risk.

The uptake of high strontium concentrations is generally not known to be a great danger to human health. In one case someone experienced an allergic reaction to strontium, but there have been no similar cases since. For children exceeded strontium uptake may be a health risk, because it can cause problems with bone growth.

Strontium salts are not known to cause skin rashes or other skin problems of any kind. When strontium uptake is extremely high, it can cause disruption of bone development. But this effect can only occur when strontium uptake is in the thousands of ppm range. Strontium levels in food and drinking water are not high enough to be able to cause these effects.

Radioactive strontium is much more of a health risk than stable strontium. When the uptake is very high, it may cause anaemia and oxygen shortages, and at extremely high concentrations it is even known to cause cancer as a result of damage to the genetic materials in cells.

Effects on the Environment. Strontium in its elemental form occurs naturally in many compartments of the environment, including rocks, soil, water, and air. Strontium compounds can move through the environment fairly easily, because many of the compounds are water-soluble.

Strontium is always present in air as dust, up to a certain level. Strontium concentrations in air are increased by human activities, such as coal and oil combustion. Dust particles that contain strontium will settle to surface water, soils or plant surfaces at some point. When the particles do not settle they will fall back onto earth when rain or snow falls. All strontium will eventually end up in soils or bottoms of surface waters, where they mix with strontium that is already present. Strontium can end up in water through soils and through weathering of rocks. Only a small part of the strontium in water comes from dust particles from the air. Most of the strontium in water is dissolved, but some of it is suspended, causing muddy water at some locations. Not much strontium ends up in drinking water. When strontium concentrations in water exceed regular concentrations, this is usually caused by human activities, mainly by dumping waste directly in the water. Exceeded strontium concentrations can also be caused by settling of dust particles from air that have reacted with strontium particles from industrial processes.

Strontium concentrations in soil may also be increased by human activities, such as the disposal of coal ash and incinerator ash, and industrial wastes. Strontium in soil dissolves in water, so that it is likely to move deeper into the ground and enter the groundwater. A part of the strontium that is introduced by humans will not move into groundwater and can stay within the soil for decades. Because of the nature of strontium, some of it can end up in fish, vegetables, livestock and other animals.

One of the isotopes of strontium is radioactive. This isotope is not likely to occur naturally in the environment. It ends up in the environment, though, as a result of human activities, such as nuclear bomb testing and radioactive storage leaking. The only way to decrease concentrations of this isotope is through radioactive decay to stable zirconium.

Certain deep-sea creatures incorporate strontium into their shells as strontium sulphate, and stony corals require it, which is why it needs to be added in the water in aquaria.

> **Editor's Note re Strontium Isotope Research.** At any given time, the Sr isotope composition in seawater is uniform throughout the ocean because the oceanic residence time of Sr (5 million years) exceeds the mixing time of the oceans (~1000 years). However, over geologic time, the $^{87}Sr/^{86}Sr$ ratio in seawater has varied as the result of fluxes of Sr to the oceans from various sources. These would include submarine hydrothermal activity, fluxes from rivers, and submarine recycling, the latter occurring by limestone recrystallization and erosion of ancient sedimentary carbonate. J. Hess and colleagues (University of Rhode Island) reported in 1986 that the seawater Sr isotope composition appears to be a smoothly varying function of time and can be useful for high-precision correlations of oceanic sediments for certain periods of time. These researchers prepared a detailed record of the Sr isotope ratio during the last 100 million years by measuring this ratio in well over a hundred foraminifera samples. Sample preservation was evaluated from scanning electron microscopy studies, measured Sr/Ca ratios, and pore water Sr isotope ratios. Results show that the marine Sr isotope composition can be used for correlating and dating well-preserved authigenic marine sediments throughout much of the Cenozoic to a precision of ±1 mil years. See also **Condrite**.

In 1990, R.C. Capo and D.J. DePaolo (University of California, Los Angeles and Berkeley, respectively) reported that "marine carbonate samples indicate that during the past 2.5 million years the $^{87}Sr/^{86}Sr$ ratio of seawater has increased by 14×10^{-7}. The high average rate of increase of this ratio indicates that continental weathering rates were exceptionally high. Nonuniformity in the rate of increase suggests that weathering rates fluctuated by as much as ±30 percent of present-day values. Some of the observed shifts in weathering rate are contemporaneous with climatic changes inferred from records of oxygen isotopes and carbonate preservation in deep sea sediments."

Studies of Metamorphism. As reported by J.N. Christensen, J.L. Rosenfield, and D.J. DePaolo (University of California, Berkeley), "Measurement of the radial variation of the $^{87}Sr/^{86}Sr$ ratio in a single crystal from a metamorphic rock can be used to determine the crystal's growth rate. Such variation records the accumulation of ^{87}Sr from radioactive decay of ^{87}Rb (rubidium) in the rock matrix from which the crystal grew. This method can be used to study the rates of petrological processes associated with mountain building." This methodology has been applied by the researchers mentioned to the study of the rates of tectonometamorphic processes from rubidium and strontium isotopes in garnet."

Isotopic Tests for Upwelling Water. In studies of the Yucca Mountain, Nevada, area as a potential site for a high-level nuclear waste repository, the area has been aggressively scrutinized geologically for possible upwelling of deep-seated waters. Strontium and uranium isotopic compositions of hydrogenic materials were used by scientists J.S. Stuckless, Z.E. Peterman, and D.R. Muhs (U.S. Geological Survey, Denver, Colorado) to assist in confirming other geological methods. Their findings indicated in 1991 that the vein deposits are isotopically distinct from groundwater in the two aquifers that underline Yucca Mountain, thus indicating that the calcite could not have precipitated from groundwater and thus providing evidence against upwelling water at the site.

STRUCTURAL GENOMICS. With the completion of the sequencing of the genomes of human and numerous other organisms, scientific interest has focused on the large-scale characterization and functional determination of proteins, the products of genes. Structural genomics is at the forefront of these new undertakings. The value of three-dimensional protein structures and the increasing capability of scientists to solve them have prompted scientific groups from many countries to undertake projects in this emerging field. Efforts center on the development of technology and automated instruments to lower costs and increase efficiencies and success rates, ultimately turning the process of protein structure determination into a high-throughput operation.

Discussions at national and international levels have focused on coordination of these efforts, and on agreements on policies related to data release, publications, target selection and other issues related to large-scale, discovery-driven projects. The goals and policies for this field have been discussed at several international scientific meetings. Following the second meeting of the International Structural Genomics Organization (ISGO) the "Agreed Principles and Procedures" was published (Agreed Principles and Procedures, 2001) http://www.nigms.nih.gov/news/meetings/airlie.html. A major objective of the field is to make the structures widely available for clinical and basic studies that expand the knowledge of the roles of proteins both in normal biological processes and in diseases.

Definition of the Field and Goals

Structure Illuminates Function. While a protein's genetic sequence can provide clues about its function, its three-dimensional structure can be far more illuminating and can reveal its role in normal and disease processes (Fig. 1). A high-resolution structure maps all of a protein's

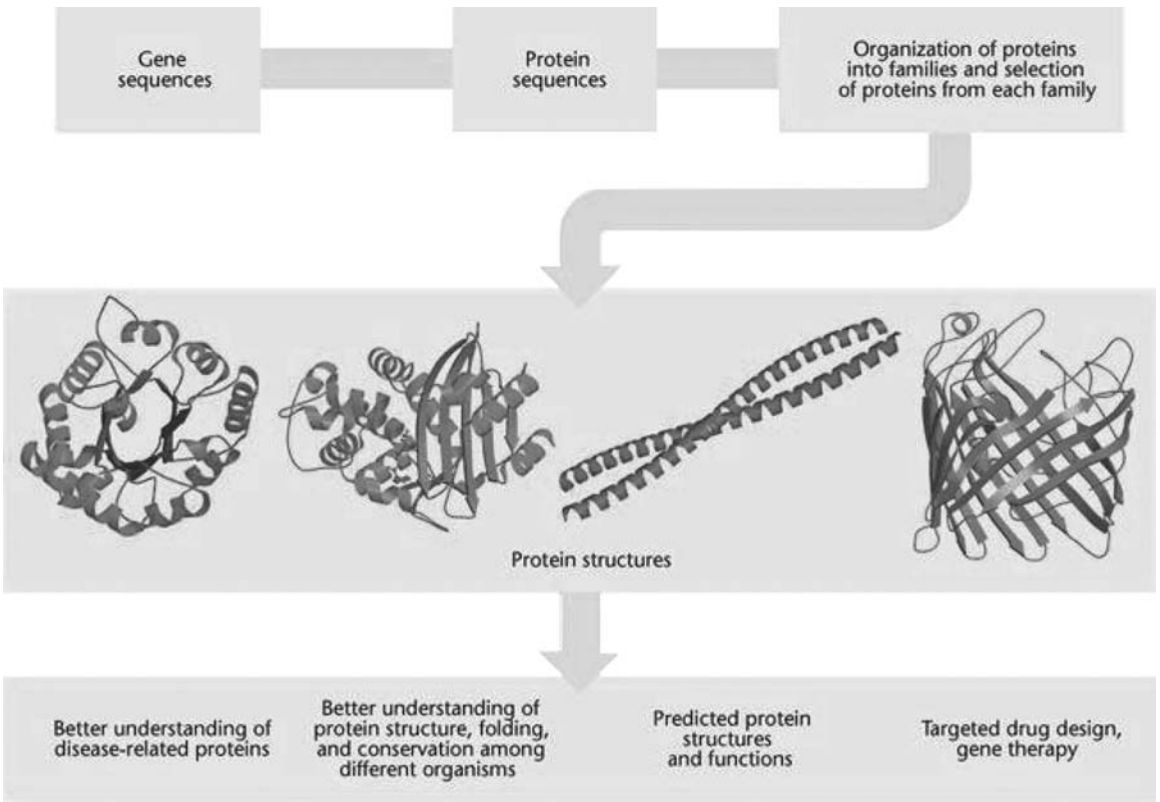

Fig. 1. Structural genomics makes use of genetic information to obtain a broad inventory of three-dimensional protein structures. This will improve our understanding of basic biological processes and lead to medical advances.

atoms, exposes surface topology and inner architecture and presents a testing ground for possible molecular partners. In particular, the structure can serve as a guide for targeted drug design, as it did in the development of protease inhibitor drugs to combat human immunodeficiency virus (HIV). The pain relievers *Vioxx* and *Celebrex*, both of which are inhibitors of cyclooxygenase-2 (COX2), were also developed using structure-based methods.

More than 20,000 protein structures have been deposited into the Protein Data Bank, a worldwide repository of three-dimensional biological molecular structures. However, most of these are redundant, representing small variations of other known structures. Such variations in a protein's structure can be enormously helpful in illuminating a protein's function and have provided invaluable information for drug design. But it is clear that a broad, discovery-based, large-scale effort is necessary to explore the many different protein structures in nature.

Structural genomics represents a radical departure from the way scientists have approached protein structure determination in the past. Rather than focusing on solving the structures of proteins that are well characterized, structural genomics takes a broader approach and is driven by the value of collections of structures as well as by the advances that come with knowledge of individual protein structures.

As defined in the goals statement of the ISGO, "such a complete knowledge will facilitate fundamental understanding and applications in biology, agriculture and medicine. The three-dimensional structures will be crucial for rational drug design, for advancing catalysis in chemistry and biotechnology and for diagnosis and treatment of diseases as well as advancing basic principles of biology." The ISGO statement also highlights a major objective of this field: "to obtain a base of freely available structural information and tools that will support advances in wide areas of biology and medicine." An excellent and comprehensive review of structural genomics (with 20 separate articles) was published in 2000 (*Structural Genomics*, November 2000).

Protein Classification Facilitates the Task. Using traditional techniques, determining a protein's three-dimensional structure can be difficult, costly and time consuming. The essential tools of high-resolution structural biology are X-ray crystallography and nuclear magnetic resonance (NMR) imaging. Both have their drawbacks — the former requires the crystallization of proteins, a laborious task, and the latter is usually slower and is limited to small- and medium-sized proteins. In contrast, structural genomics takes a highly automated, assembly line approach. The goal is to determine thousands of carefully selected structures experimentally, and to use these to model the structures of most other proteins found in nature.

Many proteins fold into globular shapes that resemble other proteins. Proteins can be classified into families of similar sequence, and proteins that share sequence homology will typically share structural features. This observation is crucial to the structural genomics approach, as the experimentally determined structure of a family representative is used to generate structural models of most other members. The accuracy of these models depends upon the degree of similarity, or sequence identity, between family members. More details on the classification of protein structures and families can be found in several review articles [Pennisi, 1998].

Proteins may also be classified according to what is called their *fold*. Proteins with the same *fold* will have the same overall shape and the same types of structural components connected in the same order, but may have significant differences in structural detail and in amino acid sequence. As structure is more conserved than sequence, proteins that vary significantly in their amino acid sequence may adopt similar structures. Therefore, the number of protein folds is expected to be far smaller than the number of protein families defined by sequence similarity. The results of structural genomics are expected to improve our understanding of protein fold and family classification, as well as our understanding of structure prediction methods and how proteins evolve.

Structural Genomics Projects Worldwide. Currently there are structural genomics projects in many countries, including the United States, Canada, the European Union, Japan, China and Israel. All of these ventures aim for large collections of protein structures, but there are somewhat different goals in various countries and in different scientific sectors. Some projects determine a large set of structures from a particular protein class or a particular pathway in order to expand the knowledge of biologically important processes. Others focus on disease-causing organisms or classes of proteins such as cancer-related proteins or human proteins. A structural genomics consortium that is part of the Protein Structure Initiative (PSI) of the National Institute of General Medical Sciences focuses on two bacterial species with extremely small genomes in order to better understand the proteins necessary for independent life. Another aims at protein families that span the kingdoms of life, which will give a broad view of the function and evolution of proteins in different organisms. Other projects determine an extensive selection of protein structures in order to study protein folding or to produce improved algorithms for structural prediction. In the private sector, several biotechnology companies have adopted the structural genomics approach for drug discovery.

Elements of Structural Genomics. Although structural genomics projects vary considerably, there are several common elements:

1. *Family Classification and Target Selection*: There are several schemes of protein sequence clustering for parsing proteins into families and choosing targets for structural determination.
2. *Generation of Proteins*: This requires cloning, expressing and purifying proteins. This task starts with a deoxyribonucleic acid (DNA) sequence and results in a purified protein solution.
3. *Sample Preparation for Structural Studies*: This involves protein crystallization for X-ray crystallography or protein labeling for NMR spectroscopy.
4. *Structure Determination*: High-resolution structures are obtained from X-ray diffraction data or NMR spectroscopy. Many new methods and instruments are utilized to permit high-throughput operation. The advent of synchrotrons and high-field magnets has been essential.
5. *Data and Laboratory Management Systems*: Although often underestimated, these are crucial components of the high-throughput aspect of structural genomics.
6. *Analysis and Dissemination of Results*: Structural genomics results are generally made available to the public in a timely manner.

The Achievements of Structural Genomics

Construction of the High-Throughput Pipeline. The primary focus of structural genomics in the years since its inception has been the development of the methodology and technology necessary for a production-line approach to protein structure determination. Recent technological developments have made the multiple steps of the process amenable to large-scale operation. However, further advances will be necessary to lower costs, increase success and output and automate all of the tasks of the structural genomics pipeline.

Software and Hardware Advances Have Been Made. A combination of software and hardware developments has contributed to the construction of high-throughput structural genomics pipelines. Target selection, the very first step in structural genomics, is now done with software that automatically clusters proteins into families, screens for proteins unlikely to crystallize (such as those with high numbers of repeats or transmembrane domains), classifies proteins according to possible function, prioritizes targets according to the size of the family they represent and finally, checks the Protein Data Bank to determine if the potential target's structure has been previously deposited. These software algorithms have significantly improved the success rates of structural genomics projects, increasing the number of targets that ultimately yield novel protein structures.

Another development has been the advent of data management software, which is now used to track the progress of targets throughout the process of structure determination — from target selection to data analysis and modeling the structure. This has enabled scientists to manage many targets simultaneously as they make their way through the pipeline and to collect information and map trends on the multiple variables of the process so as to further enhance the success rate. The final step in protein structure determination has also been facilitated by software developments. New algorithms now automate the many computer steps that convert X-ray diffraction data into a three-dimensional protein model. These kinds of programs have cut the data analysis time from days to hours.

Hardware developments have also made remarkable contributions to the development of the large-scale pipeline. Robotics are now used in the cloning and purification steps, and are used to test hundreds of

combinations of crystallization conditions. Robots also position each test crystal in the X-ray beam line, automating a process that previously occupied large amounts of valuable beam time.

Structures Solved. At this point, large-scale gene cloning and protein expression have been achieved at a number of structural genomics centers, with thousands of proteins having been cloned. Protein production and crystallization are carried out on a scale not seen previously. The cost of protein structure determination has also dropped significantly and the success rates for producing and determining the structures of proteins are increasing. As of June 2005, almost 1,100 protein structures have been deposited into the Protein Data Bank from the structural genomics projects of the PSI alone. Many of these structures represent novel structures and folds.

The Future

Future developments in this field should make the experimental determination of protein structures less expensive and more successful. As the collection of protein structures grows, attention will begin to focus on solving the structures of more challenging proteins such as membrane proteins, protein complexes and proteins from higher eukaryotes. The structural genomics results are expected to lead to a large collection of protein structures that will have a major impact on a wide range of biomedical research problems.

Note: This is a US Government work and is in the public domain in the United States of America.

STRUCTURAL GEOLOGY. That branch of geology which deals with the form, arrangement, and internal structure of the rocks, and especially with the description, representation, and analysis of structures, chiefly on a moderate to small scale. The subject is similar to tectonics, but the latter is generally used for the broader regional or historical phases. Structural petrology is the study of the internal structure or fabric of a rock, commonly with the aim of clarifying the rock's deformational history. (*American Geological Institute*.)

STRUT. A structural member subjected to compression. Its conditions of loading and analysis are the same as for a column. If there is any difference between strut and column, it rests on the following points. A column is usually thought of as being a fairly large compression member, vertical in position. Small columns are frequently called struts; also, struts are compression members which are incorporated into structures in many positions besides the vertical.

STUDENT NITRIC OXIDE EXPLORER (SNOE) MISSION. See **Space Science Missions: Sun**.

STUFFING BOX. A device for preventing leakage or transfer of fluid between moving parts, usually consisting of a relatively soft packing compressed or confined by an adjustable member called a gland. Stuffing box packings differ from gaskets in that they are used in confined spaces, and do not of themselves withstand stresses due to fluid pressure. In the usual form, the stuffing box consists of a hollow cylinder surrounding the moving (reciprocating or rotating rod or shaft) member; the space between the hole and the rod or shaft is filled with packing compressed by the gland. Packings may consist of relatively plastic material, bonding such substances as cotton fabric, rope, or asbestos, but packings of rubber, leather, pressed graphite, or molded plastics are also used.

In high-speed machinery, such as turbines and rotary compressors, where no adequate cooling is available, and in high-pressure equipment where small clearances are required, and for which packings are inadequate, devices known as labyrinths may be used. A labyrinth consists of a series of projections on the rotating element, running in close contact with grooves on the stationary element. To enable a labyrinth to function as a seal, there must be some fluid flow; the fluid first passes a restriction and then expands into a chamber, which consumes a certain amount of energy. After a series of such expansions, a considerable pressure drop will exist between the initial and terminal points of the labyrinth. In order to render the device operative, there must always be some leakage at the terminal point. The effective operation of a labyrinth is less marked for liquids than for vapors.

STURGEONS *(Osteichthyes)*. Of the order *Chondrostei*, family *Acipenseridae*, sturgeons are fishes of moderate to large size, found in the oceans and fresh waters of the Northern Hemisphere. Their chief external characteristic is the series of bony plates arranged in rows along the back and sides, separated by wide spaces containing only small hard elements. See Fig. 1. The sturgeons are considered excellent food fishes and are the source of caviar. There are about fifteen European species and nine North American species.

Fig. 1. Sturgeon.

Sturgeons have poor vision, but this is partly compensated by fleshy whiskers, which trail in the sand and assist in locating food at the bottom. Rare among the fishes, the sturgeons have taste buds external of the mouth. It is believed that these also assist in locating a food supply. Also quite rare among fishes is the fact that sturgeons eat quite slowly. The diet includes crawfish, insect larvae, snails and some small fish.

The largest of the sturgeons is the *Huso huso* (giant beluga) found in the Black and Caspian seas and the Volga River. Records indicate the largest of these to weigh 2860 pounds (1297 kilograms) with a length of 28 feet (8.4 meters). The age was unknown. A 75-year old sturgeon was weighed at 2200 pounds (998 kilograms) length 13 feet (3.9 meters). The Eurasian species frequently weigh in excess of a half-ton. The marine sturgeon *Acipenser sturo* is found in the temperate waters of the Atlantic, usually weighs about 500 pounds (227 kilograms) as an adult and attains a length of about 10 feet (3 meters). Marine sturgeons also prefer the muddy bottom and diet on shrimp, clams, worms, crustaceans, and small fishes.

The largest of American fresh water fishes is the *Acipenser transmontanus* (Pacific coast white sturgeon). They usually weigh about 300 pounds (136 kilograms) but records indicate weights up to 1300 pounds (590 kilograms) and more. The *Acipenser medirostris* is also a sturgeon of the American Pacific and averages about 350 pounds (159 kilograms) length of about 7 feet (2.1 meters).

Sturgeons are probably best known for the caviar processed from the roe. Caviar production is no longer limited to Eastern Europe, but has been undertaken in other areas, including the United States. In the interest of conservation, eggs can be stripped from the living fish (somewhat similar to practices in trout hatcheries). Various means are used to free the eggs from the egg membranes. The eggs are then placed in a brine which extracts the liquid from the eggs. After draining the brine, the eggs can be packed and sold commercially.

STURTEVANT, ALFRED HENRY (1891–1970). Sturtevant was an American naturalist and geneticist who invented the idea of the genetic map.

The youngest of six children, Sturtevant was brought up on his father's farm in Alabama. As an undergraduate at Columbia University, he read a book on Mendelism and saw how the pedigrees of his father's horses could be used to analyze the inheritance of coat color. He submitted a paper to Thomas Hunt Morgan, whose course he had attended, and was given a desk in Morgan's laboratory. This was in 1910, a few months after the discovery of the white-eyed mutant in *Drosophila*. In the following year he realized that the numerical data from breeding experiments could be used to calculate the linear sequence of genes along the chromosome. 'I went home, and spent most of the night (to the neglect of my undergraduate homework) in producing the first chromosome map' (*A History of Genetics*, 1965). This insight was crucial to the development of genetics as an experimental science. See also **Morgan, Thomas Hunt (1866–1945)**.

After this prodigious start, Sturtevant remained with Morgan for the rest of his career, from 1915 to 1928 as a research investigator funded by the Carnegie Institution of Washington and from 1928 onwards as Professor of Genetics in the new Division of Biology at the California Institute of Technology. In 1933 Morgan shared his Nobel Prize money with Sturtevant and C. B. Bridges. See also **Bridges, Calvin Blackman (1889–1938)**.

To practicing geneticists Sturtevant is perceived as the instigator of many of the later developments in the field. He delighted in solving the intellectual puzzles thrown up by apparent exceptions to the rule and, once analyzed, converted these genetic curiosities into powerful tools. For example, genetic mosaics led to the discovery of the first reparable gene defect and the technique of fate mapping; chromosomal inversions were used to explore the mechanics of meiosis (with George Beadle), and to construct evolutionary phylogenies (with Theodosius Dobzhansky), and the discovery of unequal crossing-over in the unstable *Bar* mutant provided the first demonstration of a position effect and revealed an important evolutionary mechanism. These findings helped to trigger the fields of biochemical genetics, developmental genetics, chromosome mechanics and evolutionary genetics, which grew out of work, started in the Morgan group. See also **Beadle, George Wells (1903–1989)**; **Dobzhansky, Theodosius (1900–1975)**; and **Genetics and Gene Science (Classical)**.

Sturtevant had an enduring interest in evolution. He began work on the comparative genetics of *Drosophila* species in 1914, combining this with a detailed study of their taxonomy and behavior. He also published on the taxonomy of other dipteran flies, the behavior of ants and the genetics of fowl, mice, snails, evening primroses (*Oenothera*) and iris.

STYE (Hordeolum). A stye is a lump or pimple on the edge of the eyelid caused by an infection or inflammation involving the hair follicles of the eyelashes. It most often occurs on the edge of the upper lid, but may also occur on the lower lid. An internal hordeolum is the same as a stye, but involves an internal eyelid gland located farther back on the eyelid. A stye can be painful and affect the entire eyelid.

A chalazion is similar in appearance to a stye and is caused by the blockage of one or more of the small oil-producing glands in the eyelid. The secretions within the gland harden and form a bump. A chalazion is usually painless unless it becomes infected. Styes and chalazions are quite common and easily treated.

Eyelids contain many mucus-producing glands called *Meibomian glands*, and when one of these glands becomes plugged, blocked, or infected, a stye forms. Styes are usually caused by a bacterial infection, often the staphylococcus germ, and are common among children, those with chronic eyelid infections, diabetics, and sometimes patients with poor hygiene. Styes are unrelated to any disease and are usually not harmful to the eye or vision if properly treated.

When a stye is in its early stages, the site looks red and swollen, and there is tenderness or pain on the edge of the top or bottom eyelid. Light sensitivity as well as increased tear production may be experienced. Sometimes, an abscess forms.

The best treatment for a stye is to apply hot, moist compresses to the eyelid on a frequent basis. This relieves pain and inflammation and helps speed up the formation of a white-head. Once the stye comes to a head, it should drain on its own. However, if it does not empty on its own, surgical draining may be required. The head of the stye is usually on the outside, but it can occur on the underside of the lid. Antibiotic ointment or cortisone drops may be prescribed to keep down the bacteria count of the eyelid. If the tissues surrounding the stye appear swollen and infected, oral antibiotics may also be prescribed.

Although styes are infectious, they are not contagious. It is important not to spread the infection and to practice careful personal hygiene. Do not share washcloths, hand towels and avoid close personal contact during the acute phase of the disease. If styes occur frequently, it is necessary to see eye doctor for an examination.

Vision Rx, Inc., Elmsford, NY

STYLET. Small sharp structures used for piercing. The term applies to the calcareous spines of the proboscis of some nemertine worms and to the slender piercing organs of some insect mouths. The latter are modified mandibles and maxillae.

STYLOLITE. A columnal-like structure, at right angles, or highly inclined to the bedding planes of certain limestones, believed to be produced by differential vertical movements induced under great pressure. The term is derived from the Greek words meaning column and a stone.

STYRENE. [CAS: 100-42-5], (phenylethene, vinylbenzene, phenylethylene, styrol, cinnamene), $C_6H_5CH{=}CH_2$, is the simplest and by far the most important member of a series of aromatic monomers. Also known commercially as styrene monomer (SM), styrene is produced in large quantities for polymerization. It is a versatile monomer extensively used for the manufacture of plastics, including crystalline polystyrene, rubber-modified impact polystyrene, expandable polystyrene, acrylonitrile–butadiene–styrene copolymer (ABS), styrene–acrylonitrile resins (SAN), styrene–butadiene latex, styrene–butadiene rubber (SBR), and unsaturated polyester resins. See also **Acrylonitrile Polymers**.

Properties. Styrene is a colorless liquid with an aromatic odor. Important physical properties of styrene are shown in Table 1. Styrene is infinitely soluble in acetone, carbon tetrachloride, benzene, ether, *n*-heptane, and ethanol. Polymerization generally takes place by free-radical reactions initiated thermally or catalytically. Styrene undergoes many reactions of an unsaturated compound, such as addition, and of an aromatic compound, such as substitution. It reacts with various oxidizing agents to form styrene oxide, benzaldehyde, benzoic acid, and other oxygenated compounds. It reacts with benzene on an acidic catalyst to form diphenylethane. Further dehydrogenation of styrene to phenylacetylene

TABLE 1. PHYSICAL PROPERTIES OF STYRENE MONOMER

Property			Value

heat of polymerization, kJ/mol[b]			74.48		

[a] Density at 150 °C is 0.7900 g/cm^3.
[b] To convert J to cal, divide by 4.184.

is unfavorable even at the high temperature of 600 °C (1112 °F), but a concentration of about 50 ppm of phenylacetylene is usually seen in the commercial styrene product.

Ethylbenzene Manufacture. Styrene is manufactured from ethylbenzene. Ethylbenzene [CAS: 100-41-4] is produced by alkylation of benzene with ethylene, except for a very small fraction that is recovered from mixed C_8 aromatics by superfractionation. The reaction takes place on acidic catalysts and can be carried out either in the liquid or vapor phase.

Commercial ethylbenzene is manufactured almost exclusively for captive use to produce styrene. Most of the ethylbenzene plants built before 1980 are based on use of aluminum chloride catalysts. Aluminum chloride is an effective alkylation catalyst but is corrosive. The newer plants are based on zeolite catalysts.

Styrene Manufacture. Styrene manufacture by dehydrogenation of ethylbenzene is used for nearly 90% of the worldwide styrene production. The rest is obtained from the coproduction of propylene oxide (PO) and styrene (SM).

Dehydrogenation. The dehydrogenation of ethylbenzene to styrene takes

$$C_6H_5CH_2CH_3 \rightleftharpoons C_6H_5CH{=}CH_2 + H_2$$

place on a promoted iron oxide–potassium oxide catalyst in a fixed-bed reactor at the 550–680 °C (1022–1256 °F) temperature range in the presence of steam. The reaction is limited by thermodynamic equilibrium. Low pressure favors the forward reaction. Dehydrogenation is an endothermic reaction. High temperature favors dehydrogenation both kinetically and thermodynamically but also increases by-products from side reactions and decreases the styrene selectivity.

The main by-products in the dehydrogenation reactor are toluene and benzene. The formation of toluene accounts for the biggest yield loss. Other by-products include carbon dioxide and various hydrocarbons.

Dehydrogenation catalysts usually contain 40–90% Fe_2O_3, 5–30% K_2O, and promoters such as chromium, cerium, molybdenum, calcium, and magnesium oxides. Dehydrogenation is carried out either isothermally or adiabatically.

Other than the reactor system, the distillation column that separates the unconverted ethylbenzene from the crude styrene is the most important and expensive equipment in a styrene plant. To minimize yield losses and to prevent equipment fouling by polymer formation, polymerization inhibitors are used in the distillation train, product storage, and in vent gas compressors.

The qualities of the styrene product and toluene by-product depend primarily on three factors: the impurities in the ethylbenzene feed-stock, the catalyst used, and the design and operation of the dehydrogenation and distillation units. Other than benzene and toluene, the presence of which is usually inconsequential, possible impurities in ethylbenzene are C_7–C_{10} nonaromatics and C_8–C_{10} aromatics. The condensed reactor effluent is separated in the settling drum into vent gas (mostly hydrogen), process water, and organic phase. The organic phase with polymerization inhibitor added is pumped to the distillation train.

Benzene and toluene by-products are recovered in the overhead of the benzene–toluene distillation column.

PO–SM Coproduction. The coproduction of propylene oxide and styrene includes three reaction steps: (*1*) oxidation of ethylbenzene to ethylbenzene hydroperoxide, (*2*) epoxidation of ethylbenzene hydroperoxide with propylene to form α-phenylethanol and propylene oxide, and (*3*) dehydration of α-phenylethanol to styrene.

The recovery and purification facilities in such a process are complex. One reason is that oxygenated by-products are made in the reactors. Oxygenates hinder polymerization of styrene and cause color instability. Elaborate purification is required to remove the oxygenates.

Specifications and Analysis. The freezing point measurement, standard method for the determination of styrene assay until the 1970s, has been largely replaced by gas chromatography. Color is measured spectrophotometrically and registered on the APHA or the platinum–cobalt scale.

Health and Safety Factors. Styrene is mildly toxic, flammable, and can be made to polymerize violently under certain conditions. However, handled according to proper procedures, it is a relatively safe organic chemical. Styrene vapor has an odor threshold of 50–150 ppm. For skin protection, use of protective garments and gloves of Viton, Nitrile, or PVA construction should be made.

While styrene is not confirmed as a carcinogen, it is considered a suspect carcinogen. Styrene liquid is inflammable and has sufficient vapor pressure at slightly elevated temperatures to form explosive mixtures with air. Properly inhibited and attended, styrene can be stored for an extended period of time.

Uses. Commercial styrene is used almost entirely for the manufacture of polymers.

Common applications for polystyrene include packaging, food containers, and disposable tableware; toys; furniture, appliances, television cabinets, and sports goods; and audio and video cassettes. Expandable polystyrene is widely used in construction for thermal insulation.

Derivatives. A large number of compounds related to styrene have been reported in the literature. Those having the vinyl group $CH_2{=}CH{-}$ attached to the aromatic ring are referred to as styrenic monomers. Several of them have been used for manufacturing small-volume specialty polymers. The specialty styrenic monomers that are manufactured in commercial quantities are vinyltoluene, *para*-methylstyrene, α-methylstyrene, and divinylbenzene. In addition, 4-*tert*-butylstyrene [cas: 1746-23-2] (TBS) is a specialty monomer that is superior to vinyltoluene and *para*-methylstyrene in many applications. Other styrenic monomers produced in small quantities include chlorostyrene and vinylbenzene chloride. With the exception of α-methylstyrene, which is a by-product of the phenol–acetone process,

these specialty monomers are more difficult and expensive to manufacture than styrene.

Vinyltoluene. Vinyltoluene (VT) [cas: 25013-15-4], is a mixture of *meta*- and *para*-vinyltoluenes, typically in the ratio of 60:40. This isomer ratio results from the ratio of the corresponding ethyltoluenes in thermodynamic equilibrium. Vinyltoluene is produced for special applications. Its copolymers are more heat-resistant than the corresponding styrene copolymers, and it is used as a specialty monomer for paint, varnish, and polyester applications.

para-Methylstyrene. [CAS: 627-07-9], PMS is the para isomer of vinyltoluene in high purity. PMS is made by alkylation of toluene with ethylene to *p*-ethyltoluene, followed by dehydrogenation of *p*-ethyltoluene.

Divinylbenzene. This is a specialty monomer used primarily to make cross-linked polystyrene resins. The largest use of divinylbenzene (DVB) [CAS: 1321-74-0] is in ion-exchange resins for domestic and industrial water softening. Ion-exchange resins are also used as solid acid catalysts for certain reactions, such as esterification. Divinylbenzene is manufactured by dehydrogenation of diethylbenzene, which is an internal product in the alkylation plant for ethylbenzene production.

α-Methylstyrene. This compound is not a styrenic monomer in the strict sense. The methyl substitution on the side chain, rather than the aromatic ring, moderates its reactivity in polymerization. It is used as a specialty monomer in ABS resins, coatings, polyester resins, and hot-melt adhesives. As a copolymer in ABS and polystyrene, it increases the heat-distortion resistance of the product. In coatings and resins, it moderates reaction rates and improves clarity. α-Methylstyrene (AMS) [CAS: 98-83-9] is produced as a by-product in the production of phenol and acetone from cumene.

STYRENE-BUTADIENE RUBBER. Styrene–butadiene rubber (SBR), an elastomer, is a copolymer of three parts 1,3-butadiene and one part styrene. It is a synthetic rubber used mainly in the manufacture of automobile tires.

In the late 1920s Bayer & Company began studies of the emulsion polymerization process of polybutadiene for producing synthetic rubber. Incorporation of styrene as a comonomer produced a superior polymer compared to polybutadiene. The product, Buna S, was the precursor of the single largest-volume polymer produced in the 1990s, emulsion styrene–butadiene rubber (ESBR).

In the mid-1950s, the Nobel Prize-winning work of K. Ziegler and G. Natta introduced anionic initiators which allowed the stereospecific polymerization of isoprene to yield high cis-1,4 structure, much like natural rubber. At almost the same time, another route to stereospecific polymer architecture by organometallic compounds was announced.

In the 1960s, anionic polymerized solution SBR (SSBR) began to challenge emulsion SBR in the automotive tire market. Organolithium compounds allow control of the butadiene microstructure, not possible with ESBR. Because this type of chain polymerization takes place without a termination step, an easy synthesis of block polymers is available, whereby glassy (polystyrene) and rubbery (polybutadiene) segments can be combined in the same molecule. These thermoplastic elastomers (TPE) have found use in nontire applications.

Physical Properties. Desirable properties of elastomers include elasticity, abrasion resistance, tensile strength, elongation, modulus, and processibility. These properties are related to and dependent on the average molecular weight and mol wt distribution, polymer macro- and microstructure, branching, gel (cross-linking), and glass-transition temperature (T_g).

Emulsion polymerization gives SBR polymer of high molecular weight. Because it is a free-radical-initiated process, the composition of the resultant chains is heterogeneous, with units of styrene and butadiene randomly spaced throughout. Unlike natural rubber, which is polyisoprene of essentially all cis-1,4 configuration, giving an ordered structure and hence crystallinity, ESBR is amorphous. Unlike SSBR, the microstructure of which can be modified to change the polymer's T_g, the T_g of ESBR can be changed only by a change in ratio of the monomers. Glass-transition temperature is that temperature where a polymer experiences the onset of segmental motion.

The glass-transition temperatures for solution-polymerized SBR as well as ESBR are routinely determined by nuclear magnetic resonance (NMR), differential thermal analysis (DTA), or differential scanning calorimetry (DSC).

For routine analysis of SBR polymers, GPC is widely accepted.

Advantages of natural rubber and isoprene rubber (NR/IR) are high resilience and strength, and abrasion-resistance. BR shows low heat buildup in flexing, good resilience, and abrasion-resistance. Random SBR is low in price, wears well, and bonds easily. Block SBR is easily injection-molded, and is not cross-linked. Applications of NR/IR include tires, tubes, belts, bumpers, tubing, gaskets, seals, foamed mattresses, and padding. BR is used in tire treads and mechanical goods, as is random SBR. Block SBR is used in toys, rubber bands, and mechanical goods.

Raw Materials. The monomers butadiene and styrene, are the most important ingredients in the manufacture of SBR polymers. For ESBR, the largest single material is water; for solution SBR, the solvent.

The quality of the water used in emulsion polymerization affects the manufacture of ESBR. Water hardness and other ionic content can directly affect the chemical and mechanical stability of the polymer emulsion (latex). Solution polymerization can use various solvents, primarily aliphatic and aromatic hydrocarbons. SSBR polymerization depends on recovery and reuse of the solvent for economical operation as well as operation under the air-quality permitting of the local, state, and federal mandates involved.

Polymerization. ESBR and SSBR are made from two different addition polymerization techniques: one radical and one ionic. ESBR polymerization is based on free radicals that attack the unsaturation of the monomers, causing addition of monomer units to the end of the polymer chain, whereas the basis for SSBR is by use of ionic initiators.

Free-radical initiation of emulsion copolymers produces a random polymerization in which the trans/cis ratio cannot be controlled. The nature of ESBR free-radical polymerization results in the polymer being heterogeneous, with a broad molecular weight distribution and random copolymer composition. The microstructure is not amenable to manipulation, although the temperature of the polymerization affects the ratio of trans to cis somewhat.

In solution-based polymerization, use of the initiating anionic species allows control over the trans/cis microstructure of the diene portion of the copolymer. In solution SBR, the alkyllithium catalyst allows the 1,2 content to be changed with certain modifying agents such as ethers or amines. Anionic initiators are used to control the molecular weight, molecular weight distribution, and the microstructure of the copolymer.

SBR Compounding and Processing. The art of compounding requires extensive experience and knowledge of the many compound ingredients. A typical rubber compound in addition to polymer contains one or more ingredients from the following general classes: vulcanizing agents, accelerators, accelerator activators, antioxidants, pigments, and softeners.

The vulcanizing agent, which supplies the bridge between the polymer chains, is furnished predominantly by the sulfur molecule in commercial

formulations. Peroxide vulcanizers that produce carbon-to-carbon cross-links are also important.

Accelerators are chemical compounds that increase the rate of cure and improve the physical properties of the compound. Accelerator activators are chemicals required to initiate the acceleration of the curing process.

Antioxidants are routinely added to the compounds over and above those contained in the polymer at manufacture. Antiozonants prevent or reduce polymer degradation by the active ozone molecule. Some antioxidant compounds, such as the *para*-phenylene-diamines, are excellent as antiozonants. See also **Antioxidant**.

Pigments improve or change polymer properties as well as lower product costs. Reinforcement of SBR by carbon blacks allows this family of polymers to compete with natural rubber. See also **Carbon Black**. It is the most important attribute of the pigment in SBR processing. Softeners, i.e., plasticizers, reinforcing agents, extenders, lubricants, tackifiers, and dispersing aids, are used as processing aids to enhance mixing of uncured stocks and soften cured compounds.

Uses. Styrene–butadiene elastomers, emulsion and solution types combined, are reported to be the largest-volume synthetic rubber. SBR is used on tires and tire-related products, including tread rubber, mechanical goods, other automotive uses, and adhesives, chewing gum base, shoe products, flooring, etc.

Health and Safety Factors. Air quality and plant effluent have been monitored and more or less regulated from the inception of SBR manufacture. Most local and state governments have strict discharge permits that limit what kind of chemicals and how much of it can be emitted into the environment. Both styrene and butadiene are considered suspect carcinogens.

There is an industry trend to supply SBR certifiably free of volatile nitrosamines or nitrosatable compounds. Of primary concern to local, state, and federal governments is the growing stockpile of scrap tires. The threat of huge piles of scrap tires catching fire is cited as a principal concern. Such fires pollute the air and threaten groundwater as the large quantities of oil released in the incomplete burning become a serious runoff problem. Although use of scrap tires is projected to increase rapidly, the only economically feasible use has been as a fuel or fuel supplement in utility and industrial applications.

STYRENE-MALEIC ANHYDRIDE. A thermoplastic copolymer made by the copolymerization of styrene and maleic anhydride. Two types of polymers are available — impact-modified SMA terpolymer alloys (*Cadon*®) and SMA copolymers, with and without rubber impact modifiers (*Dylark*®). These products are distinguished by higher heat resistance than the parent styrenic and ABS families. The MA functionality also provides improved adhesion to glass fiber reinforcement systems. Recent developments include terpolymer alloy systems with high-speed impact performance and low-temperature ductile fail characteristics required by automotive instrument panel usage.

Copolymers show chemical resistance generally similar to that of polystyrene and terpolymers similar to that of ABS (acrylonitrile-butadiene-styrene). Neither type is recommended for use in strongly alkaline environments. All impact versions have good natural color and products are available in a wide range of colors. Copolymer crystal grades have good clarity and gloss.

Glass-reinforced SMA polymers are used as electrical connectors, consoles, top pads, and as supports for urethane-padded instrument panels. There are several additional automotive uses. SMA are also found in coffee makers, steam curlers, power tools, audio cassette components, business machines, vacuum cleaners, solar heat collectors, electrical housing, and fan blades, among others.

SUBACUTE SCLEROSING PANENCEPHALITIS. This is a form of subacute encephalitis affecting children and young adults; it is due to persistent infection with the measles virus. SSPE and inclusion-body encephalitis are now recognized as the same disease. It most frequently follows by about six years measles contracted at an earlier age and is twice as common in boys as girls. The same vaccination programs that have controlled measles in the United States have also reduced the incidence of SSPE. In the United Kingdom, some twenty cases are notified annually.

It is not known whether persistence of the virus in the brain is the result of an abnormal incomplete form of the virus or of immunodeficiency on the part of the host.

Onset of the syndrome is usually insidious with loss of energy and interest. After some time increasing clumsiness draws attention to the organic nature of the disease and at this stage involuntary movements or myoclonus usually appear. Visual signs may be prominent with chloroidoretinal scarring present in about 30% of cases. Further progression is marked by intellectual deterioration, rigidity, and spacticity, and increasing helplessness with death in a year or two. The disease may be arrested in a state of complete incapacity or rarely some improvement may occur, but not full recovery. No treatment is known to be effective.

R. C. V.

SUBARCTIC PACIFIC WATER. An oceanic water mass extending from the Aleutians on the north to the North Pacific Central Water masses on the south, and far out into the Western Pacific. It is a major surface water mass of low temperature (2–4 °C (35.6–39.2 °F) at 50° north latitude) and low salinity, 32.2–34.1%, the last figure existing at its lower depths (400–500 meters) (1320–1650 feet). Its eastern part, which extends to the coast of America is higher in temperature and salinity, due to effects of warm air from the land.

SUBGRAPH. A graph containing a subset of the edges of the original graph.

The *complement of a subgraph* is the set of all elements of the graph not in the subgraph.

A *connected graph* is essentially one that is in "one piece." An unconnected graph must therefore be decomposable into several *connected* "pieces." This notion can be made precise by using the notion of a maximal connected subgraph.

Let two vertices β_1 and β_2 of a graph G be defined to be equivalent if there exists a path between them and denote this relation symbolically by $\beta_1 \doteq \beta_2$. Clearly, if

(a) $\beta_1 \doteq \beta_2$ and $\beta_2 \doteq \beta_3$, then $\beta_1 \doteq \beta_3$
(b) and for the same vertex, $\beta_1 \doteq \beta_1$
(c) If $\beta_1 \doteq \beta_2$, then $\beta_2 \doteq \beta_1$

Thus the relation is an equivalence relation in the strict mathematical sense because it is (a) transitive, (b) reflexive and (c) symmetric. The collection of all vertices of G is partitioned into disjoint equivalence classes such that two vertices belong to the same class if and only if they are equivalent. If G is finite, the number of these classes is also finite and can be enumerated $S_1, S_2, \ldots, S_P$. A little thought reveals that the set of all edges whose two endpoints are vertices in $S_r (r = 1, 2, \ldots, P)$ is a *connected subgraph* G_r of G. Moreover $G_r (r = 1, 2, \ldots, P)$ is a *maximal connected subgraph* of G in the sense that the addition of any more vertices to G_r renders it unconnected. Evidently, $P = 1$ if and only if G is connected.

A *proper subgraph* is a subgraph which does not contain all the edges of the graph.

Disjoint subgraphs are subgraphs of a graph which have no vertices in common.

See also **Graph (Mathematics)**.

SUBGRID-SCALE PROCESS. Atmospheric processes that cannot be adequately resolved within a numerical simulation. Examples can include turbulent fluxes, phase changes of water, chemical reactions, and radiative flux divergence. Such processes are often parameterized in numerical integrations and even neglected in some applications.

See also **Convective Adjustment**; **Mellor-Yamada Parameterization**; **Parameterization**; **Shallow Convection Parameterization**; and **Turbulent Flux**.

SUBLIMATION. Sublimation occurs when the matter passes directly from the solid phase to the vapor phase, as is shown in Fig. 1. Examples include dry ice, how a frost-free refrigerator works, and naphthalene. If solid iodine is placed in a tube and slightly warmed, it vaporizes and the vapor reforms into crystals on the cooler parts of the tube. Many crystalline substances, both metallic and nonmetallic, may be similarly sublimated in a vacuum; fairly large crystals of selenium have been thus prepared. The most familiar sublimates are frost and snow. As in the case of other changes of state, sublimation is accompanied by the absorption or evolution of heat, the quantity of which per unit mass is called the heat of sublimation of the substance. At pressures near the triple point the heat of sublimation is approximately equal to the sum of the heats of fusion and vaporization. In physical and chemical literature, it is customary to regard as sublimation only the transition from solid to vapor, not from vapor to solid; but meteorologists do not make this distinction.

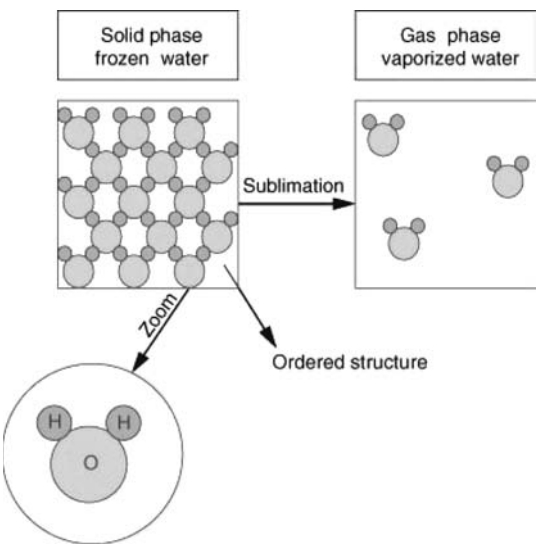

Fig. 1. Water sublimation.

Concept

Sublimation is an endothermic process:

$$\Delta H_{\text{sublimation}} > 0$$

The heat required to change the phase of a pure substance is given by

$$Q = m \cdot L$$

where m is the mass of the pure substance and L is the latent heat.

The water latent heat for sublimation is 2.83×10^6 J/Kg.

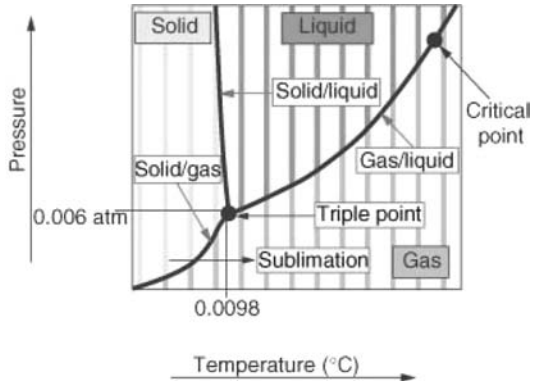

Fig. 2. Phase diagram of pure water.

Figure 2 presents the water phase diagram, which usually shows the pressure versus the temperature.

The diagram is divided into three areas, which represent the solid, liquid, and gaseous phases.

Triple point is a particular condition of temperature and pressure, which the three phases for a substance are in equilibrium.

Above the critical point, the liquid and gas phases are indistinguishable. The critical temperature is the minimum temperature for liquefaction of a gas using pressure. The critical pressure is the pressure required for liquefaction. The critical temperature of water is 374 °C (705 °F), and the water critical pressure is 218 atm.

Sublimation phenomenon happens below the triple point in the water phase diagram. The sublimation curve is the line between the solid and gas phases.

At the triple point of the water phase diagram, the temperature is 0.0098 °C and the pressure is 0.006 atm.

Application

Freeze-drying is a process by which a water or aqueous substance is removed from a frozen material or frozen solution by sublimation. Figure 3 shows an example of a frozen solution in a freeze-drying tray.

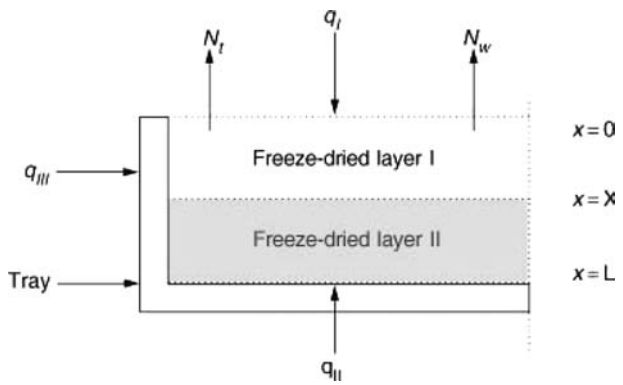

Fig. 3. Diagram of a frozen material on a tray during freeze-drying. X is the position of the sublimation interface between the freeze-dried (layer I) and the frozen material (layer II).

Here q_{I}, q_{II}, and q_{III} are the heat, which can be supplied to the surface by conduction, convection, or radiation. N_{w} and N_{t} represent the mass flow of the water vapor and the total mass flow, respectively, in the dried layer.

This process involves the following three periods: freezing, primary drying, and secondary drying periods as shown in Fig. 4.

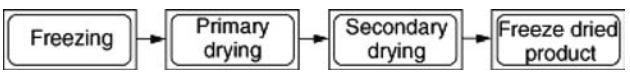

Fig. 4. Freeze-drying periods.

A batch freeze-dryer is shown in Fig. 5. This equipment is composed of a stainless steel cylinder chamber with eight connectors for connection of the bottles. Above the cylinder chamber, a cover is built by transparent material. At the cylinder, there is a system with three trays. The vacuum pump localizes outside the freeze-dryer.

1. Glass camera with trays of inoxidable steel.

2. Manifold-exits of silicon and serpentine interns.

3. System of control of refrigeration and pressure.

4. Bomb of vacuous.

Fig. 5. Freeze-drying equipment.

The freeze-drying process has a wide range of applications, including pharmaceutical products, foodstuffs (the organoleptic properties are important and have to be maintained), and other industrial byproducts (conservation of living microorganism, dehydration, or concentration of heat labile). Another example of freeze-drying is the soluble coffee process, which produces a porous product by sublimation. This porous material is eager for water.

The performance of the overall freeze-drying process depends significantly on the freezing stage. The material to be processed is cooled to a temperature below the solidification. The shape of the pores, the pore size distribution, and the pore connectivity of the porous network of the dried layer formed by the sublimation of the frozen water during the primary drying stage depend on the ice crystals formed during the freezing stage.

The solvent is removed by sublimation under a vacuum pressure, and heat addition in the primary drying stage is carried out. A significant amount of the latent heat of sublimation is also kept when the water molecules sublime and enter the vapor phase. Because of this result, the temperature of the frozen product is reduced. Then it is necessary to supply heat to the product. The heat could be provided by conduction, convection, and/or radiation.

During the secondary drying stage the solvent is removed from the chamber and a small amount of sorbed water can be removed by desorption.

A dynamic mathematical model for the freeze-drying stages was proposed by Boss et al. This model represents the process well.

The low temperature of the freeze-drying process and the low water activity resulting from this process minimize some reactions of degradation such as Maillard's reaction, protein denaturation, and enzymatic reaction. Color and flavor are important quality attributes in food, and the freeze-drying process preserves more of the pigments and reduces more of the transport rates than does the conventional drying processes. The hot air drying causes irreversible damages to the texture and incomplete rehydration. The freeze-drying process proposes good preservation of the original product characteristics and an increase in the stability of the product during the storage. See also **Freeze-Drying**.

SUBLIMATION (Heat of). The quantity of heat required at constant temperature (and pressure) to evaporate unit mass of a solid. In sublimation, the change is directly from solid to vapor, without appearance of the liquid phase.

SUBROUTINE (Computer System). 1. The set of instructions necessary to direct a computer to carry out a well-defined mathematical or logical operation. 2. A subunit of a routine. A subroutine is often written in relative or symbolic coding even when the routine to which it belongs is not. 3. A portion of a routine that causes a computer to carry out a well-defined mathematical or logical operation. 4. A routine arranged so that control may be transferred to it from a master routine and so that, at the conclusion of the subroutine, control reverts to the master routine. Such a subroutine is usually a closed subroutine. 5. A single routine may simultaneously be both a subroutine with respect to another routine and a master routine with respect to a third. Usually control is transferred to a single subroutine from more than one place in the master routine; the reason for using the subroutine is to avoid having to repeat the same sequence of instructions in different places in the master routine.

Closed Subroutine. A subroutine not stored in the main path of the routine. Such a subroutine is entered by a jump operation and provision is made to return control to the main routine at the end of the operation. The instructions related to the entry and reentry function constitute a linkage.

Open Subroutine. A subroutine, of which a replica must be inserted at each place in the computer program where the subroutine is used. Although requiring more storage, this approach avoids linkage and housekeeping overhead.

T. J. H.

SUBSIDENCE. Subsiding air is sinking air and is associated with lateral divergence. Subsidence in the atmosphere is a stabilizing influence; it also decreases relative humidity within the sinking air as it warms the air. Atmospheric pressure usually rises under the influence of subsidence, which is normally associated with anticyclones. Clear or partially clouded skies are the usual weather in a region of subsidence.

SUBSOLAR POINT. The geographical position of the Sun; that point on the Earth at which the Sun is in the zenith at a specified time.

SUBSTITUTE NATURAL GAS (SNG). A rather general term for describing an artificially produced relatively-high Btu gas that compares favorably with natural gas as a fuel. SNG also may refer to synthetic natural gas; or, on some occasions, to synthesis gas. The latter generally connotes a specially constituted gas to be used as the raw material for a chemical process, such as an ammonia synthesis — thus ammonia synthesis gas, etc. The Btu value of natural gas typically lies within the range of 975 to 1,180 Btu per standard cubic foot (110–133 calories/cubic meter). Thus, to substitute for and to compete with natural gas (where available), the artificially-produced gas must have a Btu content within this general range. Substitute or synthetic gases generally fall into two categories: (1) low-Btu-value gases with a Btu content of 400 to 600 Btu per cubic foot (50–67 calories/cubic meter) or lower, sometimes suitable for combined-cycle power generation schemes or for subsequent enrichment to increase the Btu content; and (2) high-Btu-value gases (sometimes referred to as pipeline gases) which have a Btu content generally within the 950 to 1,050 Btu per cubic foot (107–118 calories/cubic meter) range. Such gases, properly treated to remove traces of unwanted impurities and corrosives, can be introduced into transcontinental pipelines and handled essentially in the same manner as natural gas.

SNG is derived from coal, various petroleum fractions, and waste products. Gases produced from coal are described under **Coal**.

The most practical and economic source of raw material for producing SNG varies with the proximity to raw materials, the relative cost of raw materials, and by numerous other factors which affect the complex energy balance of a given nation and geographical location. Naphtha may make a logical choice of starting material in one area, whereas coal would be most logical in another area. Also, for some years to come — until SNG processes become better proved on a day-to-day operating basis — a somewhat more costly raw material, if available, may be the only practical answer. With proven processes, waste materials as a source of SNG is a very sensible approach, but in some areas the costs of collecting wastes (or the availability of sufficient waste products) may prohibit this approach. As proponents of various schemes and concepts have found upon undertaking

detailed, practical development of concepts, a process will not necessarily be successful even though initial gross statistics "prove" the wisdom of the concept.

Catalytic Rich Gas (CRG) Process

This process was developed from the work of a team at the Gas Council's Midlands Research Station (MRS) (England) led by Dr. F. J. Dent. In the late 1950s, it became apparent that, due to the postwar increase in refining capacity in Europe, naphtha was becoming available as a potential feedstock for gas making and that its use would be more economical than coal carbonization, which was then the major source of fuel gas in the United Kingdom. The first semicommercial plant, producing 4 million standard cubic feet per day of rich gas, was commissioned in 1964. Within the next five years, nearly 40 units were installed in the United Kingdom for production of rich gas and town gas (470–500 Btu per standard cubic foot; 53–56 Calories/cubic meter). Plants were also installed in Japan, Italy, Brazil, and the United States.

The overall reactions which occur in the steam reforming of naphtha are:

(1) $4C_6H_{14} + 10H_2 \longrightarrow 19CH_4 + 5CO_2$	Exothermic
(2) $CH_4 + H_2O \rightleftharpoons CO + 3H_2$	Endothermic
(3) $CO + H_2O \rightleftharpoons CO_2 + H_2$	Slightly exothermic

At all practical temperatures, reaction (1) proceeds almost to completion; no significant quantities of higher hydrocarbons exist at the outlet of the CRG reactor.

Reactions (2) and (3) are reversible; the concentrations of the five components CH_4, H_2O, CO_2, CO and H_2 which result are governed by thermodynamic equilibrium. Raising the reaction temperature shifts the equilibrium for both reactions to the right. Thus at low temperatures the exothermic reaction (1) predominates, while at high temperatures the overall reaction is endothermic. At approximately 500–550 °C (932–1022 °F) the reaction is thermally neutral.

Naphthas boiling up to 185 °C (365 °F) can be reformed at pressures up to 600 psig. Naphthas with final boiling point up to 240 °C (464 °F) may be reformed at lower pressures. Higher olefin contents may be accepted provided that sufficient hydrogen is available in the recycle gas to saturate the feed in the desulfurization section. Higher aromatic contents may be accepted but the catalyst life will be reduced.

A typical rich gas leaving the CRG reactor has the following composition:

CO_2	23.0 mol.% (dry)
CO	0.7
H_2	12.8
CH_4	63.5
	100.0%
Calorific value (Btu/standard bic foot)	675

Higher hydrocarbons are present in negligible quantities.

The calorific value of this gas is too high for direct use as town gas (470–500 Btu/standard cubic foot in the United Kingdom) and too low for SNG. However, by removing the CO_2 the calorific value is increased to about 870 Btu/standard cubic foot, which is useful for enriching lean gas (e.g., from an Imperial Chemical Industries (ICI) naphtha reformer) to town gas quality. Long has suggested that by enriching this gas with LPG (liquefied petroleum gas) a satisfactory SNG may be obtained.

Alternatively, the calorific value may be changed by bringing the components to a new equilibrium at a different temperature. In the Series "A" Process, part of the rich gas is further reformed at high temperature and remixed with the remaining rich gas. After water gas shift and partial CO_2 removal a 500 Btu/standard cubic foot product is obtained which is fully interchangeable with the town gas distributed in the United Kingdom.

If the subsequent stage is at a lower temperature, carbon oxides and hydrogen recombine to methane, increasing the calorific value. Following CO_2 removal, very little enrichment is required to achieve a product fully interchangeable with natural gas.

CRG catalyst is deactivated by low concentrations of sulfur and chlorine compounds. To achieve removal of sulfur to very low concentrations (less than 0.2 ppm), British Gas developed their own process which is always used in association with CRG catalyst. Organic sulfur compounds are hydrogenated to H_2S over nickel-molybdenum catalyst at about 380 °C (716 °F). The hydrogen is usually generated by reforming rich gas from the CRG reactor with added steam in a tubular reformer. Alternatively, gas from the reactor may be used directly, while in some plants it is normal to use CO_2-free town gas. The H_2S is then absorbed on zinc oxide or, in the case of many United Kingdom town gas plants, Luxmasse (hydrated ferric oxide).

Because of the large stream sizes involved, many of the SNG plants in the United States incorporate a bulk sulfur removal stage using a hydrofining process. The H_2S produced is commonly recovered as elemental sulfur by a Stretford plant, in which the hydrofiner off gas is washed with an aqueous alkaline solution which is regenerated by oxidation with air.

Chlorine compounds, if present in concentration higher than 1 ppm, not only deactivate the CRG catalyst but also interfere with the absorption of H_2S. Therefore they are removed by hydrogenation to HCl which is absorbed on a proprietary absorbent.

Reforming in the CRG process occurs adiabatically at 450–550 °C (842–1022 °F) at pressures up to about 600 psig (41 atmospheres). The reactor is a vertical cylindrical pressure vessel containing a bed of the special high-nickel catalyst which is supported on a grid or on inert ceramic balls. The gas flow is downwards through the bed and distributors are provided at inlet and outlet. A layer of ceramic balls on top of the bed prevents disturbance of the catalyst by the entering gas.

Normal practice is to install two reactors in parallel, of which one is working at any time. The catalyst charge in each vessel is designed for 3–6 months operation at full load. This system avoids unnecessary exposure of catalyst to high temperatures, minimizes the catalyst loss in the event of damage by maloperation and provides instant standby if such damage occurs.

The flow diagram for a rich gas plant producing gas with a calorific value of 710 Btu/standard cubic foot is shown in Fig. 1. The product is used to enrich lean gas from an ICI (Imperial Chemical Industries) naphtha reformer which has a calorific value of about 320 Btu/standard cubic foot to the town gas standard of 500 Btu/standard cubic foot (56 calories/cubic meter). Typical gas analyses are given in Table 1.

TABLE 1. GAS ANALYSES IN RICH GAS PLANT

	Recycle Gas	Gas from CRGR	Scrubbed Rich Gas
CO_2 (mol %)	0.9	20.3	13.5
CO	1.8	1.4	1.5
H_2	23.3	19.1	20.7
CH_4	74.0	59.2	64.3
	100.0	100.0	100.0
Calorific Value			
(Btu/standard cubic foot)	816	654	710
(calories/cubic meter)	91.7	73.5	79.8

In what is termed a Series "A" Process, part of the gas from the CRG reactor is reformed with additional steam and the resulting lean gas is reblended with the remaining rich gas. The mixed gas is then subjected to water gas shift and partial carbon dioxide removal, yielding a product with a calorific value of 470–500 Btu/standard cubic foot (53–56 Calories/cubic meter). Typical gas analyses are shown in Table 2. By varying the proportion of gas which flows to the tubular reformer and the degree of CO_2 removal, the characteristics of the product gas can be made interchangeable with any of the different standards employed by the United Kingdom Area Boards and Japanese and European gas companies. A variation of this process has been used in Italy. The calorific value of important Libyan LNG (1395 Btu/standard cubic foot; 157 calories/cubic meter) was too high for direct use as pipeline gas. The LNG was, therefore, fractionated and the heavy ends ($C_2H_6 - C_6H_{14}$) subjected to processing.

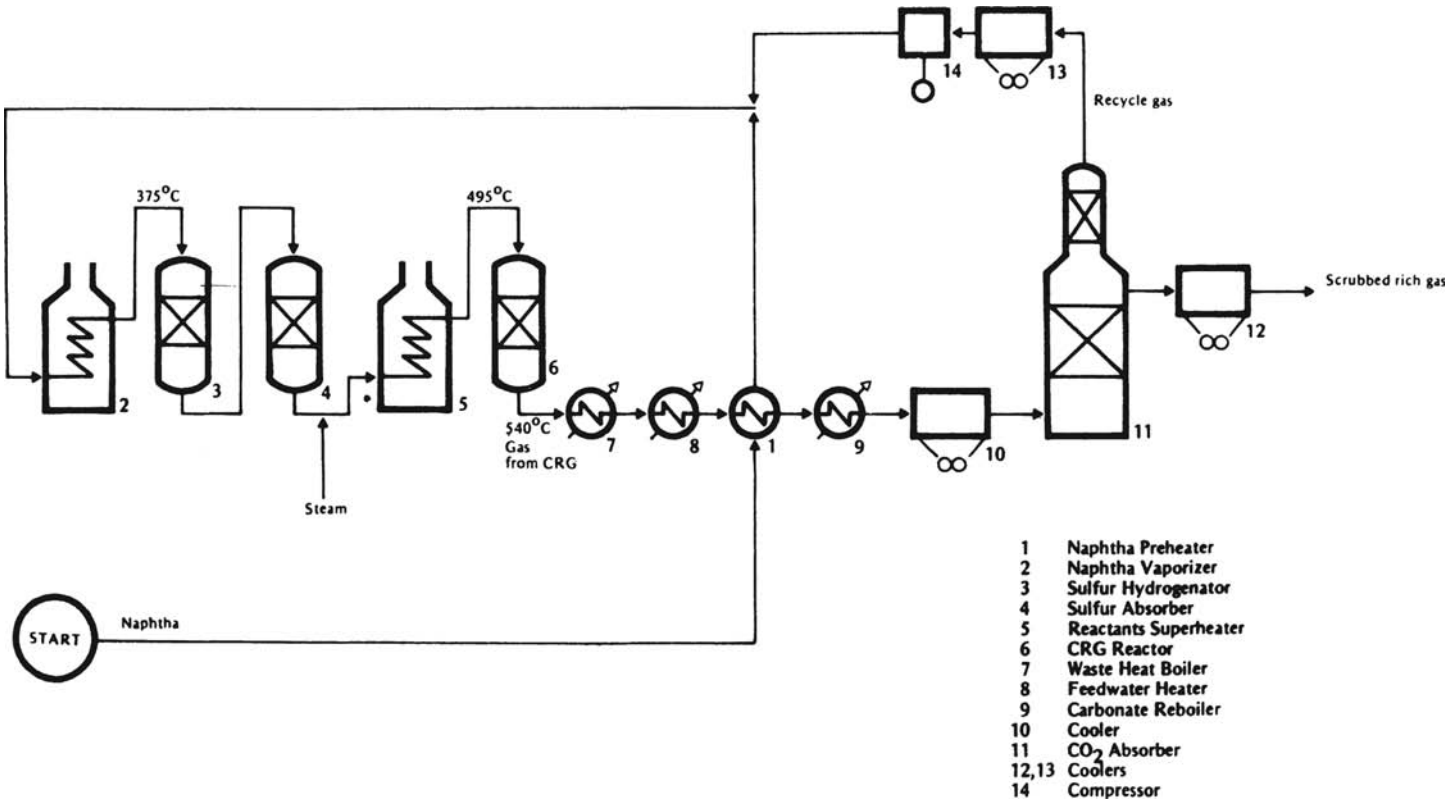

Fig. 1. Typical flowsheet for rich gas plant. (*Woodall-Duckham Limited.*)

TABLE 2. GAS ANALYSES IN SERIES "A" PLANT

	Recycle Gas	Rich Gas	Reformed Gas	Mixed Gas	Converted Gas	Product Gas
CO_2 (mol %)	1.0	21.6	13.4	16.1	21.3	13.5
CO	3.4	0.9	13.7	9.6	2.7	3.0
H_2	60.9	15.3	59.0	44.9	48.4	53.2
CH_4	34.7	62.2	13.9	29.4	27.6	30.3
	100.0	100.0	100.0	100.0	100.0	100.0
calorific value						
(Btu/standard cubic foot)	550	670	370	466	438	480
(calories/cubic meter)	61.8	75.3	41.6	52.4	49.2	53.9

If the rich gas from the CRG reactor is passed over another bed of high-nickel catalyst at a lower temperature, the equilibrium of the five components is reestablished. Carbon oxides react with hydrogen to form methane and the calorific value of the gas is increased. It should be noted that this methanation step differs from that encountered in ammonia synthesis gas production; because of the high steam content the temperature rise is reduced and there is no possibility of temperature "runaway" as the exit temperature can never rise above the temperature corresponding to equilibrium at the inlet composition, i.e. the CRG exit temperature.

In order to minimize cold enrichment and to achieve a very low carbon monoxide content in the product, a second methanation stage is frequently employed. To achieve sufficient "driving force" to make the reaction proceed, the water vapor content is reduced by cooling the gas, rejecting condensate, and reheating to the required reaction temperature.

Table 3 shows the effect of the second methanation stage on product calorific value. While consumption of LPG is minimized, the capital cost is increased and the overall thermal efficiency is slightly reduced.

If part of the purified naphtha vapor from desulfurization is allowed to bypass the CRG reactor, it can be fully gasified by reaction with the hydrogen and steam in the rich gas. This reaction occurs at lower temperatures than the CRG reaction, and is known as hydrogasification. It has the advantage that the total steam requirement for the process is reduced, although with heavier feedstocks it may be necessary to add a little steam to the hydrogasifier in order to ensure that carbon is not formed by the Boudouard reaction. Since less makeup steam has to be generated from fired boilers, the overall efficiency is improved by 1–2%. The capital cost is slightly lower than that of the methanation route.

The calorific value of the product from hydrogasification is lower than that from single methanation, particularly with high carbon/hydrogen feedstocks because of the additional steam required. However, by adding a final methanator, the calorific value can be increased to that obtained from double methanation, again with increased capital cost and reduced efficiency. This process (Fig. 2) is used in the first operational SNG plant in the United States at Harrison, N.J. Typical gas analyses are given in Table 4.

Because of the lower temperature, the catalyst in the hydrogasifier, which is the same as that in the CRG reactor, is slowly deactivated by polymer formation. The activity may be recovered "*in situ*" by heating in hydrogen. Two hydrogasifiers are therefore provided in parallel so that regeneration can be carried out without interrupting production.

The CRG process is one of a range of processes developed by the British Gas Corporation for production of fuel gases. The range and application of these processes and their impact has been described by Hebden, illustrating the effect on capital cost of increasing the carbon/hydrogen ratio of the feedstock.

An alternative method of handling crude oil is the "energy refinery" in which crude is split into a number of fractions which can be treated by proven processes to yield two products, SNG and low sulfur fuel oil.

TABLE 3. GAS ANALYSES — SNG PRODUCTION BY DOUBLE METHANATION

	Recycle Gas	1st Stage Gas	2nd Stage Gas	3rd Stage Gas	Scrubbed Gas	Product Gas
CO_2 (mol %)	0.5	21.7	22.0	21.9	0.5	0.50
CO	1.5	0.8	0.1	0.1	0.1	0.04
H_2	86.5	12.8	3.7	0.4	0.5	0.53
CH_4	11.5	64.7	74.2	77.6	98.9	97.98
C_3H_8	—	—	—	—	—	0.95
	100.0	100.0	100.0	100.0	100.0	100.0
calorific value						
(Btu/standard cubic foot)	395	687	750	773	986	1000
(calories/cubic meter)	44.3	77.2	84.3	86.9	110.8	112.4

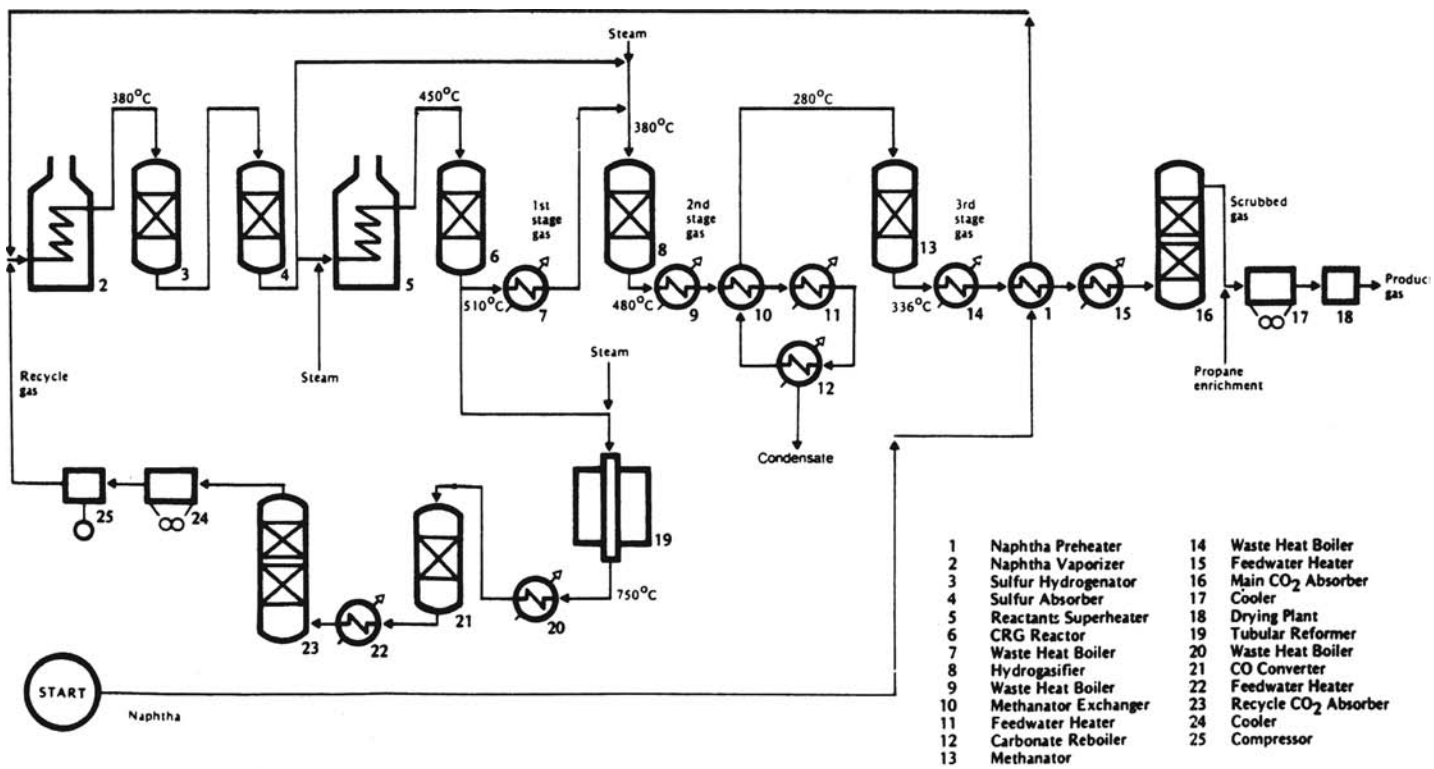

Fig. 2. Typical flowsheet for SNG plant — hydrogasification route. (*Woodall-Duckham Limited*.)

TABLE 4. GAS ANALYSES — SNG PRODUCTION BY HYDROGASIFICATION

	Recycle Gas	1st Stage Gas	2nd Stage Gas	3rd Stage Gas	Scrubbed Gas	Product Gas
CO_2 (mol %)	0.5	21.8	21.7	21.9	0.5	~0.50
CO	1.6	0.7	0.6	0.1	0.1	~0.70
H_2	86.5	13.3	6.2	0.6	0.8	~0.79
CH_4	11.4	64.2	71.5	77.4	98.6	~97.56
C_3H_8	—	—	—	—	—	~1.08
	100.0	100.0	100.0	100.0	100.0	
calorific Value						
(Btu/standard cubic foot)	395	683	733	772	984	1000
(calories/cubic meter)	44.4	76.7	82.4	86.7	110.6	112.4

One such scheme is shown in Fig. 3. The advantages of using the CRG process as the final stage in the production of SNG are high efficiency and low capital cost, the predictable quality of the product gas, and the absence of by-products.

Methane-Rich Gas (MRG) Process

A process which produces methane gas from feedstock hydrocarbons, such as naphtha, liquefied petroleum gases (LPG), and refinery gas, developed by Japan Gasoline Co., Ltd., in collaboration with its affiliate, Nikki Chemical Co., Ltd., for application to town-gas facilities. The MRG process had its origin in the high-temperature hydrocarbon steam reforming technology. First efforts culminated in a successful installation in 1956. In the tendency to employ heavier hydrocarbons as feedstock, carbon formation in the low-temperature range posed a problem. The Japan Gasoline Co. took this up as a main research subject and continued the study of low-temperature-range reaction, concentrating especially on the difference of product gas properties and carbon formation according to reaction conditions and catalyst specifications. As a result, a new catalyst was developed which converts butane or naphtha to a gas consisting mainly of methane, hydrogen, and carbon dioxide, with a negligible amount of carbon monoxide. This was the first stage of development of the present MRG process.

In 1964, while developing practical applications for the town-gas industry, a pilot plant with a daily capacity of 15,000 cubic meters

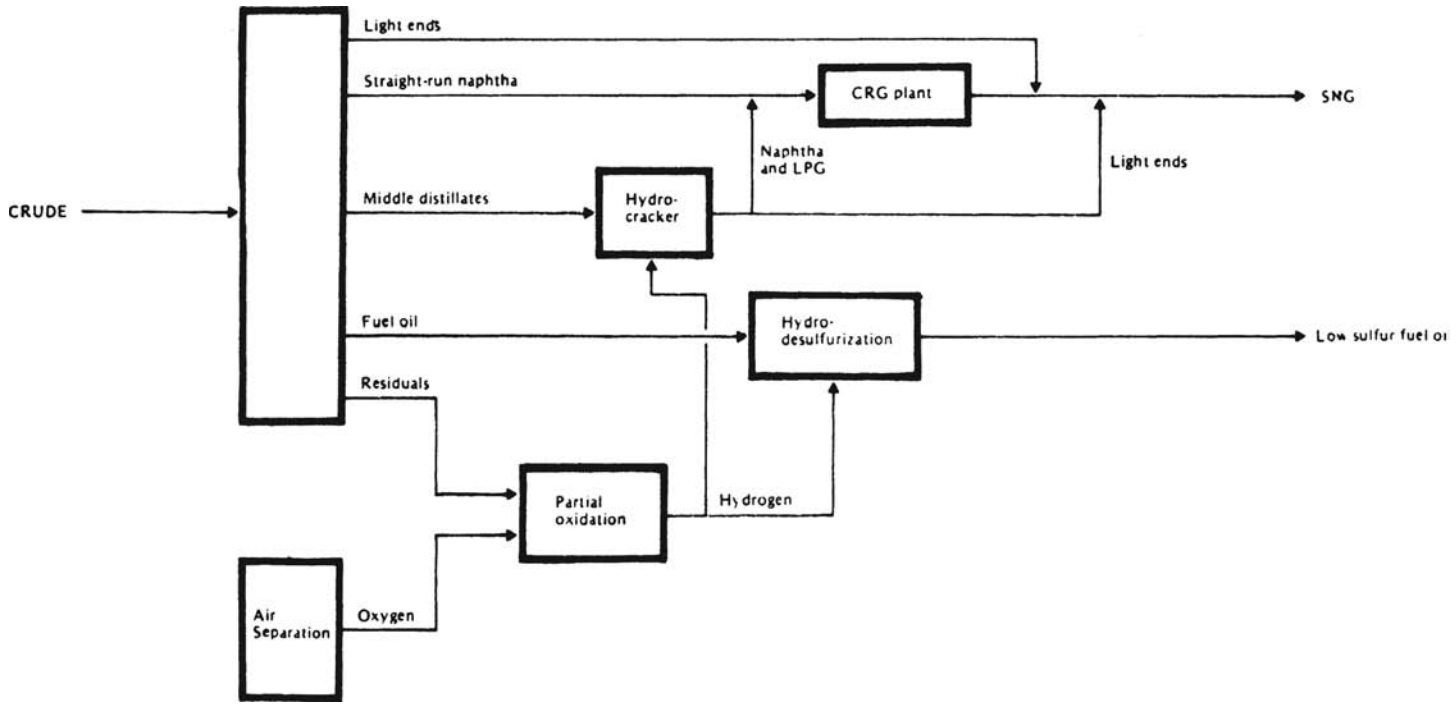

Fig. 3. SNG and low-sulfur fuel oil from crude. (*Woodall-Duckham Limited.*)

was built. Continuous test runs were conducted over a long term, in cooperation with Osaka Gas Co., Ltd., thus starting commercial production of equipment for the process. Based upon results of the aforementioned test runs, a commercial-size town-gas plant (200,000 cubic meters daily capacity) was constructed at the Hokkoh plant of Osaka Gas Co., Ltd. This was followed by two plants each of 500,000 cubic meters daily capacity in 1967 and 1969. Additional plants followed not only for town-gas uses, but also for petrochemical needs. Late in 1971, an MRG plant incorporating a wet methanation system went into operation at Keiyo Gas Co., Ltd., near Tokyo, with a capacity of 105,000 cubic meters per day. In late 1972, a complete MRG-based SNG plant, consisting of gasification, methanation, and CO_2 removal sections was completed for the same firm, with a capacity of 200,000 cubic meters per day. In early 1974, Boston Gas Co. (U.S.) started up a 1,070,000 cubic meters per day SNG plant which employs a two-stage MRG gasification system.

The basic reactions of the MRG process consist of three stages: (1) hydrodesulfurization of sulfur compounds in the hydrocarbon feedstock; (2) low-temperature steam reforming (gasification) of desulfurized hydrocarbons; and (3) methanation reaction between hydrogen and carbon dioxide in methane gas available by gassification.

Sulfur compounds contained in hydrocarbon feedstock vary, depending on the types of crudes and their boiling points. Naphtha, for example, contains mainly mercaptans, disulfides, and thiophenes. Such sulfur compounds deteriorate the activity of the low-temperature steam-reforming MRG catalyst. They should be removed to some degree before the feedstock enters the system. Major reactions of the hydrodesulfurization step are:

$$RSH + H_2 \longrightarrow RH + H_2S$$

$$R{-}S{-}R' + 2H_2 \longrightarrow RH + R'H + H_2S$$

$$R{-}S{-}S{-}R' + 3H_2 \longrightarrow RH + R'H + 2H_2S$$

$$+ 3H_2 \longrightarrow RC_4H_9 + H_2S$$

(alkyl group R not fixed to a specific carbon)

In as much as these are all exothermic reactions, low ambient temperatures are favorable from the standpoint of equilibrium theory, but in consideration of reaction rates, general processes are operated in a range of 350–400 °C with the aid of a highly active catalyst (like Co-Mo or Ni-Mo), involving the side reactions:

$$CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O$$

$$CO + 3H_2 \rightleftharpoons CH_4 + H_2O$$

The foregoing reactions are highly exothermic and significantly raise reaction temperatures. The MRG process, however, does not involve such adverse side reactions with use of a special, selective hydrodesulfurizing catalyst (developed by Japan Gasoline Co. and Nikki Chemical). The MRG process uses part of product gas for hydrodesulfurization, and even if it contains only 20–25% hydrogen and as high as 20–23% carbon oxides, only the proper hydrodesulfurization reactions take place. The MRG process features a recycle use of product gas for hydrodesulfurization purposes without any special treatment.

To eliminate hydrogen sulfide formed in hydrodesulfurization reactions, two solutions are available: (1) fixation by H_2S contact with an adsorbent (zinc oxide) via the reaction: $ZnO + H_2S \rightarrow ZnS + H_2O$; and (2) physical removal by stripping. The hydrodesulfurization system is most economically practical with feedstocks containing less than 200 to 500 ppm sulfur. The removal of H_2S by stripping after hydrodesulfurization with an external hydrogen supply may be applied to naphtha stocks contaminated by trace metals as well as those high in sulfur.

Gasification by low-temperature steam-reforming reactions, the heart of the MRG process, is carried out between liquid hydrocarbons and steam over catalyst to form methane, hydrogen, and carbon oxides. In order to increase the calorific value of product gas to the values similar to natural gas, methanation reactions are required. Hydrogen in product gas is reacted with CO_2 and CO to form methane, with only a small portion unconverted. Methanation reactions are:

$$CO + 3H_2 \rightleftharpoons CH_4 + H_2O \quad 49.3 \text{ kcal/g-mole at } 25\,^\circ\text{C}$$

$$CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O \quad 9.8 \text{ kcal/g-mole at } 25\,^\circ\text{C}$$

After methanation, the gas goes to a scrubber to remove CO_2 for further purification.

Because the MRG process is mainly based on steam reforming, the success of the process hinges on the reliable availability of steam. Steam should be controlled at a constant level somewhat above the projected requirements to assure continuous, effective reforming. Adequate steam must be on hand at all times to assure effective control of the steam/naphtha

ratio. In summary, for the proper feedstocks and economic situations, the MRG process offers the following: (1) a wide variety of feedstocks can be used; (2) broad selection of calorific value of final product gas. Product gas is available in a range of calorific values from 5,500 to 9,400 kcal/cubic meter; (3) high-pressure operation. Many conventional town-gas plants which operate at near atmospheric pressure require an additional compressor to convey product gas through pipelines. The MRG process does not require any additional compressor, but does permit operation at high pressures — up to approximately 1,140 pounds per square inch gage (77.6 atmospheres), enabling high-pressure, long-distance transportation of product gas. (4) Noncomplex equipment is used. The use of a drum-type reactor makes the reactor design quite simple, resulting in a compact design of the overall system. In terms of product gas calorific value, the MRG reactor requires only $\frac{1}{6}$ to $\frac{1}{8}$ the area of a general coke oven and about $\frac{1}{3}$ that of a conventional high-temperature steam-reforming plant; (5) sulfur-resistant catalyst; and (6) high thermal efficiency. Operation at low temperatures and high pressures permits thermal efficiency as high as 92–96%, depending on desulfurized feedstock used.

Hydrocracking-Hydrogasification Process

In a continuous, two-step process developed by the Institute of Gas Technology, crude oil can be hydrocracked to approximately diesel oil weight and then made to react noncatalytically with hydrogen at elevated pressures (500–1,500 psig; 34–102 atmospheres) and temperatures 593–760 °C (1099–1400 °F) to produce methane-rich gas containing about 30% (volume) hydrogen and 10% ethane. This gas can be desulfurized and methanated to yield pipeline gas. By adjusting the conditions of hydrocracking, enough heavy fuel oil can be produced to provide feedstock for hydrogen production by partial oxidation, or a low-sulfur fuel oil product can be made if desired.

Interest has centered on plants to produce substitute natural gas from light distillate feedstocks, such as naphtha. However, when naphtha is in short supply, a process capable of converting the more plentiful crude and residual oils to pipeline gas is needed. A number of processes were developed over 20 years ago to provide supplemental gas in winter periods when demand is high. Because the supplemental gas was required for only 20 to 30 days during the year, only cyclic thermal cracking at atmospheric pressure was used in order to avoid the high capital cost of more complex continuous processes. However, with the need for base-load gas, a continuous process would be feasible.

The major difficulty associated with the production of pipeline gas from crude and residual oils is carbon deposition during the gasification step, which leads to reactor vessel plugging. One approach to this problem has been to conduct pressure gasification with hydrogen in a fluidized bed of coke, allowing carbon to deposit on the coke particles. To avoid accumulation of these deposits, a small amount of coke is continuously withdrawn from the bed. This technique, developed by the British Gas Council, gasifies the oil in a single reaction step. An approach to the problem of carbon deposition taken by the Institute of Gas Technology is to eliminate the carbon-forming materials in the heavy oil prior to hydrogasification by catalytic hydrocracking. In developing this concept, experiments were conducted on both the hydrocracking and the hydrogasification operations for a variety of feedstocks, ranging from kerosine to Bunker-C fuel oil. Distillate feeds required no hydrocracking.

A simplified flowsheet based on this concept (hydrocracking, separation, and hydrogasification) is shown in Fig. 4, where 250 billion Btu/day (63 billion Calories/day) of pipeline-quality gas is produced from 59,350 barrels/day of Taparito crude. The overall fuel efficiency of the process is 67%, allowing for all utility requirements, including oxygen production. The design of hydrogen plants based on partial oxidation of residual oils and the design of hydrocracking operations are well established arts. The only unusual component of the process, therefore, is the hydrogasification reactor itself. Offsites not shown on the flowsheet include an oxygen plant, sulfur-recovery facilities (Claus plant), power and steam generation equipment, and water treatment facilities.

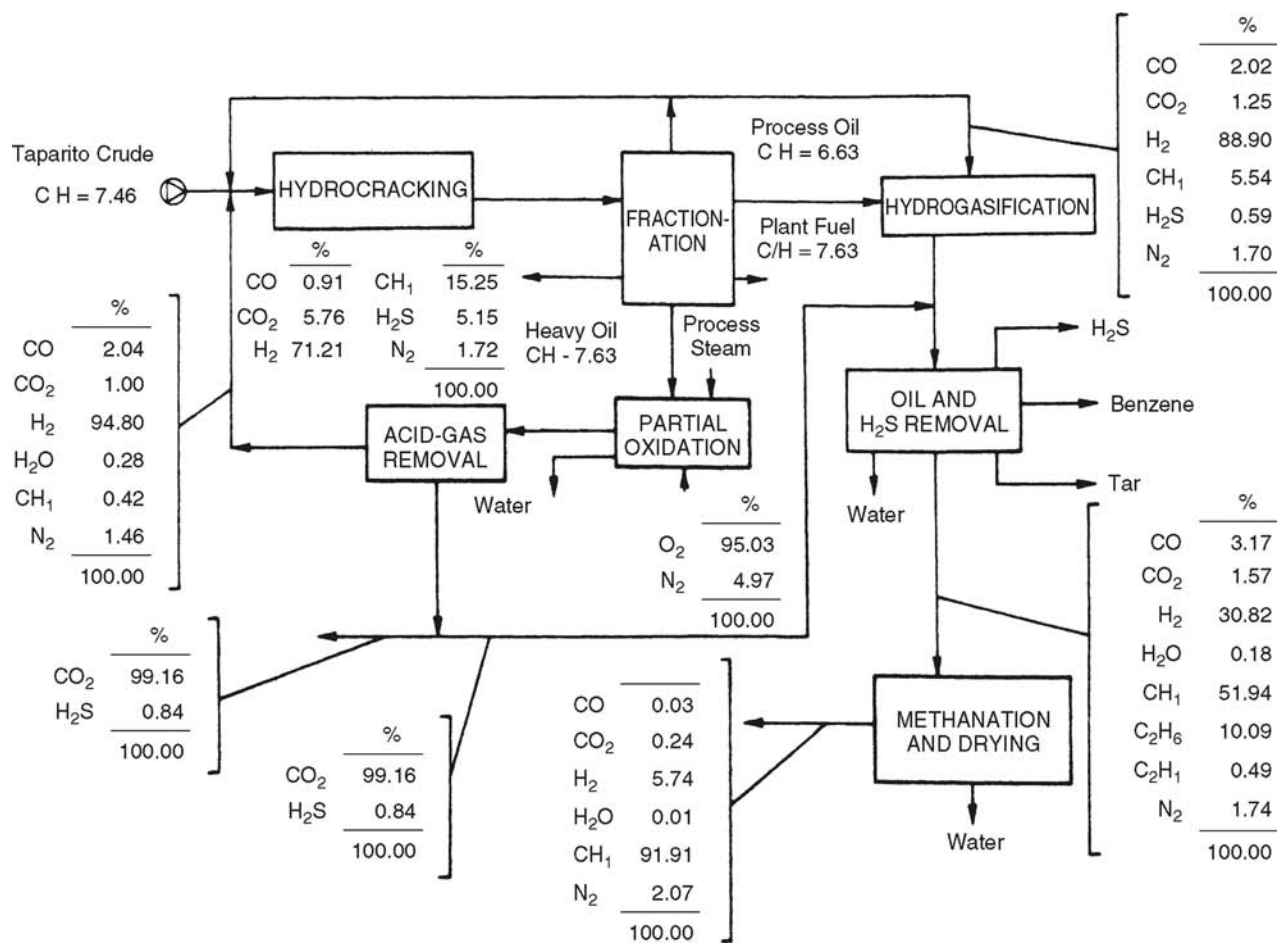

Fig. 4. Block flow diagram for pipeline gas production. (*Institute of Gas Technology*.)

At the hydrogasification conditions used, about 90% of the 360 °C (680 °F) endpoint feed oil is gasified, yielding a raw gas containing about 52% methane and 10% ethane, with the remainder principally hydrogen. About 60% of the liquid products is benzene. Total liquid products are removed first by separation in a knockout drum and then by straw oil scrubbing. Benzene, the last traces of which are removed from the gas by activated carbon, is recovered and sold. Very heavy oil is used for plant fuel. Since the excess hydrogen in the gas is to be methanated with carbon dioxide, a small amount of carbon dioxide from the hydrogen plant is added to the gas prior to the removal of hydrogen sulfide. Most of the hydrogen in the gas at this point will react with ethane during methanation. Because carbon dioxide is used for methanation, hydrogen sulfide must be selectively removed from the gas prior to methanation. Approximately 48,400 metric tons/year of elemental sulfur are recovered for disposal from waste gas streams in the plant. The waste gas streams from the acid-gas removal unit upstream of the methanator and from the first stage of the acid-gas removal unit in the hydrogen plant are sent to a Claus plant.

Noncatalytic Partial-Oxidation Gasification

Designed for the partial combustion or oxidation of hydrocarbons, a process of this type is particularly suitable for converting heavy, sulfur-containing residual fuels and heavy crude oils into a mixture of hydrogen and carbon monoxide in inert gases. The process is carried out by injecting oil and air (or oxygen) through a specially-designed burner assembly into a closed combustion vessel, where partial oxidation occurs at about 1316 °C (2400 °F). The term partial oxidation describes the net effect of a number of component reactions that occur in a flame supplied with less than stoichiometric oxygen.

In the fuel injection region of the reactor, hydrocarbons leaving the atomizer at about preheat temperature are intimately mixed with air or oxygen. The atomized hydrocarbon is heated and vaporized by back radiation from the flame and reactor walls. Some cracking of the hydrocarbons to carbon, methane, and hydrocarbon radicals may occur during this brief phase. When the fuel and air or oxygen reach the ignition temperature, part of the hydrocarbons reacts with oxygen in a highly exothermic reaction to produce carbon dioxide and water. Practically all available oxygen is consumed in this phase. The remaining hydrocarbons which have not been oxidized react with steam and the combustion products from reaction to form carbon monoxide and hydrogen. The carbon produced during gasification is recovered as a soot-in-water slurry.

Depending upon the desired heating value of the product gas, either oxygen or air may be used as oxidant. Nitrogen present in the air acts as a moderator for temperature control in the reactor and does not enter into the reactions. When either oxygen or air enriched with oxygen is used, a quantity of steam must be injected into the reactor for temperature moderation. Air oxidation alone requires no steam. The latter method produces a low heating-value fuel gas (approximately 120 Btu/standard cubic foot; 13.5 Calories/cubic meter) due to the presence of nitrogen. Oxygen feed produces a medium heating-value gas (approximately 300 Btu/standard cubic foot; 33.7 Calories/cubic meter).

The net products of the process are high-pressure steam, clean wastewater, and carbon-free fuel gas. While the high-pressure steam is saturated, pressures over 1,100 psig (74.8 atmospheres) have been commercially demonstrated and increases to substantially higher pressures in commercial practice are anticipated. Under any condition, using superheating, this steam is easily converted into an attractive feed for steam turbines. With appropriate design, oxygen-based oxidation units can be made almost entirely energy self-sufficient.

Gas from Solid Wastes

In one process, municipal refuse is charged at the top of a shaft furnace and is pyrolyzed as it passes downward through the furnace. Oxygen enters the furnace through tuyeres near the furnace bottom and passes upward through a 1425–1650 °C (2597–3002 °F) combustion zone. The products of combustion then pass through a pyrolysis zone and exit at about 93 °C (199 °F). The offgas then passes through an electrostatic precipitator to remove flyash and oil formed during pyrolysis, both of which are recycled to the furnace combustion zone. The gas then passes through an acid absorber and a condenser. The clean fuel gas has a heating value of about 300 Btu/cubic foot (33.7 Calories/cubic meter) and a flame temperature equivalent to that of natural gas. As the solid waste passes downward through the furnace, it contacts the exiting pyrolysis products and traps a portion of the oil and flyash while itself losing moisture. After passing through the pyrolysis and combustion zones, the remaining solid waste is removed as a slag from the furnace bottom. The system has a net thermal efficiency of about 65% in converting solid waste to fuel gas. Process losses include energy losses in the conversion process and energy required for the operation of the onsite cryogenic gas separation unit for production of 95% oxygen needed by the system. The clean fuel gas is low in sulfur (about 15 ppm) and is essentially free of nitrogen oxides.

Another process involves the anaerobic digestion of a solid waste and water or sewage slurry at 60 °C (140 °F) for 5 days to produce a methane-rich gas. Solid waste is prepared by shredding and air classification prior to being blended with water or sewage sludge to a 10 to 20% solids concentration. The slurry is heated and placed in a mixed digester for 5 days detention. The digestor gas is drawn off and separated into carbon dioxide and methane. The spent slurry from the digester is pumped through a heat exchanger to partially heat the incoming slurry prior to filtration. The filtrate is returned to the blender and the sludge is used as landfill. Heat addition to the refuse slurry is required to maintain the required digester temperature. This process is suited for use on sewage sludge, animal manures, and other high-moisture-content solid wastes. It is estimated that the process reduces the volume of volatile solids by 75% while producing about 3,000 cubic feet (85 cubic meters) of methane per metric ton of incoming solid waste. The major residue is a sludge that requires landfilling or incineration. About 10% of the methane is consumed in heating the digester feed.

Methanol as Source of SNG

Methanol can be produced from a large range of feedstocks by a variety of processes. Natural gas, liquefied petroleum gas (LPG), naphthas, residual oils, asphalt, oil shale, and coal are in the forefront as feedstocks to produce methanol, with wood and waste products from farms and municipalities possible additional feedstock sources. In order to synthesize methanol, the main feedstocks are converted to a mixture of hydrogen and carbon oxides (synthesis gas) by steam reforming, partial oxidation, or gasification. The hydrogen and carbon oxides are then converted to methanol over a catalyst.

The concept of utilizing associated or natural gas for production of methanol which could be transported more economically than LNG from areas of surplus to areas of shortage was examined in the mid-1960s. At that time, the largest single-stream plant designed had a capacity of 900 metric tons of methanol per day. A fuel plant which might need to produce — say 22,500 metric tons per day of methanol was assessed on the economics basis of 25 times the small plant. It was quickly ascertained that methanol fuel delivered, for example, to the United States from the Middle East could not compete with local natural gas supplies which were than available at low cost within the United States. With shorter local supplies accompanied by much greater costs, the possibilities of economically feasible large-scale fuel methanol production now appear much more promising.

Conversion of natural gas (or other petroleum components) at the source to methanol, shipment as methanol, and reconversion of methanol into pipeline gas at point of use — versus the concept of liquefying natural gas and shipping LNG for regasification at point of use — probably will be a problem of some controversy for a number of years, pending assessment of actual system operating costs for both systems on a large-scale. See also **Natural Gas**.

SUBTRACTION. An operation that is the inverse of addition. The $-$ sign is used to denote the operation of subtraction. In the equation $M - S = R$, M is the *minuend*, S the *subtrahend*, and R is the *remainder*. To perform the operation, calculate $M + (-S) = R$, i.e., change the sign of the subtrahend and add.

SUBTRACTIVE COLOR PROCESS. A method of photographic color synthesis using two or more superimposed colorants, which selectively absorb their complementary colors from white light.

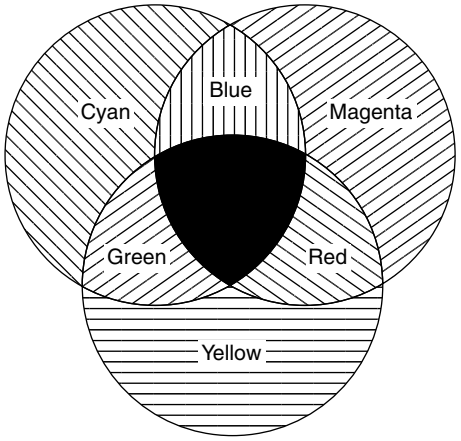

Fig. 1. Superimposed color filters.

Most modern processes of color photography make use of a subtractive synthesis to yield prints or transparencies. In a three-color process, the colorants cyan, magenta, and yellow are used to control the amounts of red, green and blue in a beam of white light. See Fig. 1. This beam of white light may be either that of a projector with its color transparency, or the light reflected from a white support, such as paper, on which the color reproduction is printed. In the first case, the light passes through the colorants once, while in the print viewed by reflection the light must traverse the colorants twice.

The colorants are positive or negative images. A cyan positive image (a cyan colorant controls red light), for example, may be prepared from the negative that recorded the red present in the subject. The magenta and yellow colorant images are likewise made from green and blue record negatives. These colorant images are superimposed in register to yield the final reproduction. The three colorants may be in separate removable layers or they may be physically inseparable as in the modern integral tripacks. The contrast of the colorant images must be approximately double for a picture to be viewed by transmitted light as compared to one to be viewed by reflection. The accuracy of color reproduction by a subtractive synthesis as compared to an additive is chiefly dependent on how satisfactorily the three colorants cyan, magenta, and yellow fulfill their role, as red, green and blue absorbers respectively. Color correction is often adopted to improve the accuracy of reproduction when using the colorants generally available.

See also **Photography and Imagery**.

SUBTROPICAL COUNTERCURRENT. See **Ocean Currents**.

SUCCESSION (Plant). The gradual replacement of one plant association by another. Succession is caused by slow changes in the environmental factors which influence the establishment, development and survival of plants. Many of these changes, such as shading, increase in the humus content or porosity of the soil, decrease in soil temperature, etc., are brought about by plants themselves.

A good example of a plant succession occurs in the filling of a shallow pond. At first the deeper parts of such a pond are occupied only by submersed aquatic species of plants. As the pond becomes shallower, as a result of the accumulation of plant remains and the deposition of the silt caught in such remains, floating-leaf species such as water lilies invade the area and largely shade out the underwater species. With further decrease in the depth of the water the floating leaf aquatics are replaced by cattails, reeds, bulrushes and other typical marsh plants. At a still later stage in succession the former pond will be occupied by a wet meadow composed largely of sedges, rushes, and spike rushes. Still later swamp shrubs such as willows, alders, and buttombush invade the area only to be replaced in turn by trees of species that can tolerate a poorly drained substratum. Still further successional stages may ultimately result in the development of a climax association on the area.

Another example of plant succession that can be observed in many parts of the country is the natural reforestation of abandoned farm land. The pioneer invaders of such an area are mostly herbaceous plants, the very first to appear being mostly annuals. Soon shrubs invade the area to be followed in turn by certain species of trees. The first tree species to occupy the area, however, seldom represent a stable plant association. In large parts of the Eastern United States, for example, pines of one species or another are usually the first kind of tree to occupy abandoned fields, but they are, in time, replaced by other species, most commonly by oaks or hickories, or both. In many regions still further successional stages will be passed through before a stable climax association is attained.

Other examples of kinds of areas on which plant succession is initiated are sand dunes, burned over forest lands, cliffs or raw talus slopes, and the bottoms of lakes which have been exposed by drainage. Important consideration should be given to the principles of plant succession in forest and range management and in other land utilization problems.

SUCCESSIVE-APPROXIMATION A/D CONVERTER. This type of analog-to-digital converter makes a direct comparison between an unknown input signal and a reference signal. The converter, as shown schematically in Fig. 1, includes a digital-to-analog (D/A) Converter. This provides an output voltage V_R, a precise fraction of the reference source voltage. The setting of analog switches, which are controlled by the digital outputs of the output register, determine the attenuation factor of the converter. Digital-output information of the A/D converter also is stored in the output register. Two input AND logic gates are used as conditional-reset gates. The shift register also functions as a step counter.

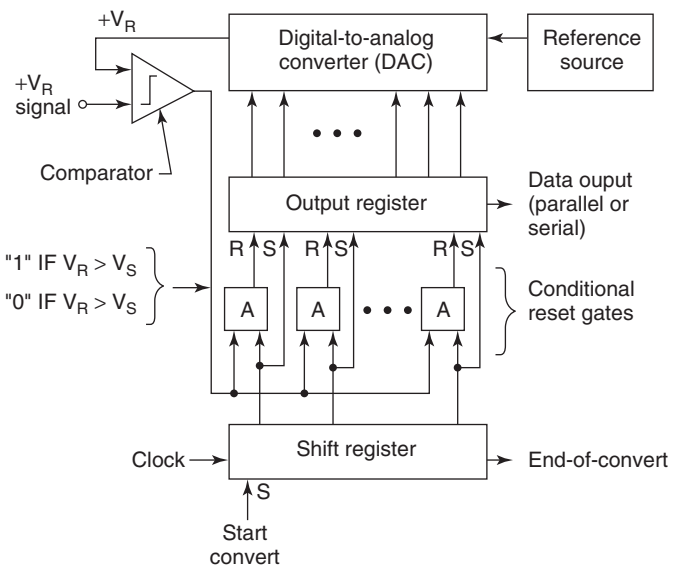

Fig. 1. Successive-approximation analog-to-digital converter.

The A/D converter shown in the diagram is a binary n-bit converter. A "start convert" pulse causes all registers to clear and sets a 1 into the first position of the shift register. In turn, this action also turns on the first switch in the A/D converter and sets the first stage of the output register to 1. The output of the D/A converter is equal to one-half the full-scale D/A converter output voltage inasmuch as the D/A converter is binary. The D/A output voltage is compared directly with signal voltage V_S by the comparator. The output of the latter is a binary 1 if V_R is greater than V_S and a binary 0 if V_R is less than V_S.

The first bit in the output register may be reset to 0 or may remain as a 1, depending upon the comparator output. Upon appearance of the next clock pulse, the 1 in the shift register moves to the second bit at which instant the comparison process is repeated — with the exception that the output of the D/A converter is either 0.25 or 0.75 of the full-scale D/A converted output. This is dependent upon whether the first bit was reset to 0 or remained as a 1, respectively.

Codes other than binary can be used in successive-approximation A/D converters. What is required is the production of an attentuation that is proportional to the weighting value of the code digit. A binary-coded

decimal converter can be constructed by using a binary-coded decimal digital-to-analog converter. The D/A converter will provide attentuation ratios of 0.8, 0.4, 0.2, 0.1, 0.08 and so on. Of course, appropriate coding of the output register is necessary so that the information can be stored in coded form.

Successive-approximation A/D converters can be used at conversion speeds up to approximately 100,000 samples/second at resolutions up to 16 bits (not including sign). At lower resolution, speeds over 250,000 samples/second are practical. Factors to be considered in the design and application of these A/D converters include: (1) stability and regulation of the reference source, (2) overload and recovery characteristics of the comparator, (3) analog-switch characteristics, and (4) speed and response of the ladder network.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

SUCCULENTS. Succulent plants are those that are fleshy, that is, have their stems or leaves greatly enlarged to serve as water-storage organs. Succulents occur wild in regions in which there is a very limited supply of available water, as in the desert lands of western America, central Asia, and many parts of Africa. Among stem succulents the outstanding representatives are the members of the Cactus family, with the milkweed and spurge families also ranking high. Leaf succulents include many plants such as *Sedums, Crassulas, Bryophyllums*, and *Gasterias*. Many of the leaf succulents are plants of extremely curious habit. In some, the leaves are so swollen with stored water that they form a nearly spherical mass growing almost buried in the ground; in others the masses of leaves form compact rosettes at the tips of the branches; while in others the swollen leaves appear like small green beads along a slender stem.

SUCKERS *(Osteichthyes).* Of the group *Cypriniformes*, family *Catostomidae*, suckers live near the bottom of streams, feeding on vegetation and small animals. The mouth is usually provided with fleshy lips and in some species opens at a downward angle. They are not highly valued as food fishes, but the common sucker (*Catostomus commersoni*) often abundant in small streams and lakes is considered of excellent taste although bony.

Buffalo fishes are in this family and have the appearance of a goldfish or carp. The largemouth buffalo (*Ictiobus cyprinellus*) which can attain a length up to 3 feet (0.9 meters) is common throughout the central portion of the United States. *Carpiodes cyprinus* (quillback carp-sucker) will often measure up to 26 inches (66 centimeters) in length and weigh up to about 12 pounds (5.4 kilograms). This fish is considered a commercial item in Lake Erie and is also found in the eastern and central regions of the United States.

Suckers are essentially an American fish. Other species include: *Catostomus latipinnis* (flannelmouth sucker) found in the Colorado River; *Minytrema melanops* (spotted sucker) found in the eastern states; *Xyaruchen texanus* (humpback sucker) found in the Colorado River Basin and attains a length up to 2 feet (0.6 meter); and *Myxocyprinus asiaticus*, similar to the *Xyaruchen*, which is one of the few suckers found outside of America, in Asia.

Suckers are sometimes difficult to differentiate from minnows. A method is described in a book by Hubbs and Lagler, "Fishes of the Great Lakes Region," Cranbrook Institute of Science, 1958.

SUCRALOSE. Sucralose is the only non-caloric sweetener made from sugar. Sucralose is derived from sugar through a multi-step patented manufacturing process that selectively substitutes three atoms of chlorine for three hydroxyl groups on the sugar molecule to produce 1,6-dichloro-1,6-dideoxy-β-D-fructo-furanosyl 4-chloro-4-deoxy-α-D-galactopyranoside. This change produces a sweetener that has no calories, yet is 600 times sweeter than sucrose. Sucralose tastes like sugar. It has a clean, quickly perceptible, sweet taste that does not leave an unpleasant aftertaste. The exceptional stability of sucralose allows both food manufacturers and consumers to use it virtually anywhere sugar is used, including cooking and baking.

Discovered in 1976, sucralose has been developed jointly by McNeil Specialty Products Company, http://www.tuberose.com/Sucralose.html, a member of the Johnson & Johnson Family of Companies, and Tate & Lyle, PLC, a world leader in sweeteners and starches. Sucralose was granted approval by the U.S. Food and Drug Administration (FDA) on April 1, 1998 and approved for use in 15 food and beverage categories. This is the broadest initial approval ever granted by FDA for a food ingredient. The FDA expanded the uses for sucralose in 1999, approving it as a "general purpose" sweetener. Sucralose has also been approved for use in foods and beverages in more than 40 countries including Canada, Australia and Mexico.

Sucralose is not utilized for energy in the body because it is not broken down like sucrose. It passes rapidly through the body virtually unchanged. Sucralose has been extensively tested in more than 100 studies during a 20-year period and found to be a safe and remarkably inert ingredient. It can be used by all populations, including pregnant women, nursing mothers, and children of all ages. No population subgroup has been excluded from using sucralose. Sucralose is beneficial for individuals with diabetes because research demonstrates that sucralose has no effect on carbohydrate metabolism, short- or long-term blood glucose control, or insulin secretion.

One advantage of sucralose for food and beverage manufacturers and consumers is its exceptional stability. It retains its sweetness over a wide range of temperature and storage conditions and in solutions over time. Because of its stability, food manufacturers can use sucralose to create a number of great-tasting new foods and beverages in categories such as canned fruit, low-calorie fruit drinks, baked goods, and sauces and syrups. Sucralose also can be used as a sweetener in nutritional supplements, medical foods, and vitamin/mineral supplements.

Sucralose is available as an ingredient for use in a broad range of foods and beverages under the name SPLENDA® Brand Sweetener. Currently, a range of products sweetened with SPLENDA are on supermarket shelves, such as carbonated soft drinks, low-calorie fruit drinks, maple syrup, and apple sauce.

Sucralose is available in supermarkets as a tabletop sweetener under the brand name SPLENDA in two forms — granular and packets. The granular tabletop sweetener can be used as a spoon-for-spoon replacement for sugar. It pours, measures, and cooks and bakes like sugar. The convenient packet form can be used to sweeten beverages and sprinkle on cereal or fruit. The two tabletop forms of SPLENDA® Low-Calorie Sweetener are available via the Internet at www.sucralose.org. Benefits of Sucralose include:

- **Tastes Like Sugar** — Sucralose tastes like sugar and has no unpleasant aftertaste. In scientific taste tests conducted by independent research organizations, sucralose was found to have a taste profile very similar to sugar.
- **Can Help Control Caloric Intake** — Sucralose is not metabolized, thus it has no calories. It passes rapidly through the body virtually unchanged, is unaffected by the body's digestive process, and does not accumulate in the body. By replacing sucralose for sugar in foods and beverages, calories can be reduced substantially, or, in many products, practically eliminated.
- **Advantageous for People with Diabetes** — Sucralose is not recognized as sugar or a carbohydrate by the body. Thus, it has no effect on glucose utilization, carbohydrate metabolism, the secretion of insulin, or glucose and fructose absorption. Studies in persons with normal blood glucose levels and in persons with either type 1 or type 2 diabetes have confirmed that sucralose has no effect on short- or long-term blood glucose control.
- **Does Not Promote Tooth Decay** — Scientific studies have shown that sucralose does not support the growth of oral bacteria and does not promote tooth decay.
- **Extraordinary Heat Stability** — Sucralose is exceptionally heat stable, making it ideal for use in baking, canning, pasteurization, aseptic processing and other manufacturing processes that require high temperatures. In studies among a range of baked goods, canned fruits, syrups, and jams and jellies, no measurable loss of sucralose occurred during processing and throughout shelf life.
- **Long Shelf Life** — Sucralose combines the taste of sugar with the heat, liquid and storage stability required for use in all types of foods and beverages. It is particularly stable in acidic products, such as carbonated soft drinks, and in other liquid based products (e.g., sauces, jelly, milk products, processed fruit drinks). Sucralose is also very stable in dry applications such as powdered beverages, instant desserts, and tabletop sweeteners.

- **Ingredient Compatibility** — Sucralose has excellent solubility characteristics for use in food and beverage manufacturing and it is highly compatible with commonly used food ingredients, including flavors, seasonings, and preservatives.

Safety Factors

The safety of sucralose is documented by one of the most extensive and thorough safety testing programs ever conducted on a new food additive. More than 100 studies conducted and evaluated over a 20-year period clearly demonstrate the safety of sucralose. Studies were conducted in a broad range of areas to assess whether there were any safety risks regarding cancer, genetic effects, reproduction and fertility, birth defects, immunology, the central nervous system, and metabolism. These studies clearly indicate that sucralose:

Does not cause:
- tooth decay
- cancer
- genetic changes
- birth defects

Has no effect on:
- carbohydrate metabolism, short- or long-term blood glucose control or insulin secretion
- male or female reproduction
- the immune system

The increasing calorie consciousness of Americans has sparked a growing consumer demand for low-calorie foods and beverages. The number of people who consume low-calorie products has more than doubled during the past decade. The availability of sucralose, aspartame, saccharin, neotame and acesulfame potassium has expanded the low-calorie food and beverage market by allowing manufacturers to use the most appropriate sweetener, or combination of sweeteners, for a given product.

This multiple sweetener approach allows the low-calorie and diet food and beverage industry to meet the growing consumer demand for new, good-tasting, reduced-calorie products. No low-calorie sweetener is perfect for all uses. On the other hand, a wide variety of low-calorie sweeteners provides products with improved taste and stability, lower manufacturing costs, and more choices for the consumer. SUDDEN INFANT DEATH SYNDROME (SIDS). Known as SIDS (sometimes crib or cot death), this syndrome may be defined as the precipitous (sudden), unexpected death of an apparently healthy infant from whom an autopsy fails to identify the cause of death. In other words, these infants die of mysterious causes, which most experts as of the late 1900s considered a puzzle that, to date, has defied statistical research. There may be preventive measures, but physicians question — on the basis of what?

Of each one thousand live births in modern industrialized nations, 990 infants can be expected to live to their first birthday (and normally beyond for many years). Of the ten babies who die before they are one year old, six do not survive the first month of life — succumbing to gross errors in growth and development, usually the result of a very low birth weight, prematurity, or some congenital defect, i.e., causes of death that are explainable. Two or three of the remaining four infants will die in hospital some time during the first year, usually as the result of a serious treatment-resisting infection or because of a late-detected birth abnormality. The remaining two or three infants will die *unexpectedly*, often in their own cribs, usually discovered too late to take to hospital, but even then, death will usually occur and a thorough necropsy examination will not yield a plausible cause of death. Even though the number two or three out of a sample of 1000 infants is small statistically, nevertheless in a large nation, there will be several thousand cases of SIDS. (Estimated to be 10,000 cases/year in the United States and the United Kingdom, collectively.)

Golding, Limerick, and Macfarlane in a 1986 book on SIDS (see references) describe a typical SIDS situation: "Three-month-old David's mother is a nurse in her early 30s. He is her third child; happily married to a physician, she does not smoke. Through normal birth, she has just mothered a normal, contented baby. At two months, he was screened at the health clinic; no abnormality at all. At three months, not long before his first immunization, she put him in his crib for his afternoon sleep. Warm but not encumbered, he went right to sleep. She heard no sound, but in 30 minutes she went up to check on him. He was very pale; when she picked him up, he was floppy and around his mouth was a blood-tinged froth. She cleared the tiny mouth, phoned for an ambulance and tried resuscitation. Within 10 minutes David was in hospital, still warm but without breath or heartbeat. The emergency staff gave up after an hour's effort. The postmortem was entirely normal except for some vomit in the infant's upper mouth and airways. Certificate of Death — Sudden Infant Death (SID)."

Studies on infant mortality in efforts to relate SIDS statistically with one or more causative factors have been conducted in Britain, Canada, the United States, Australia, New Zealand and in some European countries as well as in Japan and Israel. Statistics thus far have shown that, in contrast with other causes of infant fatality (notable decreases in most countries in recent years), the incidence of SIDS has held steady. (Only exceptions reported are in two large Swedish cities and these have not been explained satisfactorily.) Over the past 15 years, there have been at least five international conferences on the subject.

Although no convincing cause of SIDS is now under present consideration, many hypotheses have been offered over the years, only to be disproved by statistics. In a recent study in the United Kingdom in a medically well-tended region with about 14,000 births per year, some very general criteria have been offered, but these do not contain much help in terms of SIDS prevention.

- Age of mother — SIDS is relatively higher for young mothers, notably those in the lower economic sector of society and who smoke or use drugs. (Yet for one-half of cases, the mothers were not under economic stress and one-third did not smoke.)
- Season of year — SIDS occurs more frequently during winter months.
- Male babies are at higher risk of SIDS than females.
- Babies of exceptionally low birth weight are more susceptible to SIDS. (But, 80% of babies in the sample weighed a normal amount at birth.)
- Siblings of dead infants do not appear to be at much greater risk.
- Infanticide is seldom masked as SIDS.

Some of the past proposed hypotheses that have essentially been ruled out by most authorities today include: (1) sudden arrest of breathing — failure in bioelectronic development; (2) use of the birth control pill; (3) vaccines and medications normally administered to infants; (4) selenium and other trace element deficiencies in the diet; (5) overheating, perhaps augmented by fever, causing death by heat stroke (febrile convulsions are common in young children, but occur at ages far advanced of the peak of SIDS); (6) vague muscular effects. A point that has added some confusion to the diagnosis of SIDS (as defined here) is respiratory syncytial virus (common virus infection leading to bronchitis and pneumonia) — because this condition matches that of the usual period for SIDS and also has the same ratio of more male than female infants. Similar viruses may show similar patterns. Some authorities believe that anaphylactic shock to the sensitized infant in reaction to respiratory virus infection may precipitate SIDS, but they cautiously suggest that this could account for only some SIDS cases as currently understood. The strongest statistical connection for the virus hypothesis is that SIDS occurs more frequently in winter than in summer.

The real puzzler of SIDS is the usual lack of evidence at post mortem examination.

Updated Appraisals of SIDS

In an 1991 study by J.S. Kemp and B.T. Thach (Washington University of Medicine, St. Louis), data on 25 cases of SIDS were analyzed carefully. Efforts were made to distinguish the difference on postmortem examination of (a) accidental suffocation and (b) SIDS. The researchers point out that three basic assumptions generally can be used to separate the two causes

of death. (1) Healthy infants will not suffocate on ordinary bedding. (2) Infants will suffocate only if their heads are firmly restrained when the airway is occluded. (3) Infants lying with their faces straight down and their noses and mouths pressed into the bedding can turn their heads to obtain access to fresh air. In the 25% or more of infants with SIDS who are found with their faces straight down, the posture is thus considered coincidental and unrelated to the cause of death.

The Washington University study produced one very important finding — namely, that the deaths of several of the previously diagnosed SIDS cases actually were deaths from suffocation that occurred in a manner not previously reported in infants. The deaths all occurred on a particular type of cushion filled with polystyrene beads and marketed for infants.

To support their study, the researchers experimented by measuring the mechanics (simulated by machine) involved in breathing with head down on a pliable material. Thus it was found that an infant lying face down on certain materials may, in fact, rebreathe expired gases. In the tests, gas concentrations were measured. Carbon dioxide gas was used in the simulations. Thus, simulated infants with faces pressed down on certain materials resulted not in a sudden cessation of breathing, but in breathing high concentrations of carbon dioxide. Not only is air flow through such materials impeded, but the carbon dioxide content rose.

In mid-1991, the researchers concluded: "Accelerated suffocation by rebreathing was the most likely cause of death in most of the 25 infant cases studied. Consequently, there is a need to reassess the cause of death in the 28 to 52 percent of the victims of SIDS who are found with their faces straight down. Safety regulations setting standards for softness, malleability, and the potential for rebreathing are needed for infant bedding."

Obviously, the foregoing findings cannot explain all cases of SIDS, and the findings have not gone unchallenged. See Balding reference listed.

Another avenue of research on SIDS includes that of a medium-chain acyl coenzyme A dehydrogenase deficiency. See Ding reference listed.

The unusual breathing habits of seals also is being investigated for possible leads to causes of SIDS in humans. It has been known for decades that the seal has the ability to hold its breath for long periods of time. Seals halt breathing for several minutes when diving and also when they sleep. A form of sleep apnea in seals is positive in that this slows down their metabolism and conserves energy in the form of blubber. It has been found, however, that breath-holding in baby seals will cause random fluctuations in heart rate. Part of the baby seal's learning process is that of finding how to stabilize its heartbeat during apnea. Researcher M. Castellini (University of California, Santa Cruz) is studying sleep apnea in baby seals in an effort to learn how they overcome the early heart-rate problem; also, this knowledge may provide insights on human SIDS. Another group at the University of Pennsylvania is studying a similar phenomenon that occurs in bulldogs.

SUFFICIENT STATISTIC. A sufficient statistic is one which summarizes all the information in the sample concerning the relevant parameter. Thus if t_0 is a sufficient estimator of a parameter θ, and t_1 is an alternative estimator calculated from the same sample, a combination of t_0 and t_1 (such as their mean) is no better as an estimate of θ than t_0 alone. A sufficient statistic is necessarily efficient.

SUGAR. The two principal sources of sucrose (table sugar, saccharose) are sugarcane, a tropical perennial grass (*Saccharum officinarium*), accounting for slightly over 60% of world sugar production; and the sugar beet, a biennial plant (*Beta vulgaris*), accounting for nearly 40% of world sugar production. Relatively minor commercial sources of saccharose include sorghum and the sugar maple tree (sap). Sucrose also occurs in honey. The basic chemical and physical properties of sucrose, [CAS: 57-50-1] $C_{12}H_{22}O_{11}$, are described in the entry on **Carbohydrates**.

Cane Sugar Manufacture

The amount of sucrose in the natural juice of the cane ranges from 10% to nearly 17% (weight), depending upon the variety, the nature of the growing season, and the time of harvesting. In addition to sucrose, cane juice contains from 1 to 2.5% glucose or reducing sugars. Various nonsugars range from 1 to 3% and are made up of carbohydrate polymers, such as gums, and polysaccharides, such as pectins — plus a number of other substances in small quantities.

Crushing the Cane. Upon receipt of cane at the mill, the stalks are washed and cut into several smaller pieces, after which they are fed to a series (frequently three) roller mills. Three heavy, serrated roller crushers are used for each of these milling operations. Two of the rollers turn in opposite direction, while a third roller guides the flow of the stalks through the crushing operation. Where three sets of mills are used, the adjustment of the spacing between the crushing rollers will be wider for the first mill than the second mill, with the narrowest spacing for the third set of crushing rollers. The fibers are sprayed during crushing with a small amount of maceration water (from 5 to 20% of the weight of the cane). This facilitates extraction of sucrose. In some installations, the juice from the third mill is returned to the first and second mills as maceration water. The concentration of sucrose in juice from the first mill will usually be about 0.2% greater than that from the second mill; that of the third mill will be about 0.5% less than that of the first mill. However, the juice of the third mill will contain greater concentrations of gummy matter and some of the other impurities. The result of the total macerating action, which fully ruptures the plant cells, is a gray- to dark-green, cloudy juice that must be treated to effect a separation of impurities.

Liming and Clarifying. The ancient sugarmakers heated the raw juice and added ashes, causing a precipitation of many of the impurities, but the final product did not approach the purity of cane sugar marketed today which is one of the most highly purified compounds found in commerce. Over the past few centuries, lime has replaced the ashes and, during the past several decades, sulfur dioxide and phosphoric acid or phosphates also

have been added to the total clarifying process. Sulfur dioxide bleach acts as an antimicrobial agent, and assists in the coagulation of such substances as albumin present in the juice. Further, the sulfur dioxide makes it possible to use more lime in the clarifying operation. Lime functions in several ways, forming insoluble compounds with several of the impurities present, neutralizes organic acids present, and when added in sufficient quantity, also reacts with the glucose present, converting it to organic acids. Most of the calcium compounds formed are quite insoluble and thus can be removed by settling or filtration. When phosphoric acid is added, the insoluble tricalcium phosphate is formed. A number of researchers have suggested that phosphates other than phosphoric acid may be preferable. Various sodium, ammonium, potassium, and calcium orthophosphates have been proposed as additives to the sugar solution, along with lime. The control of pH is critical if all lime is to be removed from the juice. Jung (U.S. Patent 3,347,705 issued in 1967) developed the use of polyphosphoric acid in combination with a dicarboxylic acid for the clarification of sugar juices. The primary objection to any excess lime in the solution is later scaling that will be caused in processing equipment.

Upon leaving the crushing mill, the juice is first treated with sulfur dioxide. The design of clarifying equipment has changed much during the past few decades. In earlier installations, the clarifiers were rectangular or circular metal pans, each with a capacity up to 1200 gallons (45 hectoliters). A modern cane juice clarifier or proprietary design is shown in Fig. 1. As shown, the unit is equipped with separate provisions in each compartment for feed, overflow takeoff and mud withdrawal which allows the unit to operate essentially as four totally independent clarifiers enclosed in a common housing. Juice is introduced as the top-center of each compartment through a hollow rotating center tube. This tube is fitted with a series of ports and scalpers that serve as feed introduction points. Located directly below each port, and attached to the center tube, are feed deflection baffles which ensure uniform feeding and impede the natural tendency of the incoming juice to mix with the settled muds. Also attached to the center tube are the various sets of rake arms.

As the feed enters each compartment, it first strikes the deflection baffle, then flows outward at a decreasing velocity creating minimum turbulence. The various sets of rotating rake arms move the settled muds to the mud discharge boot located at the center of each tray. The mud is then withdrawn from each compartment separately. Overflow piping removes the clarified juice from each compartment independently at multiple points around the periphery of the clarifier, through a single overflow box where accurate flow distribution is easily maintained and controlled at one point. Standard capacities of the units range from 10,800 gallons (409 hectoliters) and a mud-thickening area of 312 square feet (29 square meters) to 140,800 gallons (5329 hectoliters) and a mud-thickening area of 4068 square feet (378 square meters).

Evaporation. After clarification and filtration, the juice goes to evaporators (vacuum pans), where upon concentration of the solution, small crystals grain out. Continuous evaporation produces a very thick mixture (*masscuite*), which is a mixture of sugar grains that are suspended in thick molasses. This mixture is centrifuged which throws off most of the molasses, leaving raw sugar, sometimes referred to as *centrifugal sugar*. At this point, the sugar is from 96 to 97% pure. The molasses may be reworked 2 or 3 times more to increase the yield of sugar. Although the remaining molasses may contain up to 50% sugar, the impurities present prevent any further formation of crystals. At this point the residue is called blackstrap and is further treated for use in animal feedstuffs. Molasses is described later.

Cane Sugar Refining. Raw cane sugar mills, as just described, produce the raw sugar. Refiners then further process the raw sugar into the more familiar white crystalline sugar. This 2-stage sugar production process for cane sugar stems from the economics of processing raw sugar in relatively small cane-producing regions and then refining the sugar on a much larger scale, usually thousands of miles closer to the markets. Traditionally, much of the raw sugar was imported from tropical, underdeveloped countries that lacked resources for constructing complete refineries. There are cases,

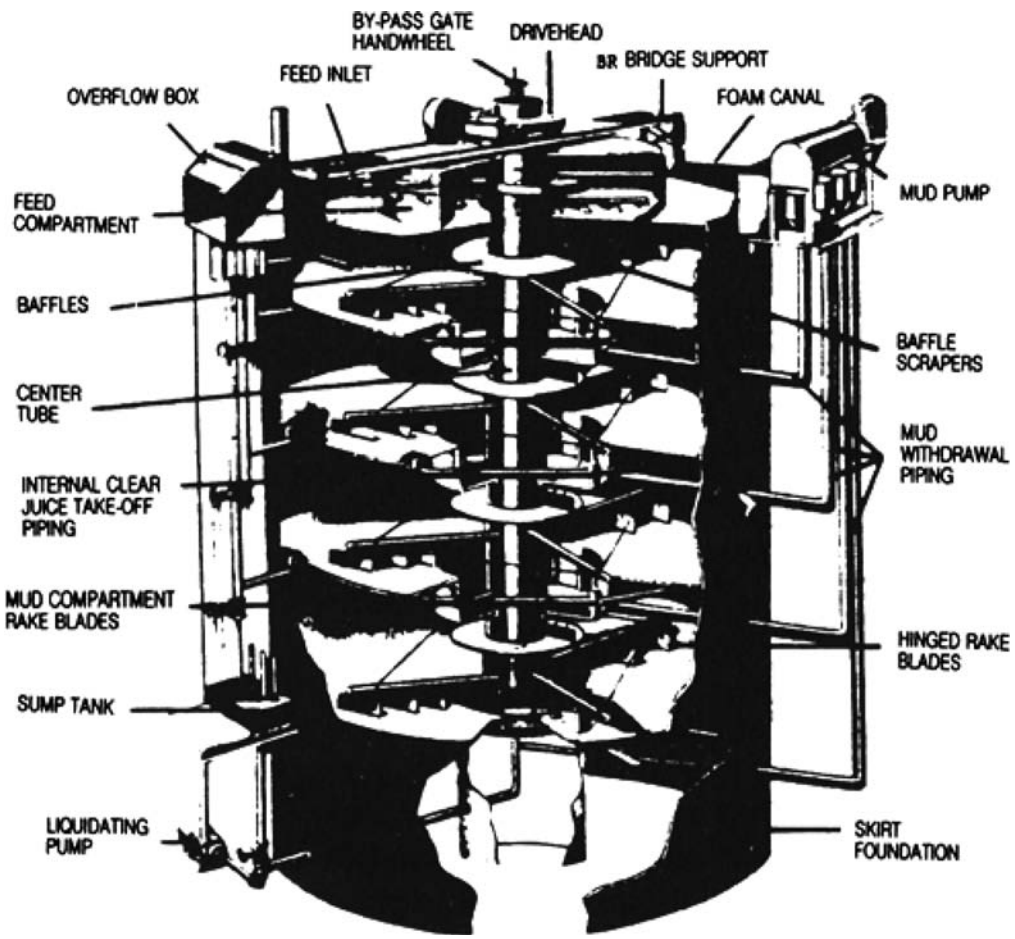

Fig. 1. Modern cane juice clarifier. (*Dorr-Oliver Rapidorr 444™*)

however, where both processing and refining are performed at a single location or where the raw mill and refinery are adjacent and operated under one ownership.

The raw sugar as received at the refinery is mixed with sugar syrup for the purpose of dissolving the molasses residuals which still stick to the crystals. The heavy mixture resulting is sometimes called *magma*. This mix is centrifuged, after which the crystals are steam-treated and at this point are almost white. Again, the sugar crystals are dissolved in sugar syrup and, once again, are treated with lime and phosphoric acid in order to precipitate impurities present. From this operation, the effluent is filtered through bone char to yield a purified solution. Again, the solution is evaporated, crystallized, centrifuged, the final moisture content adjusted, after which the product is packaged.

Beet Sugar Production

The German chemist Marggraf discovered the presence of sugar in beets as early as 1747. Early laboratory methods to extract sugar from the beet proved overwhelmingly costly as contrasted with processing the traditional source, sugar cane. Little progress was made for over a half-century, when in 1802, another German chemist, Achard, found a way to extract sugar from the beet root on a relatively large scale. For a few years, a small manufacturing operation in Silesia prospered, mainly because of political factors that drove up the price of cane sugar. In 1812, Napoleon ordered an establishment of the beet sugar industry in France. Early attempts toward beet sugar extraction were made in the United States (Massachusetts) in 1838, followed by efforts over the subsequent 30 years in Illinois, Wisconsin, and California. The first real success in the United States was achieved in the late 1870s by a factory in Alvardo, California.

The principal operations in sugar beet processing today include thorough washing of the beets, after which whirling knives slice the beets into thin strips, called *cossettes*. These are immersed in hot water where the sugar is removed from the beets by diffusion. The resulting solution is *raw juice*. This juice is purified in a process (carbonation), wherein lime and carbon dioxide are added to cause undesired impurities in the raw juice to precipitate out of the solution (as in the case of cane sugar previously described). This resulting, purified liquid is *thin juice*. Filtering and settling operations remove solid particles and impurities from the thin juice. This juice is concentrated by boiling off water to form *thick juice*. Further filtering ensures that all solid particles are eliminated. Sugar crystals are formed by boiling the thick juice under vacuum. The resulting mixture of crystals and liquid is known as *fillmass*. This mixture is spun and washed in high-speed centrifugals to separate the sugar crystals from the liquid. These crystals are now pure white sugar (sucrose). After further crystallization of the separated liquid, additional sugar and an important by-product (molasses) is obtained. The white sugar crystals are dried by tumbling in warm air in long rotating drums (granulators), after which the sugar is ready for market. The residue of the beets (*pulp*) is sold for livestock feed in either wet or dried form. Some molasses may be added to the pulp prior to drying.

Health and Safety Factors

Sugar is one of the purest foods made, from natural sources, and has never been known to contain any toxic or harmful components. Intensive investigations by the U.S. Food and Drug Administration resulted in a book in 1986 on the health and safety factors of sugar (cane and beet) in the diet.

For many years, there has been concern by medical professionals and nutritionists over the effects of dietary sugar on human health. Sucrose has been implicated as a cause of juvenile hyperactivity, tooth decay, diabetes mellitus, obesity, atherosclerosis, hypoglycemia, and nutrient deficiencies.

In 1986, the FDA's Sugars Task Force assessed the impact of sugar consumption on human health and nutrition and concluded that sucrose is not an independent risk factor for heart disease, nor does it cause or contribute to the development of diabetes. Although diet is important after the onset of diabetes, sucrose can be well tolerated by insulin-dependent diabetics.

Other studies indicate that sucrose does not cause hyperactivity. Carbohydrate ingestion increases levels of serotonin (5-hydroxytryptamine), a brain neurotransmitter that promotes relaxation and sleep. Dietary sucrose should theoretically have a calming effect and reduce activity, manifestations which have been observed in case studies. To date, clinical investigations have failed to show a significant connection between sucrose consumption and aggressive or disruptive behavior.

The rising incidence of obesity has not paralleled sucrose consumption. The FDA Task Force concluded that sugars have no unique role in obesity and that dietary fat rather than carbohydrate is a significant contributor to this condition. However, sugar can promote weight gain in individuals with life-styles marked by excess caloric intake and insufficient exercise.

The notion that complex carbohydrates elicit a gradual, steady secretion of insulin while sugars cause a sudden release of this hormone accompanied by a rapid drop in blood glucose has fostered the belief that hypoglycemia is affected by sucrose ingestion. However, research does not support this conclusion.

The Sugars Task Force's Select Committee on Nutrition and Human Needs recommended a daily consumption of sugars at 10% of total calories, which approximates current (11%) daily intake levels in the United States. At this level, sucrose does contribute to the development of dental caries; however, no firm evidence exists that it causes dietary imbalances or deficiencies of vitamins (qv), minerals, or trace nutrients.

Uses

Sucrose.

Food Applications. On the basis of intake, sucrose is the leading food additive. Its principal contribution to food is sweetness. However, it provides many other functionalities, eg, body, mouthfeel, texture, and moisture retention. Cereals and baked goods are the leading consumers of sucrose, followed closely by confectionery products.

Sucrose helps minimize earthy tastes of vegetables, while enhancing inherent flavors and aromas, and preserving color and texture. Addition of sucrose inhibits enzymatic browning of canned and frozen fruits, and prevents loss of color, flavor, and aroma from fruit during processing.

In baking, chemicals produced from sucrose by yeast contribute to bread flavor and sponginess of the dough; during cooking, reducing sugars formed by sucrose inversion combine with amino acids to form Maillard reaction products called melanoidins that impart brown color to breads, cakes, cookies, and cereals. Sugar raises the gelatinization temperature of starch, so cakes and breads rise more during baking and become softer and lighter. Sucrose also improves moisture retention by baked goods so they remain fresh for longer periods.

Subthreshold levels of sucrose enhance meat flavor; in cured meats, sucrose is a preservative and improves flavor by reducing the salty taste. Similarly, the acidity of condiments is softened by sugar. Sucrose stabilizes protein foams in meringues, and imparts body and smoothness to sauces and puddings. In candy mixes, sucrose raises the cooking temperature and minimizes formation of small sugar crystals during cooling. The reaction of milk proteins with sugars produces the caramel flavor in some candies.

Sucrose is often used as a decorative agent to impart a pleasing appearance to baked goods and confections. In jams and jellies, sugar raises osmotic pressure and lowers water activity to prevent spoilage. Sucrose is a fermentation substrate for lactic acid in cultured buttermilk and lowers the freezing point of ice cream and other frozen desserts to improve product mouthfeel and texture. See also **Sweeteners**.

Feedstock for Chemical Synthesis. It is estimated that <0.5% of the sucrose produced each year is used for nonfood purposes. An alternative application, namely the production of chemicals, is an attractive option as the feedstock is plentiful, renewable, and of consistently high purity. Moreover, the biodegradability of many sucrochemicals makes them environmentally friendly.

Sucrose reacts with fatty acids to produce esters with degrees of esterification (DE) from 1 to 8 and hydrophilic/lipophilic balances that provide them with numerous applications. Sucrose esters are nontoxic and biodegradable, and are approved for use in the EC, Japan, and the United States.

Sucrose monoesters (SMEs) are used as nonionic surfactants, in detergents and as emulsifiers in foods. Some SMEs have bacteriostatic activity and are used to prevent spoilage in beverages. Semperfresh, an SME produced in the U.K., is used as a coating to extend the shelf life of fruits and vegetables.

Sucrose esters of mixed degree of esterification improve flour and starch quality, prevent amylose crystallization in baked goods and help maintain crispiness in cereals and other starch-based snacks. They also prevent sugar crystallization in jams, jellies, and ice cream, and ice crystal growth in frozen desserts. In sugar manufacture, sucrose esters improve sucrose recovery from low grade massecuites. Other sucrose esters are used as alcohol denaturants, plasticizers, lubricants, bleach boosters, and in lacquer, ink, and cosmetic formulations.

Sucrose acrylate derivatives can be converted into polymers and hydrogels that can be used as flocculants, water adsorbents, bioimplantables, and drug delivery devices. Sucrose ethers have applications as surfactants and surface coatings, and as feedstocks for synthesis of polyurethane foams and plastics used for insulation, packaging materials, and wood replacements in furniture. Controlled oxidation of sucrose produces carboxylic acid derivatives used as cross-linking agents and detergent additives.

A chlorination process converts sucrose into sucralose [CAS: 56038-13-2] (4,1′,6′-trichloro-4,1′,6′-trideoxy-galactosucrose), a heat-stable, noncariogenic, noncaloric, high intensity sweetener. Sucralose is approved for food use in Canada, Australia, Russia, and the United States. McNeil Specialities markets sucralose as Splenda.

Several interesting and useful sucrose derivatives are enzymatically synthesized. One of these, called coupling sugar, is a mixture of glucosyl- and maltooligosyl-sucroses formed from starch hydrolysates and sucrose by cyclodextrin-transferase and is used as a noncariogenic sweetener in Japan. Similarly, fructosyloligosaccharides (FOS) are mixtures of fructosyl sucroses made from sucrose by fungal invertases and are used in foods in Japan and Europe. Although less sweet than sucrose, FOSs are noncariogenic and noncaloric, and they promote the growth of beneficial intestinal flora (Bifidobacteria).

Actilight, eg, a mixture of D-glucose, sucrose, and fructooligosaccharides with one to three fructofuranosyl residues linked by way of β-(1 $\rightarrow$ 2) bonds to the fructosyl moiety of sucrose, is commercially produced by microbial fermentation of sucrose using fructosyl transferase enzyme from *Aspergillus niger*. It is marketed by Bighen Meiji. Actilight has obtained GRAS (Generally Regarded as Safe) status in the U.S. It is a recognized food ingredient in Europe.

Fermentation Feedstock. Sucrose, in the form of beet or cane molasses, is a fermentation feedstock for production of a variety of organic compounds, including lactic, glutamic, and citric acids, glycerol, and some antibiotics. Lesser amounts of itaconic, aconitic, and kojic acids, as well as acetone and butanol, are also produced. Rum is made by fermentation of cane molasses. Beet and cane molasses are used for production of baker's and brewer's yeast.

A more abundantly produced substance is ethanol for use in alcoholic beverages, and as a fuel, solvent, and feedstock for organic syntheses. Ethanol production from sucrose is carried out in Europe (eg, France and the Netherlands), India, Pakistan, China, and on a very large scale in Brazil, where it is used as a motor fuel. A valuable by-product of ethanol fermentation is industrial CO_2. See also **Carbon Dioxide**.

The above chemicals can be obtained by fermentation (qv) of other sugars. However, some compounds require sucrose as a unique feedstock. Examples are the polysaccharides dextran, alternan, and levan, which are produced by specific strains of bacteria. Dextrans are used to make chromatographic separation media, and sulfated dextran derivatives are used as plasma extenders. Levans show promise as sweetness potentiators and, along with alternan, have potential as food thickeners and bulking agents in reduced-caloric foods. See also **Carbohydrates**.

Pharmaceutical Applications. Sucrose has a long history in the manufacture of pharmaceuticals. It imparts body to syrups and medicinal liquids and masks unpleasant tastes. Sucrose also functions as a diluent to control drug concentrations in medicines, as an ingredient binder for tablets, and to impart chewiness to the latter. Sustained-release medications and protective tablet glazes are prepared using sucrose. Sucrose-based sugar pastes are used to promote wound healing.

Sucralfate [CAS: 54182-58-0], an aluminum salt of sucrose octasulfate, is used as an antacid and antiulcer medication. Bis- and tris-platinum complexes of sucrose show promise as antitumor agents. Sucrose monoesters are used in some pharmaceutical preparations. A sucrose polyester is under evaluation as a contrast agent for magnetic resonance imaging (mri). Oral administration of this substance opacifies the gastrointestinal tract and eliminates the need for purging prior to mri.

Cane Sugar Products. There are many variations on crystalline cane sugar from refineries, in addition to the direct production and noncentrifugal sugars described above.

Refined granulated sugar is the principal output of a cane sugar refinery. The particle size of the refined granulated sugar for table use varies from region to region. Different particle sizes have different names and are not standardized. Particle size is specified by the buyer, usually at a price premium. North American fine granulated averages 0.2–0.3-mm grain size, whereas standard European fine granulated averages 0.5–0.6 mm. Sugar of standard U.S. crystal size is known as caster sugar in the United Kingdom. Sugar crystals are separated into four to eight size groups by a series of vibrating screens, after the driers in the refinery.

Large-grain specialty sugars are used for candy and cookies. White large-grain sugar can be made only from the very purest of liquors; therefore, customers interested in the best sugar specify coarse grain. The highest quality best sugar is made by redissolving large-grain sugar and recrystallizing.

Powdered sugar is made by grinding granulated sugar and adding 3% corn starch (in the United States) to help prevent caking. The fineness is designated by labels such as 4X, 6X, 10X. However, the label is misleading; 12X is not twice as fine as 6X. In other countries, calcium phosphate, or maltodextrins are used as hygroscopic additives.

Cubes are made by mixing a syrup with granulated sugar to the right consistency to form cubes. These are then dried. The process is expensive and the price of cubes is high relative to ordinary granulated sugar. Production of the cube is much greater in Europe and the Middle East than in North America. Many variations on the cubing process exist, from cutting up slabs of solidified sugar (the hardest cubes) to pressing and drying in various types of cube molds. Infrared drying is an effective modern addition. See also **Syrups**.

Liquid sucrose and liquid invert, generally made by redissolving white sugar and inverting with invertase enzyme, are refinery products in Europe and outside the United States. In the United States they have been almost completely replaced by cheaper corn syrups made by enzymatic hydrolysis of starch and isomerization of glucose.

Brown sugar, including light and dark brown and occasional intermediate grades, comprises only a small part of the output of most refiners, ranging from only 3% in warm climates to perhaps 10% in cold regions. The area of highest brown sugar consumption in the world is British Columbia, Canada, where brown sugar accounts for 20% of total use. In this region, a favorite is a distinctly yellow sugar.

Specialty Sugars. Specialty sugars do not seem to be tightly defined either in the United States or Europe. Since there are no official definitions, the products can be whatever the manufacturer wants them to be as long as they have the generally expected appearance. They do, however, are considered by health food devotees as more natural than refined sugar and considered to have a higher iron and nutrient content.

Demerara Sugar. This sugar is named from the Demerara area of Guyana, South America, from which it originally came. It is often described as a natural, unrefined cane sugar. It is a light brown sugar with large, lightly sticky crystals. Maruitius is the major supplier. It is very popular for tea and coffee in England, Australia, and Canada. It is not well known in the U.S.

Muscovado Sugar. This sugar is very dark brown with a strong molasses flavor. The crystals are larger than brown sugar, but not as large as turbinado or demerara sugar. The flavor is said to be strong, deep, dark, etc. Muscovado is an old term that was synonymous with raw sugar. Barbados sugar is a term often used as a synonym for muscovado sugar.

Turbinado Sugar. This sugar is partially refined raw sugar from which some of the molasses film has been removed. Its color ranges from golden to brown with large crystals and a mild, cane flavor.

Brown sugar is not raw sugar, but rather, as its manufacture is described herein (crystallization), it is refined. The difference between raw sugar and brown sugar is not so much the sucrose content, the color, or taste, but rather the absence of field soil, cane fiber, bacteria, yeasts, molds, and insect parts which may be present in raw sugars.

Other Products. Other products from sugarcane, in addition to cane sugar, are cane fiber (known as bagasse) and molasses, the final thick syrup from which no more sugar may be economically removed by crystallization. In some cane-growing countries, cane tops and leaves, separated during harvest, are used for cattle feed.

Bagasse. Cane fiber comes from a standard mill or diffuser at 50–55% moisture, and in most countries is used as fuel for the factory. In the People's Republic of China and some parts of India, sugarcane factories burn low grade coal, because wood is in short supply and bagasse fiber is used for paper or board manufacture. Excess bagasse is burned for cogeneration, or to run a refinery or distillery. Bagasse is also used in paper manufacture, for all grades from coarse brown to newspaper to fine papers, depending on other fibers and processing used. Some 7×10^6 t are used annually for pulp production for papers, particle boards, and fiber boards of various grades and durabilities. Bagasse has been used as a cellulose source for single cell protein production, and as animal feed. Feed quality is improved by steam hydrolysis/sodium hydroxide treatment of bagasse fiber. In the Dominican Republic, the United States, South Africa, and several countries in South America and Asia, bagasse, which contains 85–95% xylose, is treated by steam hydrolysis and subsequent dehydration to produce furfural; an estimated 90,000 t furfural is produced annually in this manner. Diacetyl (artificial butter flavor) is a by-product of this process in South Africa.

Molasses. The final molasses product from sugarcane factories is blackstrap molasses, containing 25–35% sucrose and 8–15% each glucose and fructose. Because of the high mineral (primarily KCl) and browning polymer content, blackstrap is too bitter for human consumption; most is used for animal feed, alone or as an ingredient, and it is traded in international commerce for this purpose. Refinery molasses, and blends of both factory and refinery with various lighter syrups, are the sources of a wide range of food-grade molasses, known as treacle in Europe. Molasses is fermented to ethanol at sugarcane factories in almost all cane-growing areas outside the United States, for industrial alcohol. Molasses is the basis for almost all rum production (some rum is produced directly from sugarcane juice in the French-speaking Caribbean), and for other beverage alcohol, in Asian countries. Molasses has been used as a carbon source in a multitude of chemical and microbial reactions; it is usually the sugars in molasses that serve as the carbon source; hence, these products are included herein. Chemical and fermentation reactions can cause problems in storage, if molasses is put into storage too hot: it should always be at a temperature under 45 °C (113 °F).

High test molasses is not a residual material, but cane juice, sometimes partly clarified, concentrated by evaporation, with at least half its sucrose hydrolyzed to invert (glucose and fructose) by heating at the low juice pH (5.5).

Condensed molasses solubles (CMS) is a product made by drying molasses (spray or drum drying) on a neutral carrier; CMS is a more portable and storable form of molasses for animal feed.

Special Sugars

Although sucrose is commercially the most important sugar, there are also special sugars with special applications, among which fructose is the most important. See also **Fructose**; **Maltose**; and **Lactose**.

SUGAR ALCOHOLS. The sugar alcohols bear a close relationship to the simple sugars from which they are formed by reduction and from which their names are often derived. See also **Carbohydrates**. The polyols discussed herein contain straight carbon chains, each carbon atom usually bearing a hydroxyl group. Also included are polyols derived from disaccharides. Most of the sugar alcohols have the general formula $HOCH_2(CHOH)_n-CH_2OH$, where $n = 2–5$. They are classified according to the number of hydroxyl groups as tetritols, pentitols, hexitols, and heptitols. Polyols from aldoses are sometimes called alditols. Each class contains stereoisomers. Counting meso and optically active forms, there are three tetritols, four pentitols, ten hexitols, and sixteen heptitols, all of which are known either from natural occurrence or through synthesis (Fig. 1). Of the straight-chain polyols, sorbitol [CAS: 50-70-4] and mannitol [CAS: 87-78-5] have the greatest industrial significance. However, maltitol [CAS: 585-88-6], isomalt [CAS: 64519-82-0], and xylitol [CAS: 87-99-0] are finding increasing acceptance in applications in the United States and Canada. See also **Sweeteners**.

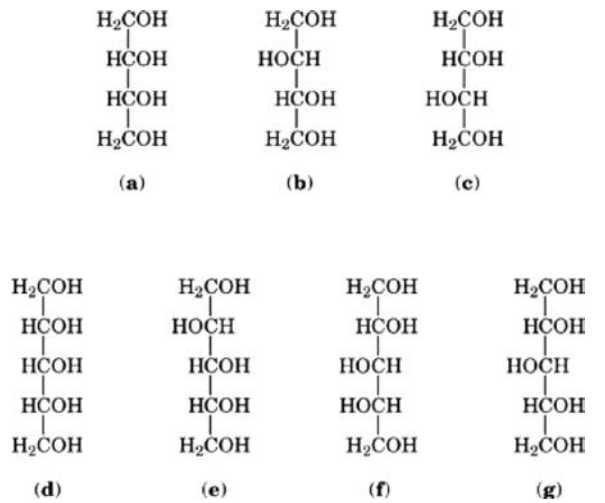

Fig. 1. Structures of the tetritols (**a**) erythritol, (**b**) D-threitol, and (**c**) L-threitol; and the pentitols (**d**) ribitol, (**e**) D-arabinitol, (**f**) L-arabinitol, and (**g**) xylitol

Physical Properties. In general, these polyols are water-soluble, crystalline compounds with small optical rotations in water and a slightly sweet to very sweet taste. Selected physical properties of many of the sugar alcohols are listed in Table 1.

Occurrence. D-Arabinitol (lyxitol [CAS: 488-82-4]) (Fig.1e) is found in lichens; in a variety of fungi; in the urediospores of wheat stem rust; in the dried herbiage of the Peruvian shrub, pichi, along with D-mannitol, dulcitol, and perseitol; and in the avocado. It is formed by fermentation of glucose and in 40% yields using blackstrap molasses. D-Arabinitol

TABLE 1. PHYSICAL PROPERTIES OF THE SUGAR ALCOHOLS

Sugar alcohol	CAS Registry Number	Melting point, °C	Optical activity in H_2O, $[\alpha]_d^{20-25}$	Solubility g/100 g H_2O[a]	Heat of solution, J/g[b]

is formed by catalytic hydrogenation of D-arabinose in the presence of Raney nickel and from the γ-lactones of D-arabinonic and D-lyxonic acids by reduction with sodium borohydride [CAS: 16940-66-2]. L-Arabinitol (Fig. 1f) is synthesized by the reduction of L-arabinose which is abundant in nature.

D, L-Arabinitol can be prepared by the action of hydrogen peroxide in the presence of formic acid on divinyl carbinol and, together with ribitol (Fig. 1d), from D, L-erythron-4-pentyne-1,2,3-triol.

Xylitol (Fig. 1g) is found in the primrose and in minor quantity in mushrooms. It can be obtained from glucose in 11.6% overall yield by a sequential fermentation process through D-arabinitol and D-xylulose [CAS: 551-84-8].

Xylitol is synthesized by reduction of D-xylose catalytically, electrolytically, and by sodium amalgam. D-Xylose is obtained by hydrolysis of xylan [CAS: 9014-63-5] and other hemicellulosic substances obtained from such sources as wood, corn cobs, almond shells, hazelnuts, or olive waste. Isolation of xylose is not necessary; xylitol results from hydrogenation of the solution obtained by acid hydrolysis of cottonseed hulls.

Xylitol also is obtained by sodium borohydride reduction of D-xylonic acid γ-lactone and from glucose by a series of transformations through diacetone glucose.

Sorbitol (D-glycitol) (Fig. 2b) was discovered initially in the fresh juice of mountain ash berries in 1872. It is found in the fruits of apples, plums, pears, cherries, dates, peaches, and apricots; in the exudate of flowers of apples, pears, and cherries; and in the leaves and bark of apples, plums, prunes, the genus *Fraxinus*, and the genus *Euonymus*. Small amounts are found in the plane tree, the African snowdrop tree, and in various algae. Because sorbitol occurs to a very small extent in grapes, assay of the sorbitol content of wine has been used to detect its adulteration with other fruit wines or apple cider. An anhydride of sorbitol, polygallitol (1,5-sorbitan), is found in the *Polygala* shrub. Sorbitol occurs in the overwintering eggs of the European red mite, the latter affording it protection against freezing. See also **Grapes and Wines**.

Sorbitol is synthesized commercially by high pressure hydrogenation of glucose, usually using a nickel catalyst. To form sorbitol, glucose is usually hydrogenated in the pH range of 4–8. Under alkaline conditions, glucose isomerizes to fructose and mannose; hydrogenation of the fructose and mannose yields mannitol as well as sorbitol. In addition, under alkaline conditions the Cannizzaro reaction occurs and sorbitol and gluconic acid are formed. Gluconic acid [CAS: 526-95-4] formation during hydrogenation can be minimized if anion exchange resins in the basic form are the source of alkalinity. Although aqueous solutions are customarily used, the monomethyl ethers of ethylene glycol [CAS: 107-21-1] or diethylene glycol [CAS: 111-46-6] are satisfactory solvents. Electrolytic reduction of glucose was used formerly for the manufacture of sorbitol. Both the γ- and δ-lactones of D-gluconic acid may be reduced to sorbitol

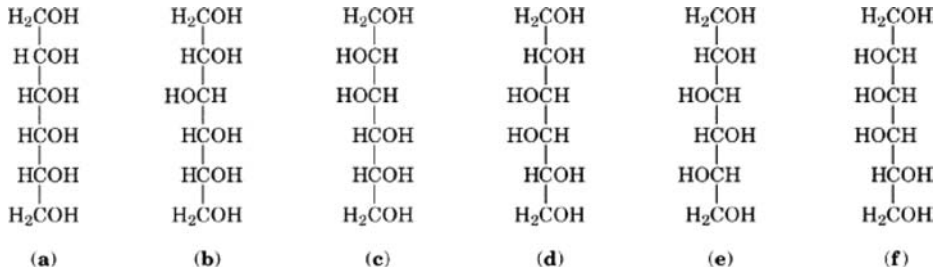

Fig. 2. Structures of hexitols (a) allitol, (b) sorbitol (D-glucitol), (c) D-mannitol, (d) dulcitol, (e) L-iditol, and (f) D-altritol

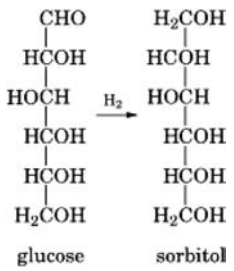
by sodium borohydride. Sorbitol results from simultaneous hydrolysis and hydrogenation of starch, cotton cellulose, or sucrose. See also **Sweeteners**.



D-Mannitol is widespread in nature. It is found to a significant extent in the exudates of trees and shrubs such as the plane tree (80–90%), manna ash (30–50%), and olive tree. The manna ash, *Fraxinus rotundifolis*, formerly was cultivated in Sicily for the mannitol content of its sap. Mannitol occurs in the fruit, leaves, and other parts of various plants. This hexitol is present in pumpkin, hedge parsley, onions, celery, strawberries, the genus *Euonymus*, the genus *Hebe*, the cocoa bean, grasses, lilac, *Digitalis purpurea*, mistletoe, and lichens. Mannitol occurs in marine algae, especially brown seaweed, with a seasonal variation in mannitol content which can reach over 20% in the summer and autumn. It is found in the mycelia of many fungi and is present in the fresh mushroom to the extent of about 1.0%. There is a direct relation between mushroom yield and mannitol content. Microbial formation of D-mannitol occurs with fungi or bacteria, starting with glucose, fructose, sucrose, or the tubers of Jerusalem artichokes. The precursor of mannitol in its biosynthesis in the mushroom *Agaricus bisporus* is fructose. Mannitol is produced from glucose in 44% yield after six days by aerobic fermentation with *Aspergillus candidus* and in 30% yield after 10 days with *Torulopsis mannitofaciens*. It is formed by submerged culture fermentation of fructose with *Penicillium chrysogenum* in 7.3% conversion. Using sodium acetate as the sole carbon source, *Aspergillus niger* forms D-mannitol as well as D-arabinitol, erythritol, and glycerol. Small quantities of mannitol are found in wine.

Reduction of D-mannose with sodium borohydride or electrolysis leads to D-mannitol in good yield. Reduction of fructose leads to sorbitol and D-mannitol in equal parts. Sucrose, on reduction under hydrolyzing conditions, also yields the same products in the ratio of three parts of sorbitol to one of D-mannitol. Commercially, D-mannitol is obtained by the reduction of invert sugar. In alkaline media, glucose, fructose, and mannose are interconverted. All of the mannose formed can be reduced to mannitol. Mannitol can be prepared by hydrogenation of starch hydrolyzates in alkaline media in the presence of Raney nickel.

L-Mannitol does not occur naturally but is obtained by the reduction of L-mannose or L-mannonic acid lactone. It can be synthesized from the relatively abundant L-arabinose through the L-mannose and L-glucose cyanohydrins, conversion to the phenylhydrazines which are separated, liberation of L-mannose, and reduction with sodium borohydride. Another synthesis is from L-inositol (obtained from its monomethyl ether, quebrachitol) through the diacetonate, periodate oxidation to the blocked dialdehyde, reduction, and removal of the acetone blocking groups.

D, L-Mannitol has been obtained by sodium amalgam reduction of D, L-mannose. The identical hexitol is formed from the formaldehyde polymer, acrose, by conversion through its osazone and osone to D, L-fructose (α-acrose) followed by reduction.

Dulcitol (galactitol) is found in red seaweed, in shrubs of the *Euonymus* genus, the genus *Hippocratea*, the genus *Adenanthera*, the physic nut, the parasitic herb *Cuscuta reflexa*, and in the mannas from a wide variety of plants. It is produced by the action of yeasts and is found in beer. D-Galactose is reduced to dulcitol catalytically, electrolytically, and chemically. Reduction of hydrolyzed lactose leads to the formation of both dulcitol and sorbitol. Dulcitol, which is relatively insoluble, is isolated by crystallization from the aqueous reduction mixture. Prehydrolysates of larch wood, which contain large quantities of galactose [CAS: 59-23-4] as well as glucose [CAS: 50-99-7], arabinose [CAS: 147-81-9], and xylose [CAS: 31178-70-8], can be simultaneously hydrolyzed and hydrogenated to a product containing 80% dulcitol, affording a pure product after repeated crystallization. Dulcitol is formed together with D-galactonic acid [CAS: 576-36-3] by treatment of D-galactose with alkali in the presence of Raney nickel. Reduction of D-galactonic acid γ-lactone with sodium borohydride leads to dulcitol. Photolysis of 1-deoxy-1-*S*-ethyl-1-thio-D-galactitol, and its sulfoxide in methanol forms dulcitol. Oxidation of a mixture and meso and racemic 1,5-hexadiene-3,4-diol with hydrogen peroxide and formic acid (trans addition of hydroxyl) leads predominantly to dulcitol, with some D, L-iditol.

Maltitol (4-*O*-α-D-glucopyranosyL-D-glucitol) formed by catalytic hydrogenation of maltose, has been obtained both as a noncrystalline powder and a viscous liquid. Structures of disaccharide alcohols are shown in Figure 3.

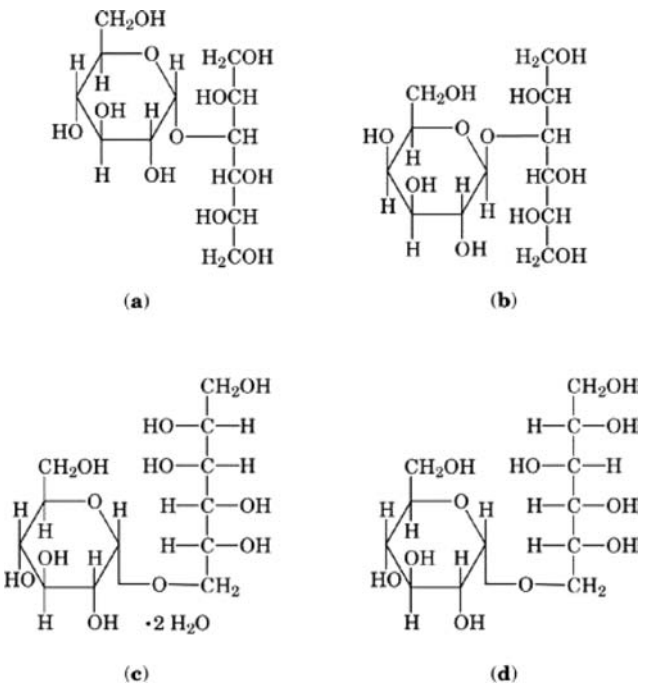


Fig. 3. Structures of disaccharide alcohols (a) maltitol, (b) lactitol, (c) α-D-glucopyranosyL-1,1-D-mannitol(dihydrate), and (d) α-D-glucopyranosyL-1,6-D-sorbitol

Lactitol (4-*O*-β-D-galactopyranosyL-D-glucitol) is obtained by sodium borohydride reduction or catalytic hydrogenation of lactose. Potentially

large quantities of this sugar alcohol are available from lactose obtained from whey.

Isomalt, a mixture of α-D-glucopyranosyL-1,1-D-mannitol dihydrate and α-D-glucopyranosyL-1,6-D-sorbitol, is obtained by hydrogenating isomaltulose which is enzymatically derived from sucrose.

Hydrogenated starch hydrolysates (HSH) is a term used to describe a range of products which do not contain sorbitol or maltitol as a primary component, i.e., at least 50%. HSH syrups contain a distribution of sorbitol, maltitol, and other hydrogenated oligo and polysaccharides. Syrups containing maltitol at a level of at least 50% are referred to as Maltitol syrups or Maltitol solutions.

Chemical Properties

Anhydrization. The sugar alcohols can lose one or more molecules of water internally, usually under the influence of acids, to form cyclic ethers. Nomenclature is illustrated by the hexitol derivatives. Monoanhydro internal ethers are called hexitans, and the dianhydro derivatives are called hexides. The main dehydration involves loss of water from the primary hydroxyl groups and the resulting formation of tetrahydrofuran derivatives having the configuration of the starting alditol.

Esterification. Both partial and complete esters of sugar alcohols are known. The most important method for the preparation of partial fatty esters involves the interaction of polyols and fatty acids at 180–250°C (356–482°F). During direct esterification of the sugar alcohols, anhydrization occurs to varying degrees depending upon the conditions. Thus, esterification of sorbitol with stearic acid [CAS: 57-11-4] leads to a mixture of stearates of sorbitan and isosorbide as well as of sorbitol. Unanhydrized esters may be prepared by reaction with acid anhydrides or acid chlorides or by ester interchange reactions. In general, use of an excess of these reagents leads to esterification of all hydroxyl groups.

Etherification. The reaction of alkyl halides with sugar polyols in the presence of aqueous alkaline reagents generally results in partial etherification. Thus, a tetraallyl ether is formed on reaction of D-mannitol with allyl bromide in the presence of 20% sodium hydroxide at 75°C (167°F). Treatment of this partial ether with metallic sodium to form an alcoholate, followed by reaction with additional allyl bromide, leads to hexaallyl D-mannitol. Complete methylation of D-mannitol occurs, however, by the action of dimethyl sulfate [CAS: 77-78-1] and sodium hydroxide[CAS: 1310-73-2]. A mixture of tetra- and pentabutyloxymethyl ethers of D-mannitol results from the action of butyl chloromethyl ether. Completely substituted trimethylsilyl derivatives of polyols, distillable *in vacuo,* are prepared by interaction with trimethylchlorosilane in the presence of pyridine. Hexavinylmannitol is obtained from D-mannitol and acetylene at 25.31 MPa (250 atm) and 160°C (320°F).

Reaction of olefin oxides (epoxides) to produce poly(oxyalkylene) ether derivatives is the etherification of polyols of greatest commercial importance. Epoxides used include ethylene oxide, propylene oxide, and epichlorohydrin. The products of oxyalkylation have the same number of hydroxyl groups per mole as the starting polyol.

Acetal Formation. In common with other glycols, the sugar alcohols react with aldehydes and ketones to yield cyclic acetals and ketals. Five-membered rings are formed from adjacent hydroxyls and six-membered rings result from 1,3-hydroxyls. From the hexitols, mono-, di-, or triacetals or ketals may be obtained. Acetal formation is extensively used to protect hydroxyl groups during transformations in the polyol and carbohydrate series since conditions for the formation and removal of cyclic acetal linkages are relatively mild and proceed without inversion of configuration at asymmetric centers.

Oxidation. Sorbitol is oxidized by fermentation with *Acetobacter suboxydans* to L-sorbose, an intermediate in the synthesis of ascorbic acid (Vitamin C) [CAS: 50-81-7]. See also **Ascorbic Acid (Vitamin C)**. The same organism, *Acetobacter xylinium* and related bacteria convert erythritol to L-erythrulose, D-mannitol to D-fructose, and allitol to L-ribohexulose. These results are generalized in the case of the more specific *Acetobacter suboxydans* by the Hudson-Bertrand rules which state that in a *cis*-glycol having a D-configuration, a secondary hydroxyl adjacent to a primary hydroxyl is oxidized to a ketone.

Reduction. Sorbitol and mannitol are each converted by the action of concentrated hydriodic acid to secondary iodides (2- and 3-iodohexanes). The results of this reduction were used in early proofs of structure of glucose and fructose. Catalytic hydrogenolysis of the polyols results in breaking of both carbon-to-carbon and carbon-to-oxygen bonds. Thus, hydrogenolysis of sorbitol leads to the formation of ethylene glycol, propylene glycol, glycerol, erythritol, and xylitol. Ethylene glycol, propylene glycol, glycerol, erythritol, and monohydric alcohols are formed by the hydrogenolysis of xylitol.

Metal Complexes. The sugar alcohols form complexes in solution with most metal ions. In aqueous solution, calcium [CAS: 7440-70-2], strontium [CAS: 7440-24-6], and barium [CAS: 7440-39-3] are more strongly complexed than are sodium [CAS: 7440-23-5], potassium [CAS: 7440-09-7], and magnesium [CAS: 7439-95-4]. Solid magnesium complexes of sorbitol and other polyols are prepared with magnesium ethoxide [CAS: 2414-98-4]; sorbitol alcoholate complexes of sodium and lithium [CAS: 7439-93-2] precipitate from anhydrous ethanol. Polyol and carbohydrate complexes of alkali and alkaline earth metals have been reviewed. The stability of some polyol metal complexes is such that precipitation of the metal hydroxide from solution is inhibited. Thus, addition of sorbitol or D-mannitol to an aqueous solution of sodium ferric tartrate prevents precipitation of ferric oxide [CAS: 1309-37-1]; D-mannitol prevents precipitation of titanium(IV) hydroxide, and at pH values above 12, precipitation of calcium, strontium, and cupric hydroxides is partially inhibited by sorbitol. Copper [CAS: 7440-50-8], iron [CAS: 7439-89-6], and cobalt [CAS: 7440-48-4] all complex with cellobiitol. Tetritols, pentitols, and hexitols complex with copper in aqueous solutions of both cupric acetate and basic cupric acetate. Separation of mannitol from a mixture with dulcitol (resulting from reduction of wood sugar mixtures containing mannose and galactose) is achieved by selective complexation of dulcitol with ferric salts. See also **Chelates and Chelation**.

Analysis

Analytical separation of the sugar alcohols from each other and from similar materials, such as carbohydrates, is done chromatographically. See also **Chromatography**. Sorbitol, for example, is readily separated from glycerol, erythritol, and other polyols by chromatography on paper using butanol–water as developing solution, and on thin layers of silicic acid [CAS: 7699-41-4] using butanol–acetic acid–ethyl ether–water as developing solution. Improved separations of sugar alcohols and carbohydrates have been obtained by including boric acid [CAS: 11113-50-1] or phenylboronic acid [CAS: 98-80-6] in the solvent, thereby forming esters with the polyols. Paper electrophoresis of polyols and carbohydrates in molybdate, tellurate, germinate, or stannate also enables the obtaining of some useful separations. Although polyols and carbohydrates can be separated by column chromatography on silicate absorbents, partition chromatography on ion exchange resins is of particular value for quantitative separations of these classes of materials. Use of cation exchange resins in the lithium form and anion exchange resins in the sulfate or molybdate form permit the separation of pentitols, hexitols, heptitols, and disaccharide alcohols as well as related carbohydrates. See also **Ion Exchange**; and **Ion-Exchange Resins**. Direct gas chromatographic determination of free sugar alcohols in biological media such as fermentation cultures has been reported. A mixture of glycerol, erythritol, D-arabinitol, and xylitol can be separated and each polyol determined by this procedure. Erythritol and other sugar alcohols are used as stationary phases for the gas chromatographic separation of volatiles in beer and wine. See also **Beer and Other Malt Beverages**; **Grapes and Wines**; and **Fermentation**.

The sugar alcohols can be determined by periodate oxidation, followed by measurement of the formaldehyde [CAS: 50-00-0] or formic acid [CAS: 64-18-6] liberated or titration of the excess periodate. Small quantities of sorbitol in biological fluids have been determined by this method. Measurement of the heat liberated in periodate oxidation of sorbitol in foodstuffs is the basis of a thermometric determination. Sorbitol is determined in wine and vinegar by precipitation with *o*-chlorobenzaldehyde forming the tris(*o*-chlorobenzylidene) derivative. Sugar alcohols may be analyzed colorimetrically after reaction with *p*-hydroxybenzaldehyde [CAS: 123-08-0] or *p*-dimethylaminobenzaldehyde [CAS: 100-10-7], thiourea [CAS: 62-56-6], and concentrated sulfuric acid [CAS: 7664-93-9]. After complexation with copper, sorbitol and mannitol are determined by iodometric titration of excess cupric ion. Enzymatic assays have been described for several polyols, including sorbitol, ribitol, and erythritol. Although nonspecific, one

of the most valuable procedures for the quantitative analysis of polyols is the determination of hydroxyl number. This method involves reaction with acetic anhydride, followed by measurement of the acetic acid liberated.

Manufacture of Sorbitol, Mannitol, and Xylitol

Sorbitol is manufactured by catalytic hydrogenation of glucose using either batch or continuous hydrogenation procedures. Corn sugar is the most important raw material, but other sources of glucose, such as hydrolyzed starch, also may be used. Both supported nickel and Raney nickel are used as catalysts. See also **Starch**; and **Sugar**. In the continuous procedure, a 50% solution of dextrose in water is prepared and transferred to a mixing tank. The catalyst, nickel on diatomaceous earth, is added to the glucose solution and the resulting slurry is pumped to the reactor after being heated to about 140°C (284°F). Hydrogen is introduced into the reactor at a pressure of approximately 12.7 MPa (125 atm) concurrently with the sugar solution. Spent catalyst is collected on a filter and is separately regenerated for reuse. The sorbitol solution is purified in two steps: (*1*) by passage through an ion-exchange resin bed to remove gluconate as well as other ions, and (*2*) by treatment with activated carbon to remove trace organic impurities. The solution of pure sorbitol is concentrated in a continuous evaporator to a solution containing 70% solids, which is sold under the trademark SORBO (a registered trademark of SPI Polyols, Inc.), meeting USP 23 standards. Crystalline sorbitol is obtained by further concentration and crystallization. It is sold in a variety of particle-size distributions, the one chosen depending on the application. See also **Crystallization**.

When invert sugar is used as a starting material, sorbitol and mannitol are produced simultaneously. Mannitol crystallizes from solution after the hydrogenation step owing to its lower solubility in water. It is sold as a white, crystalline powder or free-flowing granules (directly compressible grades) meeting USP 23 standards.

Extraction of mannitol from seaweed is a method of lesser importance commercially. In one method starting with this source, whole seaweed is steeped at 20°C (68°F) in water which has been acidified to pH 2 with sulfuric acid. After filtration, the extract is neutralized and made alkaline with lime, precipitating calcium and magnesium sulfates together with some colloids. The filtrate or centrifugate from this operation is dialyzed; mannitol and mineral salts pass through the semipermeable membrane. The dialyzate is concentrated and mannitol crystallizes from solution on cooling. If the weight ratio of mannitol to alkali chlorides in the dialyzate is less than 1, this ratio is attained by addition of pure mannitol before crystallization is begun.

Xylose is obtained from sulfite liquors, particularly from hardwoods, such as birch, by methanol extraction of concentrates or dried sulfite lyes, ultrafiltration and reverse osmosis, ion exchange, ion exclusion, or combinations of these treatments. Hydrogenation of xylose is carried out in aqueous solution, usually at basic pH. See also **Reverse Osmosis**; and **Ultrafiltration**.

Biological Properties

Toxicity. Sugar alcohols are classified as relatively harmless.

Laxation Tresholds. All sugar alcohols have the potential to cause diarrhea or flatulence owing to their slow absorption from the small intestine. Sorbitol and mannitol have laxation thresholds of 50 and 20 g/d, respectively, and where it is reasonably foreseeable that consumption will exceed these levels, foods must bear the statement "Excess consumption may have a laxation effect", per 21 CFR 184.1835 (Sorbitol) and 180.25 (mannitol). Maltitol, isomalt, lactitol, maltitol solution (syrup), and hydrogenated starch hydrolysates (HSH) are reported by manufacturers to have laxation thresholds of 100 g/d, 50 g/d, 20 g/d, 75 g/d, and 75 g/d, respectively.

Blood Glucose and Insulin Response. In humans, ingestion of sugar alcohols has shown a significantly reduced rise in blood glucose and insulin response, owing to slow absorption by the body. As a result, many foods based on sugar alcohols have been used safely in the diets of diabetics.

Absorption of mannitol, sorbitol, and xylitol from the intestinal tract is relatively slow, compared to that of glucose. In humans, approximately 65% of orally administered mannitol is absorbed in the dose range of 40–100 g. About one-third of the absorbed mannitol is excreted in the urine. The remainder is oxidized to carbon dioxide.

Anticariogenicity. Sugar alcohols are not fermented to release acids that may cause tooth decay by the oral bacteria which metabolize sugars and starches. As a result, use of sugar alcohols in sugar-free chewing gum, pressed mints, confections, and toothpaste has been widely accepted.

Caloric Values. Absorption and metabolism data for each of the sugar alcohols has been reviewed by the Federation of American Societies for Experimental Biology (FASEB) **http://www.faseb.org/.**Caloric values are lower than 4 cal/g (16.7 J/g), the caloric value of sugar. The values reported for each of the sugar alcohols are sorbitol, 2.6 cal/g (10.9 J/g); mannitol, 1.6 cal/g (6.7 J/g); maltitol, 3.0 cal/g (12.6 J/g); lactitol, 2.0 cal/g (8.4 J/g); isomalt, 2.0 cal/g (8.4 J/g); xylitol, 2.4 cal/g (10.0 J/g); and hydrogenated starch hydrolysate (HSH), 3.0 cal/g (12.6 J/g).

See also **Calorie Control Council: http://www.caloriecontrol.org/index.html**.

Uses

The hexitols and their derivatives are used in many fields, including foods, pharmaceuticals, cosmetics, textiles, and polymers.

Aqueous sorbitol solutions are hygroscopic and are used as humectants, softeners, and plasticizers in many different types of formulation. The hygroscopicity of sorbitol solutions is less than that of glycerol but greater than that of sugar solutions. In crystalline form, sorbitol does not absorb moisture greatly below the level of about 70% relative humidity. Above this level, sorbitol is deliquescent and dissolves in absorbed water. Mannitol is considerably less hygroscopic in its crystalline form. Many applications of mannitol take advantage of its low hygroscopicity and its resistance to occlusion of water.

Sweetness is often an important characteristic of sugar alcohols in food and pharmaceutical applications. The property of sweetness is measured in a variety of ways and has a corresponding variability in ratings. Based on one or more test methods, erythritol and xylitol are similar to or sweeter than sucrose. Sorbitol is about 60% as sweet as sucrose, and mannitol, D-arabinitol, ribitol, maltitol, isomalt, and lactitol are generally comparable to sorbitol. See also **Sweeteners**.

The partial fatty acid esters of the hexitols, usually anhydrized, find extensive use in surface-active applications, such as emulsification, wetting, detergency, and solubilization. Anhydrized sorbitol or mannitol moieties are versatile building blocks which confer hydrophilic properties on surfactants containing them. The less expensive sorbitol derivatives are used more extensively than the analogous mannitol compounds. Fatty acid esters of hexitans tend to be oiL-soluble and to form water-in-oil (w/o) emulsions. Hydrophilic character of sorbitan fatty esters is enhanced by attachment of poly(oxyethylene) chains. As the poly(oxyethylene) chain length is increased, the tendency for water-solubility increases and oiL-solubility decreases. Hexitan fatty esters having long poly(oxyethylene) chains tend to form o/w emulsions.

SUGARCANE. A tall tropical perennial grass (*Saccharum officinarium*) and the source of over half of the world's supply of sucrose (table sugar, saccharose), the major sweetener for foods and beverages. The remaining

sucrose comes from the sugar beet (*Beta vulgaris*) and the grain sorghum. Honey and maple trees furnish a small amount of sugar.

Sugarcane grows from 5 to 15 feet (1.5 to 4.5 meters) in height, with stalks that range from 1 to 2 inches (2.5 to 5 centimeters) in diameter. The sugarcane stalk is made up of a series of nodes and internodal sections, ranging from 1 to 10 inches (1.5 to 25 centimeters) in length. At each node there is a vegetative bud and root primordia that will "germinate" or sprout to produce a new shoot and nodal roots when placed in the proper environment. The saccharine content of the nodes is very low, whereas the internodes contain most of the sugar. As the plant commences to grow, leaves are formed on alternate sides of the nodes, reaching a length of some 3 feet (0.9 meter). At the base, the leaves are about 2 inches (5 centimeters) wide and taper gradually throughout their length to a sharp point at the end. The plant begins to display nodes and internodes when only a few weeks old. Early in the life of the plant, these parts are green, but after a while some of these parts may change color, depending upon variety. Although some may continue green, others will take on a striped pattern or a yellow-green or purple coloration. If disease-free, maturity of the plant is first indicated by yellowing and dropping of the lower leaves. Although the bottom part of the plant may be quite barren, the upper stalk will be green and vigorous. In some regions, frost may halt maturity, but if permitted to mature this will take the form of development of flowers and seeds. From 12 to 15 months are required to achieve full maturity by some varieties and in some regions, notably in the more tropical areas.

Sugarcane is not an agricultural crop that is likely to diminish over the years ahead, even though the role of sucrose in food products has been the subject of penetrating analysis and criticism during the past few years — critiques that go far beyond the more traditional negative roles of sucrose in terms of dental caries. The emergence of corn (maize) and other sugar sources also has posed a serious threat. Sugar is frequently the first substance to be attacked when obesity is mentioned, and dieting (even though usually not of a long-term nature or a permanent accomplishment) is almost a status symbol in some countries. Sugar has been identified as an ugly "empty calorie." Nevertheless, despite many of the very well justified critiques of sugar excesses in various diets, population increases in some countries, coupled with increased consumption of snacks and convenience foods in other countries, has enabled sugar to maintain a relatively high volume of production.

But, even if improvements in nutrition ultimately pose a relatively serious threat to the continued high production of sugarcane and sugar beets, it is now believed by many authorities that sugarcane production, in particular, will increase several fold during the next decade or two — not as a food product, but rather as a raw material for the chemical industry, replacing to some extent the present declining raw materials for the petrochemical industry.

Efforts of the Brazilian government to produce alcohol from sugarcane and blend that with hydrocarbons for automotive fuel are exemplary of the important role that sugarcane can play as an industrial chemical raw material. See also **Sugar**.

SULFONAMIDE DRUGS. In 1935, Domagk, a German researcher, was the first to observe the clinical value of *prontosil*, a red compound derived from azo dyes. Paraaminobenzenesulfonamide was shown to be the effective portion of the prontosil molecule. This substance was given the name *sulfanilamide*. This was the first of a group of related drugs to receive wide clinical trial. It was found to be effective in the treatment of hemolytic streptococcal and staphylococcal infections. Within a short span of years, related drugs were synthesized and given clinical trials. These included *sulfapyridine, sulfathiazole, sulfaguanidine, sulfadiazine*, and *sulfamerazine*. These drugs acted by inhibiting the growth of bacteria rather than by killing organisms.

Even though numerous adverse side effects were observed over a period of time, the sulfonamides played an important role in medicine prior to the advent of the antibiotics. In recent years, the importance of the so-called *sulfa drugs* has diminished considerably, but for certain situations they are still considered important antimicrobials. Presently the sulfonamides are mainly used to treat uncomplicated urinary tract infections, including prostatitis, due to *E. coli*. They are also used to treat a number of noncardial infections. At one time the sulfa drugs were widely used in the treatment of meningococcal meningitis and bacillary dysentery. Unfortunately, the bacilli responsible for these diseases developed, over the years, a resistance to the drugs, severely reducing their efficacy.

Within the last few years, some new sulfa drugs have been introduced, including trimethoprim-sulfamethoxazole. This drug has broadened the scope in treatment of urinary tract infections derived from species in addition to *E. coli*, namely, *Klebsiella, Enterobacter*, and *Porteus* species. This drug also is used for the treatment of acute otitis media in children, particularly those instances where strains of *H. influenzae* and *streptococcus pneumoniae* may be suspected. The drug is also used to treat systemic infections that may arise from chloramphenicol- and ampicillin-resistant *Salmonella*; as well as infections attributed to *Pneumocystis carinii*.

Also, the nature of sulfonamide compounds (relatively short duration of action, capability of entering into synergism with other drugs, poor absorption, and topical effectiveness, not to mention relatively low cost) is taken advantage of in what is sometimes called short-acting sulfonamides. Short-acting sulfonamides include sulfisoxazole, sulfadiazine, and trisulfapyrimidines. An intermediate-acting sulfonamide in current use is sulfamethoxazole. This drug does tend to cause renal damage arising from sulfonamide crystalluria.

Sulfacetamide eyedrops continue to be used for treatment of superficial ocular infections. Sometimes silver-sulfadiazine cream is applied to burn surfaces to minimize or prevent bacterial growth, as well as preventing invasive infection.

The adverse effects of sulfonamides include hypersensitivity reactions, as manifested by rashes, photodermatitis (allergic reaction to light), so-called drug fever, nausea, and vomiting. These reactions occur with some frequency when sulfonamides are administered. Less frequently encountered is crystalluria, previously mentioned, but with the risk lessened in the case of sulfisoxazole. Sulfa drugs also occasionally cause hemolytic anemia, agranulocytosis, and kernicterus (in infants) when the drugs are given to nursing mothers. In rare instances, sulfa drugs may precipitate hepatitis, aplastic anemia, renal tubular necrosis, and certain blood disorders.

SULFONAMIDES (The History). The sulfonamides were the first effective antibacterial drugs. As they were developed a decade before the general introduction of antibiotics, bacteria began to acquire resistance to them as a consequence of their overuse.

In 1927, the German chemical firm I. G. Farbenindustrie appointed Gerhard Domagk as director of its newly created Institute of Experimental Pathology in Elberfeld. His mission was to develop a synthetic drug that could be taken by mouth to overcome bacterial infections. Domagk believed that previous attempts to do this had failed because the laboratory testing had not been severe enough. Consequently, he sought out the most virulent strain of hemolytic streptococcus that could be found and then screened potential drugs in mice infected with this organism. Unless a drug showed genuine promise, all of the test mice would be expected to perish within 96 hours. See also **Domagk, Gerhard Johannes Paul (1895–1964)**.

Initially, Domagk screened gold compounds, acridines, and then azo dyes which were believed to have antibacterial properties. The gold compounds were eliminated after they were reported to cause kidney damage when tested on animals. He then examined acridine and azo dyes. The latter were initially designed by chemists Fritz Mietzsch and Joseph Klarer as analogues of the commercially available urinary antiseptic dye known as phenazopyridine. These contained the chemical side-chains that had been shown to confer antibacterial activity when incorporated into

acridine dyes. Progress was made on replacing phenazopyridine by the somewhat similar mildly antiseptic dye known as chrysoidine. Attaching certain side-chains to this resulted in compounds with good activity against the hemolytic streptococcal cultures. Unfortunately, these could still not save infected mice from the bacteria. At this point Heinrich Horlein, the director of the medical division at Elberfeld, pointed out that in 1909 he had enhanced the binding of azo dyes to wool by incorporating the sulfonamide group into their chemical structure. He suggested that Mietzsch and Klarer do likewise with their chrysoidine derivatives. This suggestion provided the long-awaited breakthrough and in November 1931 led to the testing of the first sulfonamide dyes which could prevent mice from succumbing to the streptococcal infection. This lead was consolidated during the following year, culminating in the submission on Christmas Day 1932 of a patent application covering a number of dyes. One of these was later to become universally known as Prontosil Red. Its subsequent internationally approved name of sulfamidochrysoidine became known only to health professionals.

It was not until February 1935 that Domagk published his findings with Protosil Red. Writing in the *Deutsche Medizinische Wochenschrift* he noted that nontoxic doses of it had protected every mouse that had been infected with lethal doses of the hemolytic streptococci. Because of its insolubility, Domagk had been unable to inject the dye, so instead had resorted to administering it to the mice by a fine stomach tube. Of the infected mice that had not been treated, only one survived for more than four days. Domagk also reported that Prontosil Red was effective against staphylococcal infections.

Prontosil Red was the first drug ever to have been found capable of treating generalized bacterial infection, yet its introduction was generally viewed with skepticism. This was not banished until 1936, when Leonard Colebrook and Meave Kenny of Queen Charlotte's Maternity Hospital in London published the results of a clinical trial of Prontosil Red on 38 women dangerously ill with puerperal fever following the birth of their children. If this disease was caused by hemolytic streptococci, one out of four patients would die — yet in the London trial only three died. Later trials gave even better results. Attitudes were changed by these results and in 1939 Domagk was awarded the Nobel Prize in Physiology or Medicine.

Shortly after the appearance of the paper by Domagk, researchers at the Pasteur Institute in Paris established that the azo linkage in Prontosil Red was metabolized in the body, breaking down to form a colorless compound that later became generally known as sulfanilamide. This retained all the activity of the parent compound and it could not be patented since it was an already known compound used in the dye industry. Sulfanilamide not only became widely employed as an antibacterial, but it also served as a lead for chemists upon which to design a wide variety of patentable sulfonamide antibacterials. As a result, the Elberfeld researchers lost the initiative to others in France, Switzerland, the United Kingdom and the United States. Despite a further thousand or so sulfonamides being tested at Elberfeld, none had the impact of Prontosil Red.

The first significant development after the introduction of sulfanilamide followed on the decision of Arthur Ewins, director of research at the May and Baker Laboratories in England, to prepare a derivative of it substituted on the sulfonamide group by pyridine. This was to be the first of many thousands of heterocyclic sulfonamides prepared by chemists around the world. The only reason for its synthesis had been on grounds of novelty, yet the new drug, sulfapyridine, proved not only to be more potent than sulfanilamide but also had a broader spectrum of antibacterial activity. It was used to treat infections caused by pneumococci, meningococci, gonococci and other organisms. Of particular importance was the consequent reduction of mortality in patients with lobar pneumonia from 1 in 4 to only 1 in 25.

Amongst the many sulfonamides that were introduced during the war years before penicillin became generally available in 1944 were more potent drugs which had enhanced solubility in water. This meant that crystals did not form in the fine kidney tubules as had been the case with the early sulfonamides, causing great pain and distress. Drugs such as sulfadiazine, sulfamerazine, and sulfadimidine (known as sulfamezathine in the United States America) could even be injected, thus increasing their value in life-threatening infections.

Even after the introduction of penicillin and other early antibiotics, sulfonamides held their own due to their low cost and oral activity. They eventually became a victim of their own success as an ever increasing range of bacteria gradually acquired resistance to them. Although sulfonamides are today of very limited value, they should be remembered as the first effective antibacterials that could be administered by mouth against life-threatening infections. SULFONE POLYMERS. Polysulfone is a transparent, heat-resistant, ultrastable and high-performance engineering thermoplastic. It is amorphous and has low flammability and smoke emission. Electrical properties are good; the material remains essentially unchanged up to near its glass transition temperature, 190 °C (374 °F). The molecular structure of polysulfone features the diaryl sulfone group, a group that tends to attract electrons from the phenyl rings. Oxygen atoms para to the sulfone group enhance resonance and produce oxidation resistance. High resonance also strengthens the bonds spatially, fixing the grouping into a planar configuration. Thus, the polymer has good thermal stability and rigidity at high temperatures. Ether linkages provide chain flexibility, thus imparting good impact strength.

The resistance to acids, alkalies, and salt solutions is high and also good in terms of detergents, oils, and alcohols even at elevated temperatures under moderate stress. Polysulfones, however, are attacked by polar organic solvents, such as ketones, chlorinated hydrocarbons, and aromatic hydrocarbons. The material can be used continuously in steam up to temperatures of 93 °C (300 °F). Maximum stress in water at about 82 °C (180 °F) is 2000 psi (steady loads) and 2500 psi (intermittent loads). In long-term performance at 150 °C (300 °F), polysulfone increases about 10% in strength and modulus values, retaining 90% of its dielectric strength and 70% of its impact strength.

Polysulfone is widely used in medical instrumentation and trays for holding instruments during sterilization. Food processing applications, such as piping, scraper blades, steam tables, microwave oven cookware, and beverage dispensing tanks, are numerous. Electrical/electronic applications include connectors, automotive fuses and switch housings, soil bobbins and cores, television components, capacitor film, and structural circuit boards. In chemical processing equipment, uses include corrosion-resistant piping, tower packing, pump parts, filter modules, and membranes. Polysulfone is available in both molding and extrusion grades. A special medical grade is available. Also available are polysulfone compounds with glass fiber or beads, as well as fillers, such as *Teflon*®.

SULFONIC ACIDS. Sulfonic acids are classically defined as a group of organic acids which contain one or more sulfonic, $-SO_3H$, groups, The general formula of organic sulfonic acids RSO_3H, where the R-group may be derived from many different sources. Typical R-groups are alkane, alkene, alkyne, and arene. The R-group may contain a wide variety of secondary functionalities such as amine, amide, carboxylic acid, ester, ether, ketone, nitrile, phenol, etc. Sulfonic acid derivatives, where the R-group is derived from an inorganic source such as a halide, oxygen (i.e., sulfate), or amine (i.e., sulfamic acid), are often referred to as sulfuric acid derivatives.

Properties. The physical properties of sulfonic acids vary greatly depending on the nature of the R-group. Sulfonic acids can be described as having similar acidity characteristics to sulfuric acid. Sulfonic acids are prone to thermal decomposition, i.e., desulfonation, at elevated temperatures. However, several of the alkane-derived sulfonic acids show excellent thermal stability, as shown in Table 1. Arene-based sulfonic acids are thermally unstable. These must be distilled under extreme vacuum conditions using a minimal amount of heating to avoid thermal decomposition. Polyaromatic compounds, such as 1-naphthalenesulfonic acid and 2-naphthalenesulfonic acids [CAS: 83-47-2] and [CAS: 120-18-3], respectively, readily decompose upon attempted distillation even at very high vacuum.

TABLE 1. PHYSICAL PROPERTIES OF SULFONIC ACIDS

Acid	CAS Registry Number	Mp, °C	Bp,[a] °C	Density a_4^{a5}, g/cm^3
methanesulfonic acid	[75-75-2]	20	122	1.48
ethanesulfonic acid	[594-45-6]	−17	123	1.33
propanesulfonic acid	[28553-80-2]	−37	159	1.19
butanesulfonic acid	[30734-86-2]	−15	149	1.19
pentanesulfonic acid	[35452-30-3]	−16	163	1.12
hexanesulfonic acid	[13595-73-8]	16	174	1.10
benzenesulfonic acid	[98-11-3]	44	172[b]	
p-toluenesulfonic acid	[104-15-4]	106	182[b]	
1-naphthalenesulfonic acid	[85-47-2]	78	dec	
2-naphthalenesulfonic acid	[120-18-3]	91	dec	1.44
trifluoromethanesulfonic acid	[1493-13-6]	none	162	1.70

[a] At 133 Pa (1 mm Hg) unless otherwise noted.
[b] At 13.3 Pa (0.1 mm Hg).

Sulfonic acids are such strong acids that in general they can be considered greater than 99% ionized.

Sulfonic acids are prepared on a commercial scale by the sulfonation of organic substrates using a variety of sulfonating agents, including sulfur trioxide [CAS: 7446-11-9] (diluted in air), sulfur trioxide (in sulfur dioxide [CAS: 7446-09-5]), sulfuric acid [CAS: 7664-93-9], oleum [CAS: 8014-95-7] (fuming sulfuric acid), chlorosulfuric acid [CAS: 7790-94-5], sulfamic acid [CAS: 5329-14-6], trialkylamine–sulfur trioxide complexes, and sulfite ions. Other methods of sulfonic acid production, practiced on an industrial scale, include the oxidation of thiols, sulfide, disulfides, sulfoxides, sulfones, and sulfinic acids. See also **Sulfonation and Sulfation**.

Production. There are four primary methods of sulfonic acid production in the United States: falling film sulfonation; oleum sulfonation; chlorosulfuric acid sulfonation; and SO_3 solvent-based sulfonation.

The vast majority of sulfonic acids were produced using continuous falling film sulfonation technology, which utilizes vaporized SO_3 mixed with air. This technology dominates the sulfonation industry owing to the capability of high product throughput and low by-product waste streams.

Analytical and Test Methods. Modern analytical techniques have been developed for complete characterization and evaluation of a wide variety of sulfonic acids and sulfonates. Titration is the most straightforward method of evaluating sulfonic acids. Spectroscopic methods for sulfonic acid analysis include ultraviolet spectroscopy, infrared spectroscopy, and ^{1}H and ^{13}C NMR spectroscopy. Modern separation techniques of sulfonates include liquid chromatography and ion chromatography. See also **Chromatography**.

Health and Safety Factors. In general, unneutralized sulfonic acids are regarded as moderate to highly toxic substances. However, slight detoxification, via the introduction of a sulfonic acid moiety, is observed for nitrobenzene and aminobenzene. Sulfonic acids emit toxic SO_x fumes upon heating to decomposition. Halogenated sulfonic acids, such as trifluoromethane sulfonic acid, also release toxic halogen-containing fumes when heated to decomposition.

Sulfonic acids have essentially the same corrosive characteristics as does concentrated sulfuric acid. Detergent-based sulfonic acids pose a contact hazard, as they are very corrosive to the skin.

When sulfonic acids are neutralized to sulfonic acid salts, the materials become relatively innocuous and low in toxicity, as compared to the parent sulfonic acid.

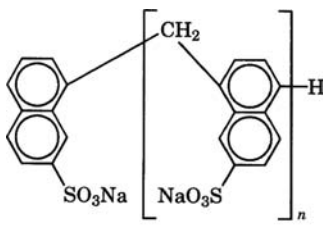
Environmental Issues. Linear alkylbenzenesulfonic acid is the largest intermediate used for surfactant production in the world. Owing to the large volumes of production and consumption of linear alkylbenzenesulfonate, much attention has been paid to its biodegradation and a series of evaluations have been performed to thoroughly study its behavior in the environment. Much less attention has been paid to the environmental impact of other sulfonic acid-based materials.

Linear alkylbenzenesulfonate showed no deleterious effect on agricultural crops exposed to this material. Kinetics of biodegradation have been studied in both wastewater treatment systems and natural degradation systems. Studies have concluded that linear alkylbenzenesulfonate does not pose a risk to the environment. Linear alkylbenzenesulfonate has a half-life of approximately one day in sewage sludge and natural water sources and a half-life of one to three weeks in soils. Aquatic environmental safety assessment has also shown that the material does not pose a hazard to the aquatic environment.

Uses. Perhaps the largest use of sulfonic acids is the manufacture of surfactants and surfactant formulations. In almost all cases, the parent sulfonic acid is an intermediate which is converted to a sulfonate prior to use. The largest volume uses for sulfonic acid intermediates are the manufacture of heavy-duty liquid and powder detergents, light-duty liquid detergents, hand soaps, and shampoos. See also **Soaps**; and **Surfactants**.

Lignosulfates, a complex mixture containing sulfonated lignin, are used as dispersing agents, wetting agents, binding agents, and sequestering agents. Dry forms of the materials are used as road binders, concrete additives, animal feed additives, and in vanillin production.

Naphthalenic, lignin, and melamine-based sulfonic acids are used as dispersion and wetting agents in industry. The sulfonate (**1**) is also widely used as a dispersing agent in dyestuff manufacture and high temperature dyeing of polyester fibers. A derivative of (**1**) based on 4-aminobenzene sulfonic acid has also been produced.



(**1**)

Other commercial naphthalene-based sulfonic acids, such as dinonylnaphthalene sulfonic acid, are used as phase-transfer catalysts and acid reaction catalysts in organic solvents.

Sulfonic acid-derived dyes are utilized industrially in the areas of textiles, paper, cosmetics, foods, detergents, soaps, leather, and inks, both as reactive and disperse dyes. Of the principal classes of dyes, sulfonic acid derivatives find utility in the areas of acid, azoic, direct, disperse, and fiber-reactive dyes. Sulfonic acid-based azo dyes and intermediates are characterized by the presence of one or more azo, RN=NR, groups.

Biological Uses. Taurine (2-aminoethanesulfonic acid), is the only known naturally occurring sulfonic acid. The material is an essential amino acid for cats and is used extensively by Ralston Purina Company as a food supplement in cat food manufacture.

Sulfonic acids have found greatly expanded usage in biological applications. Whereas the toxicity of sulfonic acids is in general rather high, several sulfonic acids are beneficially utilized *in vivo*. Taurocholic acid is an important bile component, aiding in the digestion of fat.

Potent inhibition of the herpes simplex virus has been observed using biphenyl disulfonic acid urea copolymers. Sulfonic acid derivatives have been shown to be potent antihuman immunodeficiency virus (anti-HIV) agents.

Other Applications. Hydroxylamine-*O*-sulfonic acid has many applications in the area of organic synthesis. The acid has found application in the preparation of hydrazines from amines, aliphatic amines from activated methylene compounds, aromatic amines from activated aromatic compounds, amides from esters, and oximes.

Petroleum sulfonates have found wide usage in enhanced oil recovery technology.

A variety of barium sulfonates have found use in antifriction lubricants for high speed bearing applications. Calcium and sodium salts of sulfonated olefins, esters, or oils are used for the enhancement of extreme pressure properties of grease and gear lubricants.

SULFOXIDES. Sulfoxides are compounds that contain a sulfinyl group covalently bonded at the sulfur atom to two carbon atoms. They have the general formula RS(O)R′, ArS(O)Ar′, and ArS(O)R, where Ar and Ar′ = aryl. Sulfoxides represent an intermediate oxidation level between sulfides and sulfones. The naturally occurring sulfoxides often are accompanied by the corresponding sulfides or sulfones. The only commercially important sulfoxide is the simplest member, dimethyl sulfoxide [CAS: 67-68-5] (DMSO) or sulfinylbismethane.

Sulfoxides occur widely in small concentrations in plant and animal tissues.

Properties. For the most part, sulfoxides are crystalline, colorless substances, although the lower aliphatic sulfoxides melt at relatively low temperatures (Table 1). The lower aliphatic sulfoxides are water soluble; but as a class the sulfoxides are not soluble in water. They are soluble in dilute acids and a few are soluble in alkaline solution. DMSO is a colorless liquid; and generally undergoes typical sulfoxide reactions. It is used herein as an illustrative example.

Thermal Stability. Dimethyl sulfoxide decomposes slowly at 189 °C (372 °F) to a mixture of products that includes methanethiol, formaldehyde, water, bis(methylthio)methane, dimethyl disulfide, dimethyl sulfone, and dimethyl sulfide. The decomposition is accelerated by acids, glycols, or amides. Sulfoxides undergo oxidation, reduction, carbonsulfide cleavage, and Pummerer reactions.

Methylsulfinyl Carbanion. Strong bases, eg, sodium hydride or sodium amide, react with DMSO producing solutions of methylsulfinyl carbanion, known as the dimsyl ion, which are synthetically useful. The solutions also provide a strongly basic reagent for generating other carbanions.

Methoxydimethylsulfonium and Trimethylsulfoxonium Salts. Alkylating agents react with DMSO at the oxygen. For example, methyl iodide gives methoxydimethylsulfonium iodide as the initial product. The alkoxysulfonium salts are quite reactive and, upon continued heating, either decompose to give carbonyl compounds or rearrange to the more stable trimethylsulfoxonium salts.

Complexes. The sulfoxides have a high (ca 4) dipole moment, which is characteristic of the sulfinyl group, and a basicity about the same as that of alcohols. They are strong hydrogen-bond acceptors. They would be expected, therefore, to solvate ions with electrophilic character, and a large number of DMSO complexes of metal ions have been reported.

Synthesis and Manufacture. The sulfoxides are most frequently synthesized by oxidation of the sulfides.

Dimethyl sulfoxide is manufactured from dimethyl sulfide (DMS), which is obtained either by processing spent liquors from the kraft pulping process or by the reaction of methanol or dimethyl ether with hydrogen sulfide.

Health and Safety Factors. Dimethyl sulfoxide is a relatively stable solvent of low toxicity. However, DMSO can penetrate the skin and may carry with it certain chemicals with which it is combined under certain conditions. Dimethyl sulfoxide has received considerable attention as a useful agent in medicine. In veterinary medicine, DMSO is used for horses and dogs as a topical application to reduce swelling resulting from injury or trauma.

Uses of Dimethyl Sulfoxide. Dimethyl sulfoxide is used as a solvent for the polymerization of acrylonitrile and other vinyl monomers, and as a reaction solvent for other polymerizations. It is also used as a solvent for displacement reactions, solvent for base-catalyzed reactions, extraction solvent, solvent for electrolytic reactions, cellulose solvent, pesticide solvent, and clean-up solvent.

SULFUR. [CAS: 7704-34-9], Chemical element, symbol S, at. no. 16, at. wt. 32.064, periodic table group 16, mp 112.8 °C (235 °F) (rhombic), 119.0 °C (246 °F) (monoclinic), 120.0 °C (248 °F) (amorphous), bp 444.7 °C (832.5 °F) (all forms), sp gr 2.07 (rhombic), 1.96 (monoclinic), 2.046 (amorphous). Atomic weight varies slightly because of naturally occurring isotopes 32, 33, 34, and 36, the total possible variation amounting to ±0.003.

History

Sulfur has been known since antiquity. Early humans used sulfur to color cave drawings, employed sulfur fumes to kill insects and to fumigate, and knew about sulfur's color-removing or bleaching action. Mystical powers were attributed to the ethereal blue flame and pungent odor given off by burning the yellow rock. Medicinal use of sulfur was known to the Egyptians and Greeks. One contemporary use was developed as early as 500 BC, when the Chinese used sulfur as an ingredient of gunpowder. Although the modern history of sulfur may have begun with Lavoisier's proof in the late-eighteenth century that sulfur is an element, the first commercial sulfur was produced in Italy early in the fifteenth century. Sulfur production become Italy's main industry when, in 1735, development of a process to make sulfuric acid from sulfur was commercialized. When a French company gained an effective monopoly on the Sicilian deposits in 1839 and tripled the price, other countries, particularly England and the United States, developed internal sources of sulfur and sulfuric acid. Consumers in many countries quickly learned that sulfuric acid could be made from sulfur dioxide obtained from the roasting of iron pyrites, obviating the need for Sicilian sulfur. See also **Chemical Elements: The History of the Origin**.

The United States continued to depend on foreign sources of elemental sulfur even after the mineral was discovered in the United States in 1867 by oil prospectors investigating a salt dome in Calcasieu Parish, Louisiana.

TABLE 1. MELTING AND BOILING POINTS OF SULFOXIDES

Name	CAS Registry Number	Formula	Mp, °C	Bp, °C
sulfinylbismethane	[67-68-5]	$(CH_3)_2SO$	18.55	189.0
1,1′-sulfinylbisethane	[70-29-1]	$(C_2H_5)_2SO$	15	88–90[a]
1,1′-sulfinylbispropane	[4253-91-2]	$(n\text{-}C_3H_7)_2SO$	18	
1,1′-sulfinylbisbutane	[2168-93-6]	$(n\text{-}C_4H_9)_2SO$	32	
1,1′-sulfinylbis(2-chlo-roethane)	[5819-08-9]	$(ClCH_2CH_2)_2SO$	110.2	
1,1′-sulfinylbisbenzene	[945-51-7]	$(C_6H_5)_2SO$	70.5	340 dec[b]
methylsulfinylbenzene	[1193-82-4]	$C_6H_5S(O)CH_3$	30–30.5	139–140
phenylmethylsulfinyl-benzene	[833-82-9]	$C_6H_5S(O)CH_2C_6H_5$	125.5	
1,1′-sulfinylbis(methyl-enebenzene)	[621-08-9]	$(C_6H_5CH_2)_2SO$	135	

[a] At 2.0 kPa (15 mm Hg).
[b] Slowly.

Various attempts were made to sink mine shafts. Realizing that conventional mining processes would be too uneconomical to compete with Sicilian sulfur, H. Frasch conceived of melting the sulfur underground by injecting superheated water into the formation and then lifting the melted sulfur to the surface using a sucker-rod pump. In 1894, the first flow of molten sulfur was pumped from the Calcasieu Parish deposit. In 1902, the Frasch process was successfully commercialized. This mining method later became important in the development and production of sulfur not only from the Texas–Louisiana salt dome area, but also from areas in western Texas, Mexico, Poland, and Iraq. The Frasch process is no longer used in the U.S.

Today sulfur is recovered as a by-product, involuntary sulfur, accounts for a larger portion of world supply than does mined or voluntary material. Sulfur is obtained from hydrogen sulfide, which evolves when natural gas, crude petroleum, tar sands, oil shales, coal, and geothermal brines are desulfurized. Other sources of sulfur include metal sulfides such as pyrites; sulfate materials, including gypsum and elemental sulfur in native and volcanic deposits mined in the traditional manner. See also **Coal**; **Natural Gas**; **Petroleum**; and **Tar Sands**.

Sulfur constitutes about 0.052 wt % of the earth's crust. The forms in which it is ordinarily found include elemental or native sulfur in unconsolidated volcanic rocks, in anhydrite over salt-dome structures, and in bedded anhydrite or gypsum evaporate basin formations; combined sulfur in metal sulfide ores and mineral sulfates; hydrogen sulfide in natural gas; organic sulfur compounds in petroleum and tar sands; and a combination of both pyritic and organic sulfur compounds in coal.

Properties

Sulfur occurs in a number of different allotropic modifications, that is, in various molecular aggregations which differ in solubility, specific gravity, crystalline form, etc. Like many other substances, sulfur also exhibits dynamic allotropy, ie, the various allotropes exist together in equilibrium in definite proportions, depending on the temperature and pressure. The molecular formulas for the various allotropes are $S-S_n$, where n is a large but unidentified number, such as n^3 10^6. The particular allotropes that may be present in a given sample of sulfur depend to a large extent on its thermal history, the amount and type of foreign substance present, and the length of time that has passed for equilibrium to be attained.

In the solid and liquid states, the principal allotropes are designated traditionally as Sλ, $S\mu$, and $S\pi$. Of these, only Sλ is stable in the solid state. Upon solidification of molten sulfur, $S\pi$ rapidly changes into $S\mu$, which is converted into Sλ, although at a much slower rate. The molecular structure of $S\pi$ is that of an octatomic sulfur chain. The symbol $S\mu$ designates long, polymerized chains of elemental sulfur. Sλ is perhaps the most characteristic molecular form of sulfur, namely, that of a crown-shaped, octatomic sulfur ring designated in more recent literature as $S_{(r/8)}$. The allotropes have different solubility in carbon disulfide. $S\pi$ and Sλ are soluble in carbon disulfide, whereas $S\mu$ does not dissolve in this solvent.

Sulfur crystallizes in at least two distinct systems: the rhombic and the monoclinic forms. Rhombic sulfur, $S\alpha$, is stable at atmospheric pressures up to 95.5 °C (204 °F), at which transition to monoclinic sulfur, $S\beta$, takes place. Monoclinic sulfur is then stable up to its natural melting point of 114.5 °C (238 °F). The basic molecular unit of both of these crystalline forms of sulfur is the octatomic sulfur ring $S_{(r/8)}$. Other forms of solid sulfur include hexatomic sulfur as well as numerous modifications of catenapolysulfur.

The molecular constitution of liquid sulfur undergoes significant and reversible changes with temperature variations. These changes are evidenced by the characteristic temperature dependence of the physical properties of sulfur. In most studies of liquid sulfur, some striking changes in its physical properties are observed at about 160 °C (320 °F). For example, the viscosity of purified sulfur, which at 120 °C (248 °F) is about 11 mPa·s (=cP), drops to a minimum of 6.7 mPa · s at about 157 °C (315 °F), and then begins to rise. At 159–160 °C (318–320 °F), the viscosity of liquid sulfur rises sharply, increasing to 30 mPa · s at 160 °C (320 °F) and reaching a maximum of about 93 Pa · s (930 P) at 187 °C (369 °F). Above this temperature, the viscosity gradually drops off again to about 2 Pa · s (20 P) at 306 °C (583 °F). A qualitative exploration of these viscosity changes in terms of the allotropy of sulfur implies that below 159 °C (318 °F), sulfur consists mainly of S_8 rings. A normal decrease of viscosity with rising temperature is observed. The sudden increase in the viscosity of sulfur above 159 °C (318 °F) is attributed to the formation of polymeric sulfur chain molecules. Then, as the temperature rises further, the concentration of polymeric sulfur continues to increase, but the opposing effect of decreasing chain length resulting from thermal sulfur–sulfur bond scission causes a gradual decrease in viscosity in the temperature range between 187 °C (369 °F) and the boiling point of sulfur. The chemical equilibria between the various forms in molten sulfur have been extensively investigated. A critical review of the literature concerning the molecular composition of molten sulfur is also available [Steudel, 1981]. Experiments that added much to the knowledge of the species present under different time–temperature parameters have been described [Sreudel and Mausle, 1981]. Previous theories concerning the polymerization of S_8 were shown to be in disagreement with well-established experimental facts and are considered unsatisfactory.

The molecular composition of sulfur vapor is a complex function of temperature and pressure. Vapor pressure measurements have been interpreted in terms of an equilibrium between several molecular species. Mass spectrometric data for sulfur vapor indicate the presence of all possible S_n molecules from S_2 to S_8 and negligible concentrations of S_9 and S_{10}. In general, octatomic sulfur is the predominant molecular constituent of sulfur vapor at low temperatures, but the equilibrium shifts toward smaller molecular species with increasing temperature and decreasing pressure.

There are four stable isotopes of sulfur ^{32}S, ^{33}S, ^{34}S, and ^{36}S which have relative abundances of 95.1, 0.74, 4.2, and 0.016%, respectively. The relative abundance of the various isotopes varies slightly, depending on the source of the sulfur; the ratio of ^{32}S to ^{34}S is 21.61–22.60. There are three known radioactive isotopes, ^{31}S, ^{35}S, and ^{37}S having half-lives of 2.6 sec's, 87 days, and 5 min, respectively, have been generated artificially. See also **Radioactivity**.

Sulfur falls between oxygen and selenium in Group 16 and resembles oxygen in its chemical reactions with most of the elements. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^4$. Ionic radius S^{2-} 1.855Å, S^{6+} 0.29 Å (Pauling). Covalent radius 1.07Å. In terms of abundance, sulfur ranks fourteenth among the elements occurring in the earth's crust, with an estimated 520 grams per metric ton. In seawater, the element ranks fifth, with an estimated 894 grams per metric ton.

First ionization potential 10.357 eV; second, 23.3 eV; third, 34.9 eV; fourth, 47.08 eV; fifth, 63.0 eV; sixth 87.67 eV. Oxidation potentials $H_2S(aq) \rightarrow S + 2H^+ + 2e^-$, −0.141 V; $H_2SO_3 + H_2O \rightarrow SO_4^{2-} + 4H^+ + 2e^-$, −0.20 V; $S + 3H_2O \rightarrow H_2SO_3 + 4H^+ + 4e^-$, −0.45 V; $SO_3^{2-} + 2OH^- \rightarrow SO_4^{2-} + H_2O + 2e^-$, 0.90 V; $S^{2-} \rightarrow S + 2e^-$, 0.508 V; $HS^- + OH^- \rightarrow S + H_2O + 2e^-$, 0.478 V. Other important physical properties of sulfur are given under **Chemical Elements**.

Sulfur is insoluble in water but soluble to varying degrees in many organic solvents, such as carbon disulfide [CAS: 75-15-0], benzene [CAS: 71-43-2], warm aniline [CAS: 62-53-3], warm carbon tetrachloride [CAS: 56-23-5], and liquid ammonia [CAS: 7664-41-7]. Carbon disulfide is the most commonly used solvent for sulfur.

Sulfur combines directly and usually energetically with almost all of the elements. Exceptions include gold [CAS: 7440-57-5], platinum [CAS: 7440-06-4], iridium [CAS: 7439-88-5], and the helium-group gases. In the presence of oxygen or dry air, sulfur is very slowly oxidized to sulfur dioxide. When burned in air, it forms predominantly sulfur dioxide [CAS: 7446-09-5] SO_2 with small amounts of sulfur trioxide [CAS: 7446-11-9] SO_3. When burned in the presence of moist air, sulfurous acid and sulfuric acids are slowly generated.

Hydrochloric acid [CAS: 7647-01-0] reacts with sulfur only in the presence of iron to form hydrogen sulfide. Sulfur dioxide forms when sulfur is heated with concentrated sulfuric acid at 200 °C (392 °F). Dilute nitric acid [CAS: 7697-37-2] HNO_3 up to 40% concentration has little effect, but sulfur is oxidized by concentrated nitric acid in the presence of bromine with a strongly exothermic reaction.

Sulfur combines directly with hydrogen [CAS: 1333-74-0] at 150–200 °C (302–392 °F) to form hydrogen sulfide [CAS: 7783-06-4] H_2S. Molten sulfur reacts with hydrogen to form hydrogen polysulfides. At red

heat, sulfur and carbon unite to form carbon disulfide (CS_2). This is a commercially important reaction in Europe, although natural gas is used to produce carbon disulfide in the United States. In aqueous solutions of alkali carbonates and alkali and alkaline-earth hydroxides, sulfur reacts to form sulfides, polysulfides, thiosulfates, and sulfites.

At room temperature, sulfur unites readily with copper [CAS: 7440-50-8], silver [CAS: 7440-22-4], and mercury [CAS: 7439-97-6] and vigorously with sodium [CAS: 7440-23-5], potassium [CAS: 7440-09-7], calcium [CAS: 7440-70-2], strontium [CAS: 7440-24-6], and barium [CAS: 7440-39-3] to form sulfides. Iron [CAS: 7439-89-6], chromium [CAS: 7440-47-3], tungsten [CAS: 7440-33-7], nickel [CAS: 7440-02-0], and cobalt [CAS: 7440-48-4] react much less readily. In a finely divided state, zinc [CAS: 7440-66-6], tin [CAS: 7440-31-5], iron [7439-89-6], and aluminum [CAS: 7429-90-5] react with sulfur on heating.

Various sulfides of the halogens are formed by direct combination of sulfur with fluorine [CAS: 7782-41-4], bromine [CAS: 7726-95-6], and chlorine [CAS: 7782-50-5]. No evident reaction occurs with iodine; instead, the elements remain as components of a mixture. Mixtures of sulfur and potassium chlorate [CAS: 3811-04-9], or sulfur and powdered zinc, are highly explosive.

Sulfur is involved in numerous organic reactions. When dissolved in amines, chemical interaction between sulfur and the solvent results in the formation of colored species ranging from deep yellow to orange and green. Many organic reactions involving sulfur are commercially significant. Sulfur is important in the manufacture of lubricants, plastics, pharmaceuticals, dyes, and rubber goods. See also **Lubricant**; **Lubricating Agents**; and **Pharmaceuticals**.

Sulfur is not considered corrosive to the usual construction materials. Dry, molten sulfur is handled satisfactorily in mild steel or cast-iron equipment. However, acid-generating impurities, which may be introduced in handling and storage, create corrosive conditions. The exposure of sulfur to moisture and air causes the formation of acids which attack many metals. To combat such corrosion difficulties, protective coatings of organic compounds, cement, or sprayed resistant metals are often applied to exposed steel surfaces, including pipe and equipment used in handling liquid sulfur, and to structural members that come in contact with solid sulfur. Also practical in some applications is the use of resistant metal alloys, particularly those of aluminum and stainless steel. Naturalization of the generated acids by the addition of basic chemicals is sometimes employed.

Elemental Sulfur

Sources of sulfur are called voluntary if sulfur is considered to be the principal, and often the only, product. Sulfur has also been recovered as a by-product from various process operations. Such sulfur is termed involuntary sulfur and accounts for the largest portion of world sulfur production.

Occurrence

Salt-Dome Sulfur Deposits. The sulfur deposits associated with salt domes in the Gulf Coast regions of the southern United States and Mexico have historically been the primary sources of U.S. sulfur. These remain an important segment of both U.S. and world sulfur supply. Although the reserves are finite, many are large and voluntary productive capacity ensures the importance of these sources for some time to come.

Salt domes of the U.S. Gulf Coast are vertical structures, usually circular in outline, with steeply dipping flanks, and composed of coarsely crystalline halite, ie, NaCl, interspersed with anhydrite, $CaSO_4$. The cap rock that surmounts the salt dome consists of anhydrite in contact with the salt and gypsum, $CaSO_4 \cdot 2H_2O$, derived from the anhydrite. Limestone in the form of fine gray carbonate interspersed with vugs, seams, fissures, and cavities is frequently associated with the gypsum and anhydrite formations. It may be present as a stratum overlying these formations, as lenticular beds covering part of them, or as disseminated lenses and nodules included in the upper part of the cap rock.

The sulfur occurs as well-developed crystal aggregates in veins and vugs or as disseminated particles in the porous limestone and gypsum section of the cap rock. Several theories have been proposed for the occurrence of sulfur in salt domes. One theory suggests the formation of limestone and hydrogen sulfide from anhydrite in the presence of reducing agents. This reaction, however, requires temperatures of about 650 °C (1,202 °F) and, although oil or other hydrocarbons may be present to act as reducing agents, the temperature actually attained is not sufficient to support this theory. In 1946, the presence of anaerobic, sulfate-reducing bacteria was discovered in cap rock. The ability of these bacteria to promote reaction at normal temperatures is recognized as the more likely origin of sulfur. Anaerobic bacteria consume hydrocarbons as a source of energy, but combine sulfur instead of oxygen with the hydrogen. The hydrocarbon-fueled bacteria reduce anhydrite to hydrogen sulfide, calcium carbonate, and water. The hydrogen sulfide remains dissolved in the formation waters until it precipitates as crystalline sulfur through various oxidation reactions, possibly initiated by oxygen and carbon dioxide dissolved in water percolating from the upper sediments. In 1966, 329 salt-dome structures were identified by the U.S. Bureau of Mines in the U.S. Gulf Coast area and offshore tidelands. Of these, 27 have been commercial sulfur producers. In 2000, one of the salt-dome sulfur deposits, Main Pass operated by Freeport McMoRan Sulphur Inc. in Louisiana, that was mined by the Frasch Process was the last to close. Some could be reactivated if justified by economic circumstances.

Evaporite Basin Sulfur Deposits. Elemental sulfur occurs in another type of subsurface deposit similar to the salt-dome structures in that the sulfur is associated with anhydrite or gypsum. The deposits are sedimentary, however, and occur in huge evaporite basins. It is believed that the sulfur in these deposits, like that in the Gulf Coast salt domes, was derived by hydrocarbon reduction of the sulfate material and assisted by anaerobic bacteria. The sulfur deposits in Italy (Sicily), Poland, Iraq, the CIS, and the United States (western Texas) are included in this category.

Mining techniques similar to the Frasch salt-dome mining systems have been applied successfully. These developments and particularly those in western Texas and Poland have significantly contributed to world sulfur production and reserves. Hot-water mining of the Polish deposits began in 1966 at Gryzbow. In 1979, production at Gryzbow and at another deposit, Jeziorko, was nearly five million metric tons. By 1995, production declined to $\sim$ 2 million metric tons. The new Osiek Mine officially opened near Grzybow in September, 1993 after several months of test production. The cost of production there was reported to have been cut about 50% by using a system to recycle hot water from nearby power stations, cutting labor costs, and closing nonproductive facilities. Production ceased at the Machow Mine in 1992. However, final transfer of the operation to local authorities has been delayed. Environmental problems continue at Machow, and the cost of remediation, including the elimination of hydrogen sulfide emissions from the pit has been estimated at more than $200 million. Poland is the only country using the Frasch process today. Salt domes and similar sulfur-bearing structures occur in regions other than the United States, Mexico, Poland, Iraq, and the CIS, but sulfur deposits that could be economically productive have not been discovered in any of them.

Frasch production has not been very successful because of the low porosity of the sulfur-bearing ore. There are problems also with product quality owing to bitumen contamination. In addition, significant environmental problems have also constrained production. In Russia, there are some small operations mining sulfur from underground volcanic deposits.

Volcanic and Native Sulfur Deposits. Elemental sulfur occurs in other types of surface or underground deposits throughout the world, but seldom in sufficient concentration to be commercially important. Sulfur of volcanic origin occurs in many parts of the world. These deposits originated from gases emitted from active craters, solfataras, or hot springs, which contain deposited sulfur in fractures of rock, by replacement in the rock itself or in the sediments of lake beds. Volcanic deposits usually occur in tufas, lava flows, and similar volcanic rocks but also in sedimentary and intrusive formations. Scattered deposits of this type have been discovered throughout the mountain ranges bordering the Pacific Ocean, particularly in Japan, the Philippine Islands, and Central and South America. Some volcanic deposits are worked profitably and are important in the countries in which this type of deposit is found. The Japanese deposits are among this group and have had a long and productive history of considerable tonnages. Most volcanic deposits, however, are in isolated regions and at high elevations where production and transportation costs are prohibitive.

Extraction

Frasch Process. In the Frasch process, large quantities of hot water are introduced through wells drilled into buried deposits of native sulfur. The heat from the water melts the sulfur in the vicinity of the wells; the melted sulfur is then removed to the surface as molten elemental sulfur of high purity. Economical operation of a salt dome or a subsurface sulfur deposit by the Frasch process requires a porous sulfur-bearing limestone, a large and dependable supply of water, and a source of inexpensive fuel. A power plant is required, in which the necessary volume of hot water is produced, as is compressed air for pumping molten sulfur from the wells and electric power for drilling, lighting, operating maintenance equipment, loading sulfur for shipment, and similar operations.

A typical setting of equipment for a sulfur well and the principles of mining are illustrated schematically in Fig. 1. First, a hole is drilled to the bottom layer of the salt-dome cap rock with equipment of the same type as that used in oil fields. Three concentric pipes within a protective casing are placed in the hole. A 20 centimeter (8 inch) pipe inside an outer casing is sunk through the cap rock to the bottom of the sulfur deposit. Its lower end is perforated with small holes. Then, a 10 centimeter (4 inch) pipe is lowered to within a short distance of the bottom. Last and innermost is a 2.5 centimeter (1 inch) pipe, which is lowered more than halfway to the bottom of the well.

Water-heated under pressure to 160 °C (320 °F) is pumped down the space between the 20 centimeter (8 in.) and 10 centimeter (4 in.) pipes and, during the initial heating period, also down the 10 centimeter pipe. The superheated water flows out the holes at the bottom into the porous sulfur-bearing formation (Fig. 1**a**). When the temperature of the sulfur-bearing formation exceeds the melting point of sulfur, the liquid sulfur, being approximately twice as heavy as water, percolates downward through the porous limestone to form a pool at the bottom of the well. A heating period of 24 hours or longer is required to accumulate a liquid sulfur pool of sufficient size, and then pumping of hot water down the 10 centimeter (4 in.) pipeline is stopped. Static pressure of the hot water pumped into the formation then forces the liquid more than 100 meters (328 feet) up into the 10 centimeter (4 in.) pipe (Fig. 1**b**). Compressed air forced down the 2.5 centimeter (1 in.) pipe aerates and lightens the liquid sulfur so that it rises to the surface (Fig. 1**c**). Injection of hot water is continued down the 20 centimeter (10 inch) pipe to maintain the sulfur melting process, and the compressed-air volume is adjusted to equalize the sulfur pumping rate with the sulfur melting rate. If the pumping rate exceeds the melting rate, the sulfur pool is depleted and the well produces water. At this point, the compressed-air flow is stopped, and hot water is again injected until the liquid sulfur pool is reestablished.

The sulfur-bearing cap rock, being an enclosed formation, is essentially the equivalent of a pressure vessel. Hot water, pumped into the formation to melt sulfur, must be withdrawn after cooling at approximately the same rate as it is put in, otherwise the pressure in the formation would increase to the point where further water injection would be impossible. Bleedwater wells, used to extract water from the formations, usually are located on the flanks of the dome away from the mining area where the water temperature is lowest. The water is treated to remove soluble sulfides and other impurities before being discharged to disposal ditches or canals.

On the surface, the liquid sulfur moves through steam-heated lines to a separator where the air is removed. Depending on the mine location, the liquid sulfur may be pumped to storage vats to be solidified, to tanks for storage as a liquid, to pipelines, or to thermally insulated barges for transport to a central shipping terminal.

Sulfur wells that are favorably located produce continuously over long periods. Some may last a year or more; other may be abandoned within a few weeks, because denseness of the rock formation may retard circulation of hot water and molten sulfur. The extraction of sulfur weakens the rock formation and subsidence may follow. This may break the pipes in the well, ending productivity. Although subsidence is desirable in mining, wells may be lost as a result. The advantage of subsidence is that the volume of exhausted formation through which hot water can circulate is reduced. After caving, the crushed exhausted formation is relatively impervious and therefore confines the circulation of hot water to the more porous sulfur-bearing parts of the deposit.

Directional drilling techniques were an important advance in sulfur mining methods. Casings are placed in the hole in such a manner as to extend into the sulfur formation somewhat horizontally. Thus, substantial amounts of sulfur in the deposit overlie the hole. Also, the casings in the subterranean volume likely to be affected by subsidence are parallel to the expected earth movement and therefore are less affected by shear. The result is better utilization of heating water and longer well life. Directional drilling has also permitted efficient reworking of areas exhausted to vertical mining techniques.

Another advance in sulfur mining technology has been the development of a method involving seawater in the Frasch process, making it feasible to mine deposits distant from freshwater supplies. In such a plant, seawater is first deoxygenated by bringing it in direct contact with combustion gases in a packed tower. The seawater is preheated by these gases and its temperature raised to 106 °C in indirect heat exchangers by means of steam (qv) furnished by high pressure boilers. Condensate from the heat exchangers is recycled to the boilers; this limits freshwater requirements to leaks and other small losses in the system. Production from several sulfur mines involves seawater from both stationary systems and portable, barge-mounted power plants.

Hydrodynamic Process. The hydrodynamic process is similar to the Frasch process in that superheated water is used to melt the underground

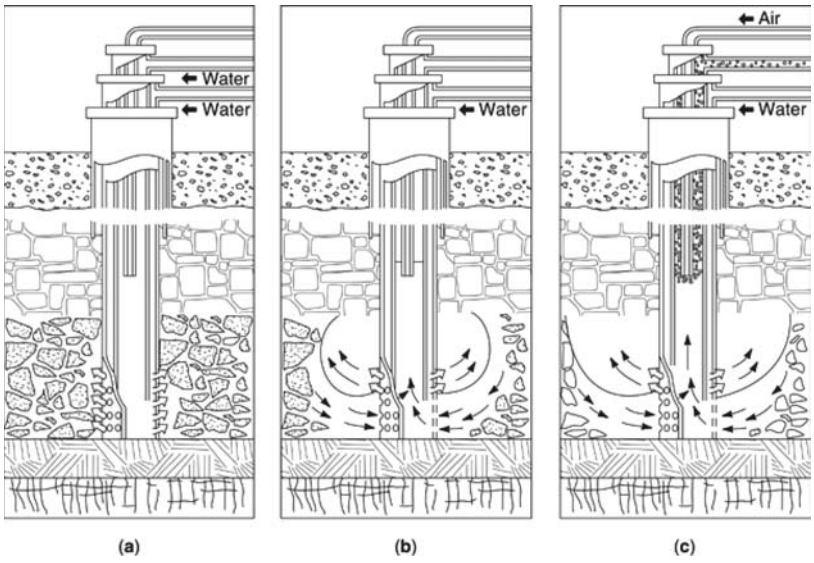

Fig. 1. The Frasch process: (a) initial heating; (b) movement of liquid sulfur; and (c) result of pumping compressed air. The thinner arrows indicate the flow of molten sulfur. (Courtesy of Freeport Minerals Company.)

sulfur. However, the techniques involved are different. The process was developed in Poland to exploit sulfur deposits, which, because of thin bedding, wide dispersion, and frequent impermeability, did not appear to be amenable to production by the Frasch method, which requires some degree of deposit isolation. The techniques employed include the use of explosives to control permeability or to create sealed-off gases and the calculated manipulation of underground water pressure, temperature, and flow conditions by control at injection and breakwater points. The system requires a constant rate of fuel consumption throughout the life of the mine and improves the rate of sulfur recovery. Hydrodynamic mining is used in Poland and was used in Iraq where the mining area was developed with Polish assistance.

Volcanic and Other Surface Deposits. Sulfur is recovered from volcanic and other surface deposits by a number of different processes, including distillation, flotation, autoclaving, filtration, solvent extraction, or a combination of several of these processes. The Japanese sulfur deposits are reached by tunnel, and mining is done by the room-and-pillar, chamber-and-pillar with filling, and cut-and-fill systems. Sulfur was historically extracted from the ore by a distillation process performed in rows of cast-iron pots, each containing about 180 kilograms (397 pounds) of ore. Each row of pots is connected to a condensation chamber outside the furnace. A short length of pipe connects each pot with a condenser. Brick flues connect combustion gases under the pots. Sulfur vapor flows from the pots to the condensation chamber where the liquid sulfur is collected. The Japanese ore contains 25–35 wt % sulfur. This method has been superseded by other sources of sulfur production.

The sulfur deposits in Italy have been worked since ancient times. Originally, sulfur was removed by piling the ore in central heaps, covering it with earth, and then igniting the pile. By this method, 30–50 wt % of the sulfur was burned to provide heat for melting the remainder of the sulfur in the ore. Less than 50 wt % of the sulfur originally contained in the ore was recovered. In about 1880, the first Gill gas furnace was installed. The original furnace had two chambers arranged so that the heat from burning ore in one chamber passed through ore in the other chamber to melt a considerable portion of the sulfur. When the sulfur in the first chamber burned, the chamber was refilled. When the partially extracted ore in the first chamber burned, it was refilled and the partially extracted ore in the other chamber was ignited. This method involved better utilization of the heat of combustion. Later, furnaces contained as many as six chambers and permitted up to 80% sulfur recovery.

Extensive experimentation has led to numerous patents for various thermal processes for extracting sulfur from ores, either as elemental sulfur or as SO_2, but very few of these processes have been operated commercially. The proposed processes involve shaft furnaces, multiple-hearth furnaces, rotary kilns, and fluidized-bed roasters. In all of these, ground ore is heated with oxygen-free, hot combustion gases to distill elemental sulfur; or the sulfur in the ore is burned with air to yield SO_2 for sulfuric acid production. In 1953, a commercial plant was brought on-stream at the Yerrington, Nevada, copper mine for recovering the sulfur as SO_2 from the Leviathan deposit of low grade sulfur ore in Alpine Country, California. The process consisted of four fluid-bed reactors, in which the ore was roasted in air to produce SO_2 for a contact sulfuric acid plant. For the production of elemental sulfur, the use of oxygen-free, hot combustion gases in a fluidized bed has been proposed to distill sulfur from the ore as a vapor, which is then condensed to liquid sulfur.

Various processes have been proposed and tested for the recovery of sulfur from native ores by solvent extraction, and many patents have been issued. Carbon disulfide, the best solvent for sulfur, has often been suggested for extraction of sulfur from ore. Some plants in Italy, Germany, South America, and the United States have used carbon disulfide for this purpose, but the cost of the solvent, the high losses, and its flammability detract from low operating costs. Many other solvents have been tried, including hot caustic solution, chlorinated hydrocarbons, ammonium sulfide, xylene, kerosene, and various high boiling oils. The sulfur is recovered either by volatilizing the solvent or by crystallizing the sulfur.

Various combinations of autoclaving, filtration, and centrifuging are used in some processes to recover sulfur from ore. One such process, involving continuous autoclaving, flotation, and filtration, was first used commercially at a plant in Columbia. The ore is finely ground to less than 625-μm (28-mesh) and suspended in water to form a slurry of about 30% solids, which is pumped continuously to a three-compartment, agitated autoclave. In the autoclave, the slurry is heated and the sulfur melts by steam injection into the bottom of each compartment. Agitation causes the sulfur to coalesce into globules that separate from the gangue. Hot slurry from the autoclave flows into a quench pot to be cooled by water injection, and the sudden cooling solidifies the separated sulfur particles. The cooled slurry is throttled to atmospheric pressure and flows into a 625-μm (28-mesh) vibrating screen. The oversize material passes directly to a sulfur melter, whereas the underflow from the screen passes to a flotation circuit for separation of the smaller sulfur particles. This gives a concentrate of 90–95 wt % sulfur which then passes to the sulfur melter. Melted sulfur is pumped through a filter for removal of gangue.

One more variation to the many methods proposed for sulfur extraction is the fire-flood method. It is a modern version of the Sicilian method, by which a portion of the sulfur is burned to melt the remainder. It would be done in situ and is said to offer cost advantages, to work in almost any type of zone formation, and to produce better sweep efficiency than other systems. The recovery stream would be about 20 wt % sulfur as SO_2 and 80 wt % elemental sulfur. The method was laboratory-tested in the late 1960s and patents were issued. However, it was not commercially exploited because sulfur prices dropped.

Sulfide Ores

The metal sulfides, which are scattered throughout most of the world, have been an important source of elemental sulfur. The potential for recovery from metal sulfides exists, although these sources are less attractive economically and technologically than other sources of sulfur. Nevertheless sulfide ores are an important source of sulfur in other forms, such as sulfur dioxide and sulfuric acid.

Some of the most important metal sulfides are pyrite [CAS: 1309-36-0], FeS_2; chalcopyrite [CAS: 1308-56-1], $CuFeS_2$; pyrrhotite [CAS: 1310-50-5], $Fe_{n-1}S_n$; sphalerite [CAS: 12169-28-7], ZnS; galena [CAS: 12179-39-4], PbS; arsenopyrite [CAS: 1303-18-0], $FeS_2 \cdot FeAs_2$; and pentlandite [CAS: 53809-86-2], $(Fe,Ni)_9S_8$. Sulfide deposits often occur in massive lenses, but may occur in tabular shape, in veins, or in a disseminated state. The deposits may be of igneous, metamorphic, or sedimentary origin. See also **Arsenopyrite**; **Chalcopyrite**; **Galena**; **Pentlandite**; **Pyrite**; **Pyrrhotite**; and **Sphalerite Blende**.

Pyrite is the most abundant of the metal sulfides. For many years, until the Frasch process was developed, pyrite was the main source of sulfur and, for much of the first half of the twentieth century, comprised over 50% of world sulfur production. Pyrite reserves are distributed throughout the world and known deposits have been mined in about 30 countries. Possibly the largest pyrite reserves in the world are located in southern Spain, Portugal, and the CIS. Large deposits are also in Canada, Cyprus, Finland, Italy, Japan, Norway, South Africa, Sweden, Turkey, the United States, and Yugoslavia. However, the three main regional producers of pyrites continue to be Western Europe; Eastern Europe, including the CIS; and China.

Sulfates

The largest untapped source of sulfur occurs in the ocean as dissolved sulfates of calcium, magnesium, and potassium. The average sulfur concentration in seawater is 880 ppm. Thus, 1 km^3 of seawater contains about 0.86×10^6 t of elemental sulfur in the form of sulfates. See also **Ocean**; and **Ocean Water**. Natural and by-product gypsum, $CaSO_4 \cdot 2H_2O$, and anhydrite, $CaSO_4$, rank second only to the oceans as potential sources of sulfur. Mineral deposits of gypsum and anhydrite are widely distributed in extremely large quantities. Gypsum [CAS: 13397-24-5] is a by-product waste material from several manufacturing processes; most notable is the waste gypsum produced in manufacturing phosphoric acid from phosphate rock and sulfuric acid.

Although many processes have been developed to recover elemental sulfur from gypsum or anhydrite, high capital and operating costs have precluded widespread use of these processes and are expected to continue to do so while less expensive sources remain available. Obtaining sulfur from gypsum processes has been attractive during periods when sulfur has been in short supply and energy costs remained relatively low. Because these processes require large amounts of energy when energy costs are high, sulfur extraction is unlikely to be competitive. However, gypsum and

anhydrite remain economical sources of sulfur in other forms, including sulfuric acid, cement, and ammonium sulfate, in areas such as India where sulfur must otherwise be imported.

Sulfur Production

The manufacture of H_2SO_4 accounts for nearly 90% of all sulfur consumed. Of this, about 50% of the H_2SO_4 goes into fertilizer production, nearly 20% into chemical manufacture, 5% into pigments, about 3% each for iron and steel production and the manufacture of rayon and synthetic films, and about 2% for various petroleum processes. The balance of over 15% of H_2SO_4 is consumed by a large number of other industries, this all giving credence to the use of H_2SO_4 production figures as an overall economic index. The 10% of the sulfur not going into H_2SO_4 is converted into numerous chemicals that are consumed by a variety of industries, the largest among these being pulp and paper production and the manufacture of carbon disulfide.

Sulfur Terminology

Many terms are used to describe the commercial forms of sulfur. The most common of these terms, along with brief descriptions and typical uses or references, are listed in Table 1.

Environmental Concerns

Increasing environmental concerns and subsequent governmental regulations have had a large impact on the sulfur industry. Even before the U.S. Clean Air Act was enacted in 1977, oil refineries and natural-gas processors realized the necessity of removing sulfur from both upstream products and off-gases. The U. S. Bureau of Mines (USBM) began collecting data on recovered sulfur in 1938. Although references were made to this type of sulfur prior to that time, no official data are available to quantify recovery. At first, recovered sulfur was considered a waste material, not a commercial by-product. As time went on, the importance of recovered sulfur increased as sulfur demand increased faster than the supply of Frasch and other native sulfur. Recovered sulfur became the primary domestic source of elemental sulfur in 1982.

The U.S. Clean Air Act set limits on the quantity of pollutants that could be released into the atmosphere. Sulfur dioxide was identified as one of the most common pollutants and also one of the principal contributors of acid rain, known to damage both natural and artificial environments. Gas-cleaning apparatus removed as much sulfur dioxide as was technologically possible from off-gases. Petroleum refiners and gas processors have recovered increasingly greater percentages of sulfur from

TABLE 1. SULFUR TERMINOLOGY

Term	Description and use
Amorphous sulfur	See insoluble sulfur
Bright sulfur	Crude sulfur free of discoloring impurities; bright yellow
Brimstone	See crude sulfur
Broken rock sulfur	Sulfur broken and sold as a mixture of lumps and fines; see refined sulfur
Broken sulfur	Solid crude sulfur crushed to <2.38 mm (−8 mesh)
Colloidal sulfur	Finely divided sulfur typically suspended in water; can be prepared by physical or chemical means; uses are mainly pharmaceutical
Crude sulfur	Commercial nomenclature for elemental sulfur; may be bright or dark but is free of arsenic, selenium, and tellurium
Dark sulfur	Crude sulfur discolored by minor quantities of hydrocarbons having up to 0.3 wt % carbon content
Dusting sulfur	Finely divided crude or refined sulfur prepared for pesticidal uses
Elemental sulfur	Processed sulfur in the elemental form produced from native sulfur or combined sulfur sources, generally having a minimum sulfur content of 99.5 wt %
Flour sulfur	Crude sulfur ground through 50–74 μm sieves (300–200 mesh), depending on the brand; used in rubber vulcanization, dyes, gun powder, agricultural dusts, dusting and wettable sulfur
Flowable sulfur	Synonymous with colloidal sulfur but-used more frequently to describe agricultural sulfur; uses are mainly pesticidal
Flowers of sulfur (sublimed sulfur)	Powdered form of sulfur produced by sublimation; may contain up to 30% of the amorphous allotrope; used in rubber vulcanization, agricultural dusts, pharmaceutical products, stock feeds
Formed sulfur	Sulfur formed to a specific shape, such as prills, granules, pellets, pastilles, or flakes; see prilled sulfur
Frasch sulfur	Elemental sulfur produced from native sulfur sources by the Frasch mining process
Ground sulfur	Solid sulfur ground into different physical size particles to serve various applications; may be combined with additives for special properties such as reduced dusting or improved dispersion
Insoluble sulfur (Crystex)	Produced by extracting flowers of sulfur with CS_2 or by fast quenching liquid or vaporized sulfur and extracting with CS_2 to remove soluble sulfur allotropes; used in rubber vulcanization, rubber cements, cutting oils, high pressure lubricants
Lac sulfur	Precipitated from polysulfide solutions by sulfuric acid; contains up to 45 wt % calcium sulfated liquid sulfur; uses are almost entirely pharmaceutical
Liquid sulfur	See molten sulfur
Molten sulfur	Crude sulfur in the liquid phase
Native sulfur	Sulfur that occurs in nature in the elemental form
Precipitated sulfur	Precipitated from polysulfide solution by hydrochloric acid and washed to remove all calcium chloride; uses are almost entirely pharmaceutical
Prilled sulfur	Solid crude sulfur in pellets; produced by cooling molten sulfur with air or water
Recovered sulfur	Elemental sulfur produced from combined sulfur sources by any method
Refined sulfur	Elemental sulfur produced by distilling crude sulfur; purity not less than 99.8%; when burned in small quantities, refined sulfur provides sulfur dioxide for fumigation, sugar and starch refining, preserving and bleaching
Roll sulfur	Refined sulfur cast into convenient sizes; uses include chemical manufacturing, burned for curing, fumigating, and preserving or bleaching effects; see refined sulfur
Rubbermaker's sulfur	Ground sulfur of various fineness having special specifications for low acid ash, and moisture contents
Run-of-mine sulfur	Mined by the hot-water process; solid shipments may contain 50 wt % fines; lump diameters up to 20 cm or more
Screened commercial sulfur	Run-of-mine sulfur having particle size determined by screening, Generally 9.5 and 1.68 mm (2 and 12 mesh), plus associated fines
Slated sulfur	Solid crude sulfur in the form of slate-like lumps; produced by allowing molten sulfur to solidify on a moving belt
Specialty sulfur	Prepared or refined grades of elemental sulfur that include amorphous, colloidal, flower, precipitated, wettable, or paste sulfur
Spray sulfur	Finely divided sulfur combined with various wetting agents and water; prepared for pesticidal uses; see wettable sulfur
Wettable sulfur	Powdered sulfur that has been treated for easy dispersion in water

the gas stream as elemental sulfur; metal smelters (especially nonferrous metals) have recovered by-product sulfuric acid; and coal and oil burning electric power plants have recovered by-product gypsum (calcium sulfate). Each industry has cut emissions dramatically. The type of by-product recovered is determined by the sulfur content of the gas stream; elemental sulfur is recovered when the sulfur dioxide content was relatively high.

The 1990 Amendments to the U.S. Clean Air Act required a 50% reduction of sulfur dioxide emissions by the year 2000. Electric power stations are believed to be the source of 70% of all sulfur dioxide emissions.

Existing technology to recover elemental sulfur from power plant off-gases has a cost estimated to be 50% higher than the cost of recovering by-product gypsum, much of which is disposed as waste. As landfill costs become higher, elemental sulfur recovery is expected to become a more attractive alternative to by-product gypsum production.

Over the years, larger quantities of sulfur have been recovered for a number of reasons. These include increased petroleum refining and natural-gas processing, more stringent limitations on sulfur dioxide emissions, and higher sulfur contents of the crude oil refined. Another contributing factor is the lower sulfur content limits set on petroleum-based fuels.

Because sulfur supplies, either as elemental sulfur or by-product sulfuric acid, have grown owing to increased environmental awareness, demand for sulfur has decreased in some consuming industries for the same reason. Industries such as titanium dioxide productions, which traditionally utilized sulfuric acid, have concerted to more environmentally friendly processes. In addition, many consumers who continue to use sulfuric acid are putting an emphasis on regenerating or recycling spent acid.

Another area where improved air quality has impacted on sulfur use is in agriculture. As sulfur dioxide emissions have decreased, sulfur content of soils has also decreased. Sulfur, recognized as the fourth most important plant nutrient, is necessary for the most efficient use of other nutrients and optimum plant growth.

Because many soils are becoming sulfur-deficient, a demand for sulfur-containing fertilizers has been created. Farmers must therefore apply a nutrient that previously was freely available through atmospheric deposition and low grade fertilizers.

Environmental regulations governing the desulfurization of transportation fuels have also resulted in significant quantities of sulfur being recovered from refinery operations and will continue to lead to increased recovery of byproduct sulfur. For many years, sulfuric acid recovered at nonferrous smelters has been the main concern. Of greater significance today is the recovery of elemental sulfur from crude oil refineries as the sulfur content of crudes has increased and as regulations on the sulfur content of oil and gasoline products have become increasingly stringent. Ultralow-sulfur diesel fuel will soon be the major form sold.

One of the few unregulated sources of human pollution is marine shipping. Marine pollution has thus far been left to shippers under the International Marine Organization's (IMO) Marine Pollution Treaty (MARPOL). An amendment to MARPOL that was ratified in October 2004 limited sulfur to 4.5% for ships in general operation beginning May 19, 2005. The allowable sulfur content of fuel burned in ships operating in the most crowded European waters [the North Sea, the English Channel, and the Baltic Sea, collectively known as the SO_x emission control area (SECA)] was reduced to 1.5% effective May 19, 2006.

The European environmental ministers' final proposal for the sulfur content in fuels for vessels sailing in European waters was a limit of 1.5% sulfur for all vessels in the SECA starting in 2007. The 1.5% limit applies to passenger vessels between ports within the European Union (EU) and the Baltic Sea beginning in May 2006 and the North Sea and the English Channel by 2007. Ships at berth in EU ports will be required to burn 0.1% sulfur fuel starting in January 2010.

Uses

Sulfur is unusual compared to most large mineral commodities in that the largest portion of sulfur is used as a chemical reagent rather than as a component of a finished product. Its predominant use as a process chemical generally requires that it first be converted to an intermediate chemical product prior to use in industry. In most of the ensuing chemical reactions between these sulfur-containing intermediate products and other minerals and chemicals, the sulfur values are not retained. Rather, the sulfur values are most often discarded as a component of the waste product.

Sulfuric acid is the most important sulfur-containing intermediate product. In 2005, 62% of U.S. sulfur demand was for sulfuric acid, to be used in fertilizer production: 29% was used in petroleum refining, 3% was used in metal mining; 6% was used for a multitude of other minor uses.

Agriculture. Sulfur is one of the elements essential for plant growth. Its functions within the plant are related closely to those of nitrogen and the two nutrients are synergistic. Sulfur is required for plant growth in quantities equal to, and sometimes exceeding, those of phosphorus. Sulfur has a variety of vital functions within the plant's biochemistry. It is a principal constituent of amino acids such as cysteine and methionine. It is also essential in the formation of enzymes, vitamins such as biotin and thiamine, and a variety of other important compounds in the plant, including chlorophyll. When sulfur is deficient, both plant yield and quality suffer. Plants that are sulfur-deficient are characteristically small and spindly. The younger leaves are light-green to yellowish, and in the case of legumes, nodulation of the roots is reduced. The oil content of seeds is diminished and the maturity of fruits is delayed in the absence of adequate sulfur. See also **Amino Acids**; and **Vitamins**.

Plant nutrient sulfur has been growing in importance worldwide as food production trends increase while overall incidental sulfur inputs diminish. Increasing crop production, reduced sulfur dioxide emissions, and shifts in fertilizer sources have led to a global increase of crop nutritional sulfur deficiencies. Despite the vital role of sulfur in crop nutrition, most of the growth in world fertilizer consumption has been in sulfur-free nitrogen and phosphorus fertilizers. See also **Fertilizer**.

Agriculture is the largest industry for sulfur consumption. Historically, the production of phosphate fertilizers has driven the sulfur market. Phosphate fertilizers account for approximately 60% of the sulfur consumed globally. Thus, although sulfur is an important plant nutrient in itself, its greatest use in the fertilizer industry is as sulfuric acid, which is needed to break down the chemical and physical structure of phosphate rock to make the phosphate content more available to plant life. Other mineral acids, as well as high temperatures, also have the ability to achieve this result. Because of market price and availability, sulfuric acid is the most economic method. About 90% of sulfur used in the fertilizer industry is for the production of phosphate fertilizers. Based on this technology, the phosphate fertilizer industry is expected to continue to depend on sulfur and sulfuric acid as a raw material.

Another fertilizer use is in the production of ammonium sulfate by reaction of sulfuric acid and ammonia. Some of this production is deliberate, but the greater portion is by-product material resulting from coke-oven operations, synthetic fiber manufacture, and, to a lesser extent, utility stack-gas scrubbing. Furthermore, a small amount of sulfuric acid is used, mainly in Europe, to produce potassium sulfate using the Mannheim process. Finally, sulfur has been safely used for centuries in agriculture as a natural fungicide and pesticide, and as an amendment to ameliorate soils and irrigation waters.

Petroleum Refining. Petroleum refining includes not only the refining of petroleum but associated chemical processes where process streams may serve both the refinery and the chemical complex. About 60% of the sulfuric acid used in petroleum refining is returned as spent acid for reclaiming; therefore, the demand for new sulfuric acid is about 3% of the total sulfur demand. The principal use for sulfuric acid is as a catalyst for alkylation, a process by which liquid high octane gasoline components having very good stability are produced from a combination of gaseous streams. Sulfuric acid and hydrofluoric acid are competing catalysts in this process. See also **Alkylation**. Sulfuric acid for refinery processes is manufactured from recovered sulfur produced at the refinery and from contaminated acid (acid sludge) returned to the acid plants for reconstitution.

Nonferrous Metal Production. In the case of copper, sulfuric acid is used for the extraction of the metal from deposits, mine dumps, and wastes, in which the copper contents are too low to justify concentration by conventional flotation techniques or the recovery of copper from ores containing copper carbonate and silicate minerals that cannot be readily treated by flotation processes. See also **Flotation**. The sulfuric acid required for copper leaching is usually the byproduct acid produced by copper smelters.

Sulfuric acid is the most commonly used reagent for the recovery of uranium from ores, and vanadium is often recovered as a coproduct. The

sulfuric acid used is either the byproduct sulfuric acid produced at smelters or sulfuric acid produced from elemental sulfur.

Iron and Steel Production. Consumption of sulfur in the iron and steel industry is in the form of sulfuric acid. The sulfuric acid is used as a pickling agent to removal mill scale, rust, dirt, and grease from the surface of steel products prior to further processing. The sulfuric acid pickling process faces increasing competition from hydrochloric acid pickling, largely because of the problem of disposing of the ferrous sulfate waste product. Hydrochloric acid is expected to replace sulfuric acid for pickling over the long term. There are no well-defined sources of sulfuric acid for steel pickling. Rather, it is generally obtained from merchant sulfuric acid plants that use the cheapest form of sulfur available in the area where it is produced. See also **Iron Metals, Alloys, and Steels**.

Plastics and Other Synthetic Products. Sulfur is used in the production of a wide range of synthetics, including cellulose acetate, cellophane, rayon, viscose products, fibers, and textiles. Sulfur intermediates for these manufacturing processes are equally divided between carbon disulfide and sulfuric acid.

Paper Products. The largest single segment of demand is in the manufacture of wood pulp by the sulfite process. In this process, the main sulfur intermediate is sulfur dioxide, which is generally produced at the plant site by burning elemental sulfur. Some sulfur dioxide, however, is produced as a by-product at smelter operations, purified and liquefied, and shipped to the pulp mills. The sulfur dioxide is converted to sulfurous acid, and the salt of this acid is a principal component of the cooking liquor for the sulfite process. See also **Pulp (Wood) Production and Processing**.

Paints. The main sulfur use is for the production of titanium dioxide pigment by the sulfate process. Sulfuric acid reacts with ilmenite or titanium slag and the sulfur remains as a ferrous sulfate waste product. Difficulties with this process have led to the development of the chloride process. See also **Paints and Coatings**.

Soil and Water Treatment. Agricultural soils and waters in the irrigated, arid regions of the world frequently benefit by the application of sulfur and its compounds. These benefits result from improvements in water penetration and movement and from increased availability of phosphorus and certain micronutrients which are otherwise unavailable owing to high soil pH. There are extensive areas of such soils in the western provinces of Canada and in many areas west of the Mississippi River in the United States. Throughout the other parts of the world, large tracts of arid, irrigated soils exist, notably in the Middle East, northern Africa, Australia, and many places in both Eastern and Western Europe.

Animal Nutrition. Sulfur in the diets of ruminant animals is beneficial to the animals' growth. See also **Feeds and Feed Additives: Nonruminant Feeds**. Sulfur increases feed intake, cellulose and dry matter digestion, and the synthesis of microbial protein. This results in increased meat, milk, and wool production. The special uses for sulfur in agriculture demonstrate a significant and continuing need for increased use of sulfur.

Highway Construction. The preparation and use of sulfur–asphalt (SA) paving materials have been reviewed. In the 1930s, asphalt was easily available and priced lower than sulfur. This is no longer the case. There are four different types of sulfur paving materials. See also **Asphalt (or Asphaltum)**.

During 1974–1985, about 200 sulfur–asphalt roads were constructed worldwide, half of which were in the United States. All U.S. SEA experimental sections designed and constructed according to standard practices using standard materials are performing as well as the control sections of conventional asphalt in these experimental projects.

The physical properties of elemental sulfur can be modified by its reaction with various organic and inorganic compounds. Many of the resulting sulfur products tend to have properties similar to paving asphalt.

Sand–Asphalt–Sulfur. Sulfur can be utilized as a means of upgrading poorly graded aggregates. Sand–asphalt–sulfur (SAS) does not provide an appreciable reduction of asphalt content of the paving material, but the utilization of sand rather than crushed stone is economically important. This technology was developed by Shell Canada Resources, Ltd., under the trade name Thermopave, which is a high quality paving material. After being tested in various provinces of Canada, SAS roads were constructed in the U.S.

Recycling of Commercial Asphalt Materials. For many years, repair and maintenance of roads and highways has consisted of putting a layer of asphalt concrete over the existing pavement. In many areas, the road level is at the maximum height for proper drainage and to satisfy safety considerations. As a result, these roads must have exposed surfaces removed before additional paving can take place. The increasing cost of both asphalt and aggregate has presented a greater incentive to reuse rather than to discard the removed material.

Many existing roads fail because the asphalt becomes stiff and brittle. If the materials are too stiff, additives that lower the viscosity must be used. The feasibility of using sulfur to soften or reduce the viscosity of the oxidized binder in recycled pavements has been successfully demonstrated by the U.S. Bureau of Mines and others.

Sulfur Concrete. Sulfur concrete (SC) is a mixture of sulfur and fine and coarse aggregates. These materials are heated to about 140 °C (284 °F), placed, and then allowed to cool and solidify into a rigid, concrete-like material. Concretes prepared with sulfur as the binder have mechanical properties comparable to portland cement concretes. Methods of preparing sulfur concretes that are not subject to rapid deterioration have been developed and evaluated in Austria, Canada, Denmark, Poland, and the United States. A modified sulfur binder called sulfur polymer cement (SPC), which contains 3–5 wt % organic material, has been developed for mixing with aggregates and the resulting SC products maintain substantially all of the initial strength gain, even after 300 freeze–thaw cycles.

Sulfur concretes are used in many specialty areas where Portland cement concretes are not completely satisfactory. Because SC can be formulated to resist deterioration and failure from mineral acid and salt solutions, it is used for construction of tanks, electrolytic cells, thickeners, industrial flooring, pipe, and others. See also **Cement**.

Sulfur Polymer Cement. SPC has been proven effective in reducing leach rates of reactive heavy metals to the extent that some wastes can be managed solely as low level waste (LLW). When SPC is combined with mercury and lead oxides (both toxic metals), it interacts chemically to form mercury sulfide, HgS, and lead sulfide, PbS, both of which are insoluble in water. A dried sulfur residue from petroleum refining that contained 600-ppm vanadium (a carcinogen) was chemically modified using dicyclopentadiene and oligomer of cyclopentadiene and used to make SC. This material was examined by the California Department of Health Services (Cal EPA) and the leachable level of vanadium had been reduced to 8.3 ppm, well below the soluble threshold limit concentration of 24 ppm.

Sulfur polymer cement shows promise as an encapsulation and stabilization agent for use with low level radioactive and mixed wastes. Use of SPC allows accommodation of larger percentages of waste than PCC. SPC-treated waste forms have met requirements of both the Nuclear Regulatory Commission (NRC) and the Environmental Protection Agency (EPA).

Foams. Sulfur can be foamed into a lightweight insulation that compares favorably with many organic types of foam and other insulating materials used in construction. It has been evaluated as thermal insulation for highways and other applications to prevent frost damage. See also **Foamed Plastics**.

Sulfur Impregnation. Impregnation of bonded, abrasive grinding wheels using sulfur improves strength and provides both lubricating and cooling qualities during grinding operations. Sulfur-impregnated wheels are well suited for grinding tough materials, including stainless steel, brass, bronze, and nickel. The impregnated wheels cut faster and prevent the welding of metal chips. In more difficult jobs, including gear grinding and surface grinding, the sulfur-impregnated wheels have four to eight times the life span of nonimpregnated wheels.

Sulfur can be used to impregnate ceramic tile. Sulfur impregnation reduces water absorption and makes the tile frost-resistant when used on exterior surfaces, including floors, roofs, or entrances to buildings.

SULFURIC ACID. [CAS: 7664-93-9] Infrequently termed "oil of vitriol," sulfuric acid, H_2SO_4, is a colorless, oily liquid, dense, highly reactive, and miscible with water in all proportions. Much heat is evolved when concentrated sulfuric acid is mixed with water and, as a safety precaution to prevent spluttering, the acid is poured into the water rather than vice versa. Sulfuric acid will dissolve most metals. The concentrated acid oxidizes, dehydrates, or sulfonates most organic compounds, sometimes causing charring. There are numerous commercial and industrial uses for H_2SO_4 and these include the manufacture of fertilizers, chemicals, inorganic pigments, petroleum refining, etching, as a catalyst in alkylation processes, in electroplating baths, for pickling and other operations in iron and steel production, in rayon and film manufacture, in the making of explosives, and in nonferrous metallurgy, to mention only some of its numerous uses. Because of its wide use industrially, some economists over the years have included sulfuric acid consumption among their economic indicators.

Most countries with significant industrial activity and particularly in chemicals production will have significant capacities for making sulfuric acid. In some countries, H_2SO_4 is the leading chemical in terms of tonnage production. Depending upon suppliers, H_2SO_4 is commercially available in a number of strengths, ranging from 77.7% H_2SO_4 (60° Baumé, sp. gr. 1.71) through 93.2% H_2SO_4 (66° Baumé), 98% H_2SO_4, 99% H_2SO_4, and 100% H_2SO_4 (sp. gr. 1.84).

Fundamentally, there are two kinds of sulfuric acid plants: (1) those that use the dry gas (sulfur burning) process; and (2) those that use the wet gas process. In the first type, the raw materials are elemental sulfur and water. In the second type, the sulfur dioxide feed may come from a variety of sources, including metallurgical smelters (copper, zinc, lead, etc.), pyrite roasters, waste acid decomposition furnaces, and hydrogen sulfide burners. In these plants, the SO_2 gas stream enters the acid plant containing a large amount of water vapor. The gas is usually hot (260–430 °C) and dusty, and also may contain a number of impurities, such as fluorides, that could harm the catalyst in the contact section of the plant. These incoming gases thus require cooling and purification in the series of scrubbers and electrostatic precipitators, followed by drying prior to entering the contact section of the plant.

In either type of plant, sulfur dioxide is converted to sulfur trioxide in the contact portion of the plant. The reaction $SO_2 + \frac{1}{2}O_2 \rightarrow SO_3$ is effected by passing the SO_2 over a catalyst, usually vanadium pentoxide (V_2O_5). The catalyst in the converter vessel is usually in the form of small pellets and typically arranged in four layers. Provision is made for removal of the heat of reaction after each layer or stage. The catalyst may be used for a number of years with only a very moderate decrease in activity.

From this fundamental point, the sulfuric acid plant designer has a number of alternatives and options to consider. Two factors are of major import in sulfuric acid plant design today, namely, recovery and conservation of energy, and minimizing environmental impact. For example, in the relatively simple plants of a few years age, the SO_2 need contact the catalyst but once and the absorption of the resulting SO_3 in water (a solution of sulfuric acid) could be handled in a single absorption tower. Recycling could be kept to a minimum. In the modern sulfuric acid plant, double contact (DC) of the gases with catalyst and double absorption (DA) of the gases is commonly practiced. Designs are available in numerous configurations, each offering various advantages in terms of energy conservation, pollution minimization, initial and operating costs. A typical sulfur-burning DC/DA sulfuric acid plant is shown in Fig. 1.

Of the approximately 40 million tons (36 million metric tons) of sulfuric acid manufactured in the United States per year, about 90% is used in the production of fertilizers and other inorganic chemicals. Much of the remaining 10% of H_2SO_4 is used by the petroleum, petrochemical, and organic chemicals industries. Much of this latter acid is involved in recycling kinds of processes. As pollution regulations in various countries become more restrictive, spent acid may become a much more attractive raw material than has been the case in the past.

As pointed out by Sander and Daradimos (1978), a regeneration of sulfuric acid of high quality can only be attained by thermal decomposition back to sulfur dioxide at high temperatures, where all organic impurities are completely burned — followed by reprocessing the SO_2 gases by the contact process to concentrated acid or oleum.

Reactivity of Sulfuric Acid. Dilute sulfuric acid reacts: (1) with many hydroxides, e.g., sodium hydroxide, to yield two series of sulfates (the

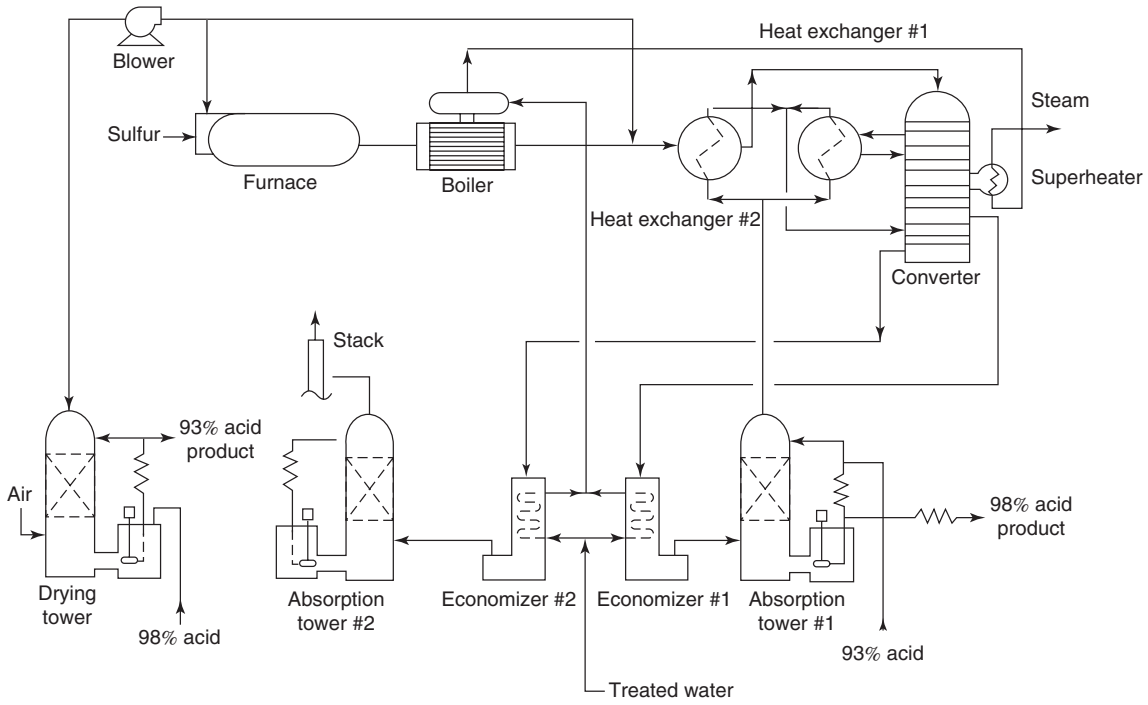

Fig. 1. Representative sulfuric acid plant of the sulfur-burning, double contact (DC), double absorption (DA) type.

acid is dibasic), e.g., sodium sulfate or sodium hydrogen sulfate, depending upon the ratio of acid to base reacting, (2) with many ordinary oxides, e.g., magnesium oxide, to yield the corresponding sulfate, e.g., magnesium sulfate solution, (3) with some carbonates, e.g., zinc carbonate, to yield the corresponding sulfate, e.g., zinc sulfate solution plus carbon dioxide gas (calcium carbonate is soon coated by a layer of calcium sulfate, which prevents further reaction), (4) with some sulfides, e.g., ferrous sulfide, to yield the corresponding sulfate, e.g., ferrous sulfate plus hydrogen sulfide gas, (5) with many metals, e.g., zinc, if not too pure (but not copper), to yield the corresponding sulfate, e.g., zinc sulfate solution plus hydrogen gas, (6) with solutions of some salts to yield the corresponding sulfate, e.g., barium chloride, changed to barium sulfate precipitate, calcium citrate, malate, tartrate to calcium sulfate precipitate and the free organic acid in solution.

Higher strengths of sulfuric acid react similarly in kind to the cases of (1), (2), (3), (6) above, but not, in general, as in cases (4) and (5) above. Copper and concentrated sulfuric acid yield copper sulfate and sulfur dioxide gas. Iron reacts similarly, yielding ferric sulfate in the place of copper sulfate.

A number of other reactions of sulfuric acid are characteristic of its higher strengths. Concentrated sulfuric acid is thus (7) an oxidizing agent, and a further example is the oxidation of sulfur to sulfur dioxide (the reacting sulfuric acid is reduced to sulfur dioxide), (8) a sulfonating agent, e.g., naphthalene sulfonated to naphthalene-sulfonic acids (mono-, alpha or beta, di- several), (9) an esterification agent, e.g., methyl alcohol esterified to dimethyl sulfate $(CH_3O)_2SO_2$, melting point $-32\,^{\circ}C$, boiling point $189\,^{\circ}C$, or methyl hydrogen sulfate $CH_3O \cdot SO_2OH$, ethyl alcohol esterified to diethyl sulfate $(C_2H_5O)_2SO_2$, melting point $-26\,^{\circ}C$, boiling point $208\,^{\circ}C$, or ethyl hydrogen sulfate $C_2H_5O \cdot SO_2OH$, (10) a dehydration agent, e.g., formic acid into carbon monoxide, sugar blackened with separation of carbon, (11) an addition agent, e.g., ethylene into ethyl hydrogen sulfate, (12) a nonvolatile acid upon heating, e.g., with sodium chlorite or nitrate, hydrogen chloride or nitric acid, respectively, is volatilized and sodium sulfate or sodium hydrogen sulfate remains as a residue.

SULFUR (In Biological Systems). Sulfur, in some form, is required by all living organisms. It is utilized in various oxidation states, including sulfide, elemental sulfur, sulfite, sulfate, and thiosulfate by lower forms and in organic combinations by all. The more important sulfur-containing organic compounds include the amino acids (cysteine, cystine, and methionine, which are components of proteins); the vitamins thiamine and biotin; the cofactors lipoic acid and coenzyme A; certain complex lipids of nerve tissues, the sulfatides; components of mucopolysaccharides, the sulfated polysaccharides; various low-molecular-weight compounds, such as glutathione and the hormones vasopressin and oxytocin; and many therapeutic agents, such as the sulfonamides and penicillins, as well as oral hypoglycemic agents sometimes used in treatment of diabetes mellitus. Sulfhydryl groups of the cysteine residues in enzyme proteins and related compounds, such as hemoglobin, play a key role in many biocatalytic processes; sulfhydryl-disulfide interchange reactions involving the cysteine residues of proteins are critical events in the immune processes, in transport across cell membranes, and in blood clotting. The S — S bridges between these residues are important in the maintenance of the tertiary structure of most proteins.

The electronic structure of sulfur is such that a variety of oxidation states are readily obtainable. It can be said that a sulfur cycle exists in nature, as noted in Fig. 1.

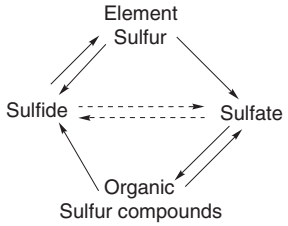

Fig. 1. Sulfur cycle.

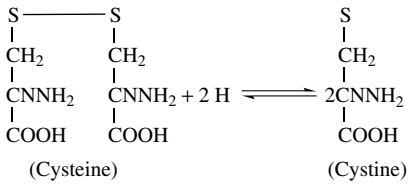
The oxidation and reduction of elemental sulfur and sulfide occur in different species of bacteria, e.g., the oxidation of sulfides via elemental sulfur to sulfate takes place in *Chromatia*, the alternative oxidation to sulfate in *Thiobacillus*. The reduction of sulfate to sulfide occurs in *Desulfovibrio*. The biosynthesis of organic sulfur compounds from sulfate takes place mainly in plants and bacteria, and the oxidation of these compounds to sulfate is characteristic of animal species and of heterotrophic bacteria.

The amino acids cysteine and cystine are interconverted by oxidation-reduction reactions, as shown by



Cystine was first isolated from a urinary calculus by Wollaston in 1805. It was shown to be a component of protein by Morner in 1899 and independently by Embden in 1900. Proof of its structure was given by Friedman in 1902. See also **Amino Acids**; **Coenzymes**; **Proteins**; and **Vitamins**.

In the chain from soils to plants to humans, inorganic sulfur, or more accurately, the sulfate ion (SO_4^{2-}), is taken up by plants and converted within the plant to organic compounds (the sulfur amino acids). These amino acids combine with other amino acids to make up plant protein. When the plant is eaten by a human or by livestock animals, the protein is broken down and the amino acids are absorbed from the digestive tract and recombined in the proteins of the animal body. The most important feature of sulfur in the food chain is that plants use inorganic sulfur compounds to make sulfur amino acids, whereas animals and humans use the sulfur amino acids for their own processes and excrete inorganic sulfur compounds resulting from the metabolism of the sulfur amino acids.

Ruminants, such as cattle, sheep, and goats, can use inorganic sulfur in their diets because the microorganisms in the rumen convert the inorganic sulfur into sulfur amino acids and these are then absorbed farther along in the digestive tract.

Soils very low in available sulfur are common in a number of regions of the world. In the United States, low-sulfur soils are frequently found in the Pacific Northwest and in some parts of the Great Lakes states. For many years, sulfur in the form of calcium sulfate was an accessory part of most commercial phosphate fertilizers, and this probably helped to prevent development of widespread sulfur deficiency in crops grown where these fertilizers were used. Volatile sulfur compounds from smoke, particularly before tight pollution controls, were an important source of sulfur for plants growing near industrial centers. In some cases, excessive sulfur in the air can cause injury to the plants. The trend toward high-analysis fertilizers without sulfur and air pollution abatement diminishes some of the inadvertent sources of sulfur for plants and crops and creates a need for more deliberate use of sulfur-containing fertilizers.

The extent to which any plant will convert inorganic sulfur taken up from the soil into amino acids and incorporate these into protein is controlled by the genetics of the plant. Increasing the available sulfur in soils to levels in excess of those needed for optimum plant growth will not increase the concentration of sulfur amino acids in plant tissues. To meet the requirements for sulfur amino acids in human diets, the use of food plant species with the inherited ability to build proteins with high levels of sulfur amino acids is required in addition to that supplied by way of the soil.

Since animals tend to concentrate in their own proteins the sulfur amino acids contained in the plants they eat, such animal products (meat, eggs, and cheese) are valuable sources of the essential sulfur amino acids in human diets. In regions where the diet is composed almost entirely of foods of plant origin, deficiencies of sulfur amino acids may be critical in human nutrition. Frequently, persons in such areas (also voluntary vegetarians) are also likely to suffer from a number of other dietary insufficiencies unless supplemental sources are used.

Diets of corn (maize) and soybean meal are usually fortified with sulfur amino acids for pigs and chickens. Sometimes fishmeal, a good source of sulfur amino acids, is added to the diets, or sulfur amino acids synthesized by organic chemical processes may be used.

Since ruminants can utilize a wide variety of sulfur compounds, any practice to increase the sulfur in plants may help to meet the requirements of these animals. Sheep appear to have a higher requirement for sulfur than most other animals, perhaps because wool contains a fairly high level of sulfur. Adding sulfur fertilizers to soils used to produce forage for sheep may improve growth and wool production, even though no increased yield of the forage crop per se may be noted.

Sulfate and Organic Sulfates. Inorganic sulfate ion (SO_4^{2-}) occurs widely in nature. Thus, it is not surprising that this ion can be used in a number of ways in biological systems. These uses can be divided primarily into two categories: (1) formation of sulfate esters and the reduction of sulfate to a form that will serve as a precursor of the amino acids cysteine and methionine; and (2) certain specialized bacteria use sulfate to oxidize carbon compounds and thus reduce sulfate to sulfide, while other specialized bacterial species derive energy from the oxidation of inorganic sulfur compounds to sulfate.

Among the variety of sulfate esters formed by living cells are the sulfate esters of phenolic and steroid compounds excreted by animals, sulfate polysaccharides, and simple esters, such as choline sulfate. The key intermediate in the formation of all of these compounds has been shown to be 3′-phosphoadenosine-5′-phosphosulfate (PAPS). This nucleotide also serves as an intermediate in sulfate reduction.

In organisms that utilize sulfate as a source of sulfur for synthesis of cysteine and methionine, the first step in the reduction process is the formation of PAPS. This is not surprising since the direct reduction of sulfate ion itself is an extremely difficult chemical process. It is known that the reduction of esters and anhydrides occurs much more readily than the reduction of corresponding anions. Following activation, the sulfuryl group of PAPS is reduced to sulfite ion (SO_3^{2-}) by reduced triphosphopyridine nucleotide (TPNH) and a complex enzyme system. Following the reduction of PAPS to sulfite, additional reduction steps readily produce hydrogen sulfide, which appears to be a direct precursor of the amino acid cysteine.

Sulfur Compounds in Onion and Garlic. Dating back to antiquity, there have claims made for the curative and preventative physiological powers of onion and garlic. Dr. Eric Block (State University of New York at Albany), a specialist in the organic chemistry of sulfur, and colleagues, have investigated the chemistry of onion and garlic over a period of years. Some of the results were reported in the Block (1985) reference listed. As pointed out by Block, the cutting of an onion or a garlic bulb releases a number of low-molecular-weight organic molecules that incorporate sulfur atoms in bonding forms rarely encountered in nature. These molecules are highly reactive and they change spontaneously into other organic sulfur compounds, which in turn participate in further transformations. Researchers have cataloged a number of biological effects of the extracts from these bulbs, including antibacterial and antifungal properties. Other extracts act as antithrombotic agents (inhibit blood platelets). As early as 1721, a drink consisting of wine and macerated garlic (*vinaigre des quatre voleurs*) was used as an antibiotic in France and is still available today! Pasteur (1858) reported on the antibacterial properties of garlic. Albert Schweitzer is reported to have used garlic in the treatment of amoebic dysentery in Africa. As reported by Block, laboratory investigations have shown that garlic juice diluted in one part in 125,000 inhibits the growth of bacteria of the genera *Staphylococcus, Streptococcus, Vibrio* (including *V. cholerae*) and *Bacillus* (including *B. typhosus, B. dysenteriae*, and *B. Enteritidis*). Lacrimatory factors contained in these bulbs are well known.

Serious research commenced in 1844 by Theodor Wertheim, a German chemist. He attributed some of the properties of garlic, "*mainly to the presence of a sulfur-containing, liquid body, the so-called garlic oil. All that is known about the material is limited to some meager facts about the pure product, which is obtained by steam distillation of bulbs of Allium sativum. Since sulfur bonding has been little investigated so far, a study of this material promises to supply useful results for science*." Wertheim suggested the name *allyl* for the oil. Today, allyl is used for chemicals in the C_3H_5 series ($CH_2{=}CHCH_2$).

Another German investigator (Semmler, 1892) also produced garlic oil via steam distillation. The oil yielded diallyl disulfide, $CH_2{=}CHCH_2$ $SSCH_2CH{\equiv}CH_2$, with minor amounts of diallyl trisulfide and diallyl tetrasulfide present. The oil yielded by similar experimentation with onions was different, containing essentially propionaldehyde, C2H5CHO, plus

a number of sulfur compounds, of which dipropyl disulfide, $C_6H_{12}S_2$, was one.

Using less harsh methods, Cavallito (1944) produced an oil, $C_6H_{10}S_2O$, by extracting the garlic with ethyl alcohol (room temperature). This oil was found to be more powerful than penicillin or sulfaguanidine against *B. typhosus*. The exact formula of Cavallito's oil was found to be allyl-2-propenethiosulfinate, $CH_2{=}CHCH_2S(O)SCH_2CH{=}CH_2$. Cavallito gave this substance the common name, *allicin*. Precursor molecules for allicin have been identified and it has been established that allicin is not developed in garlic until it is initiated by an enzyme, termed *allinase*.

As pointed out by Block, allinin is the "first natural substance found to display optical isomerism due to mirror-image forms at sulfur as well as at carbon." The research by Block and others is well delineated in the Block (1985) reference. Although much remains to be learned, there is now a long line of hard scientific evidence that garlic and onion have beneficial physiological properties. Most scientists to date suggest that the properties of these bulbs are best exploited by consuming the fresh products, rather than from extracts, particularly when the latter are derived from harsh methodologies, such as steam distillation.

Preservatives. Sulfur compounds, such as sulfur dioxide and sodium bisulfite, are used commercially to preserve the color of various food products, such as orange juice, dehydrated fruits and vegetables, such as apricots, carrots, peaches, pears, potatoes, and many others. Concentrated sulfur dioxide is used in wine-making to destroy certain bacteria. The color preservation of canned green beans and peas is enhanced by dipping the produce in a sulfite solution prior to canning. In 1986, some of these compounds and uses were put under closer regulation in the United States.

The sulfatases are a widely distributed group of enzymes that hydrolyze simple sulfate esters to inorganic sulfate.

Sulfur-Based Pesticides. Sulfur (elemental) has been used as an effective acaricide, fungicide, and insecticide. For ease of use, a number of special formulations are available, ranging from sulfur dusts (up to 95% sulfur); a wettable powder (30 to 90%); and paste-like solutions in which the sulfur is ground to a fine colloidal form. Such formulations may contain up to 50% sulfur. Target plant diseases of sulfur when used as a fungicide include: apple scab, brown rot, downy and powdery mildew, and peach scab. Against insects, sulfur is effective for mite, scale, and thrip. Most formulations are not injurious to honeybees.

Specific sulfur control chemicals include: (1) Calcium polysulfide (lime-sulfur), dating back to the 1850s and available as a solution (up to 31% sulfur) or as a dry powder (up to 70% sulfur). The compound is effective against anthracnose, apple scab, brown rot, powdery mildew, and peach leaf curl — and against mite and scale insects. (2) Sodium polysulfide and sodium thisulfate mixtures — used for spraying and dipping fruit, adding color to the product, and prolonging the period during which the fruit can be picked. (3) Sodium thiosulfate pentahydrate, which prevents discoloration of some green vegetables (use is regulated).

Role of Sulfur in Tidal Wetlands. As pointed out by Luther, et al. (1985 reference listed), the biogeochemical role of sulfur in tidal wetlands presently is subject to considerable research. Sulfur is an important redox element under natural aquatic conditions and is responsible for several important biogeochemical processes, including (1) sulfate reduction, (2) pyrite formation, (3) metal cycling, (4) salt-marsh ecosystem energetics, and (5) atmospheric sulfur emissions. These processes depend upon the formation of one or more sulfur intermediates, which may have any oxidation state between $+6$ and -2. The intermediate oxidation states may be organic or inorganic. In their study, Luther and colleagues analyzed sulfur species in pore waters of the Great Marsh, Delaware. Anticipated findings reported were bisulfide increases with depth due to sulfate reduction and subsurface sulfate excesses and pH minima, the result of a seasonal redox cycle. Not expected was the pervasive presence of thiols, such as glutathione, particularly during periods of biological production. It appears that salt marshes may be unique among marine systems in producing high concentrations of thiols. Polysulfides, thiosulfate, and tetrathionate also showed seasonal subsurface maxima. The findings suggest a dynamic seasonal cycling of sulfur in salt marshes involving abiological and biological reactions and dissolved and solid sulfur species. The researchers suggest that the chemosynthetic turnover of pyrite to organic sulfur is the likely pathway for this sulfur cycling. It follows that the material, chemical, and energy cycles in wetlands appear to be optimally synergistic.

SULFUROUS ACID. [CAS: 7782-99-2] H_2SO_3, formula weight 82.08, colorless liquid, prepared by dissolving SO_2 in H_2O. Reagent grade H_2SO_3 contains approximately 6% SO_2 in solution. As a bleaching agent, sulfurous acid is used for whitening wool, silk, feathers, sponge, straw, wood, and other natural products. In some areas, its use is permitted for bleaching and preserving dried fruits. The salts of sulfurous acid are sulfites.

Sulfurous acid is a strong reducing agent, being oxidized to H_2SO_4: (1) on standing in contact with air; (2) by chlorine, bromine, iodine, yielding HCl, HBr, or HI, respectively; (3) by HNO_3 or nitrous acid yielding nitric oxide; and (4) by permanganate. Sulfurous acid is itself reduced by zinc and dilute H_2SO_4 to H_2S. Sulfurous acid also may be formed by the reaction of a sulfite or bisulfite solution and an acid.

Sodium sulfite [CAS: 7757-83-7] Na_3SO_3 and sodium hydrogen sulfite [CAS: 7631-90-5] $NaHSO_3$ are formed by the reaction of sulfurous acid and NaOH or sodium carbonate in the proper proportions and concentrations. Sodium sulfite, when dry and upon heating, yields sodium sulfate and sodium sulfide. Sodium pyrosulfite (sodium metabisulfite) [CAS: 7681-57-4] $Na_2S_2O_5$ is a common sulfite. Crystalline sulfites are obtained by warming the corresponding bisulfite solutions. Calcium hydrogen sulfite $Ca(HSO_3)_2$ is used in conjunction with excess sulfurous acid in converting wood to paper pulp. Sodium sulfite and silver nitrate solutions react to yield silver sulfite, a white precipitate, which upon boiling decomposes forming silver sulfide, a brown precipitate.

An esterification agent, sulfurous acid forms dimethyl sulfite $(CH_3O)_2SO$, bp 126 °C and diethyl sulfite $(C_2H_5O)_2SO$, bp 161 °C. Sulfites give a white precipitate with barium chloride, soluble in HCl with evolution of SO_2. Sulfites decolorize iodine in acid solution.

SULFUR (VULCANIZATION). See **Rubber (Natural)**.

SULTRINESS. An oppressively uncomfortable state of the weather that results from the simultaneous occurrence of high temperature and high humidity. It is often enhanced by calm air and cloudiness. This term is gaining technical recognition in light of the increased study of human comfort and air conditioning. Sultriness has been expressed in terms of the values of various measures of comfort. Some of the lower limits are water vapor pressure of 14 mm; dewpoint of 19 °C (65 °F); equivalent temperature of 56 °C (133 °F); effective temperature of 24 °C (75 °F); and the following pairs of temperature and relative humidity, 35 °C (95 °F) and 25%, 30 °C (86 °F) and 40%, 25 °C (77 °F) and 65%.

SUM. The answer when two or more quantities are combined by addition. In group theory, the term direct sum has a special meaning. See also **Representation of Groups**.

The usual symbol for the operation of summation is the Greek capital letter *sigma* (Σ). Thus, Insert Equation

$$\sum_{n=0}^{\infty} a_n x^n = f(x)$$

means to add the terms $a_n x^n$, assigning every integral value from zero to infinity to the letter n. When two or more sums are to be taken with respect to several subscripts or indices only one summation sign may be used and the summation limits are often omitted, if they are understood from the accompanying text. Even the summation sign can be omitted and this is common, especially in tensor analysis. Thus, an expression like

$$A^m = \frac{\partial x^{-m}}{\partial x^i} A^i$$

by convention means that summation is to be made over the repeated index, i. Still further condensation is customary in matrix algebra, where $\mathbf{Ab} = \mathbf{C}$ means that the matrix $\mathbf{C}$ has elements C_{ij} calculated by the equation

$$c_{ij} = \sum A_{ik} B_{kj}$$

with A_{ik} and B_{kj} as elements of $\mathbf{A}$ and $\mathbf{B}$. The summation over k is to be extended from unity to n, where n is the number of columns in $\mathbf{A}$ and the number of rows in $\mathbf{B}$.

SUMATRA. See **Meteorology**.

SUMMER SOLSTICE. 1. That point on the ecliptic occupied by the Sun at maximum northerly declination. Sometimes called *June solstice, first point of Cancer*.

2. That instant at which the Sun reaches the point of maximum northerly declination, about June 21.

SUMNER, JAMES BATCHELLER (1887–1955). Sumner was born at Canton, Massachusetts on 19 November 1887, the son of a textile manufacturer. He lost an arm in a shooting accident as a child, but this did not inhibit his study of chemistry at Harvard University between 1906 and 1910. He joined his uncle's cotton factory for a time, and then taught chemistry and physiology at a college at Sackville, New Brunswick. This led to a lectureship in chemistry in 1911 at the Polytechnic Institute, Worcester, Massachusetts. In 1912 he returned to Harvard to study biochemistry and gained his PhD in 1914. In 1929, after several years teaching biochemistry at the medical school at Cornell University, Ithaca, New York, he was made Professor of Biochemistry (and from 1947) Director of the Enzyme Chemistry Laboratory at Cornell. He was married three times and had seven children. He was a gifted linguist, cook and textbook writer. He died of cancer at Buffalo, New York on 12 August 1955.

Sumner began his quest to crystallize an enzyme in 1917, choosing urease extracted from the jackbean as his subject. Not until 1922, when he began to use alcohol as a solvent, did he obtain sufficient quantities of urease to attempt crystallization. He succeeded in 1926, but was met with skepticism, especially from German chemists like Richard Willstätter. Sumner's claim that urease was a crystallizable protein was irrevocably proved by John Northrop in 1935. He shared the Nobel Prize in Chemistry in 1946 with Northrop and W. M. Stanley for his work on the crystallization of enzymes. See also **Northrop, John Howard (1891–1987)**; and **Stanley, Wendell Meredith (1904–1971)**.

SUMNER LINE. A line of position obtained from the observation of altitude of some celestial object. This method for obtaining a line of position was discovered by Captain Thomas H. Sumner in 1837, and circumstances leading to the discovery are described in "The American Practical Navigator," Bowditch.

The method employed by Sumner for obtaining a celestial line of position was standard procedure for American ship masters until the early part of the twentieth century. For this reason, it is worthy of consideration here, in spite of the fact that it has been almost completely superseded by the methods described in the article on celestial navigation. Captain Sumner used the old-fashioned method for determining latitude and longitude at sea from an observation of the altitude of a celestial object. These methods require the solution of the astronomical triangle. To solve this triangle, at least three parts must be known. At sea, the altitude of the object, as obtained from sextant observations, will give one part, and the declination of the object will give another. To obtain the third part, either the latitude or the longitude of the observer must be known. Since latitude and longitude are the coordinates that the navigator is seeking, it would seem at first glance that a solution of the problem is impossible. However, if the object observed is approximately due east or west, a change in latitude of several miles will produce but slight effect on the computed longitude. On the other hand, if the object is nearly due north or south, a change in longitude will produce but slight effect in the computed latitude. An approximate value of latitude and longitude can be obtained by methods of dead reckoning (DR). If the observed object is within 45° of east or west, the DR latitude is used and the longitude is computed. When the object is within 45° of the meridian, the DR longitude is used in the computation of the latitude. If the DR position is known to within 20 miles (32 kilometers), the computed latitude or longitude will be accurate to within $\frac{1}{4}$ of a mile, unless the observed object is close to the zenith.

In Captain Sumner's case, his ship had experienced gales and fog for a number of days, and the DR position was very uncertain. When the clouds broke away, he obtained an altitude of the sun in the forenoon. Since his DR position was uncertain, he assumed several values for latitude separated by about 20 miles (32 kilometers), and computed the corresponding longitudes. On plotting these positions, he found that they lay along a straight line on a mercator chart. He made the assumption, which has since been established as sound, that his ship must be on the line.

After the publication of this discovery, the use of Sumner lines became the standard procedure for most navigators. If two objects, differing in bearing by at least 45°, are available for observation, two Sumner lines can be obtained and a fix determined. If, as is frequently the case during daylight hours, only one object is available, this one object is observed twice, with an interval of time between the two observations sufficient to produce a change in bearing of at least 45°. The fix of these two lines is obtained by moving one line to the time of the other by the method of running fix.

A Sumner line is, in reality, a small circle on the earth, with a point on the earth directly under the observed object as center. Unless the object is within 10° of the zenith, the curvature is so slight as to be negligible in drawing the line on a mercator chart.

SUMPTNER PRINCIPLE. When a source of light is placed at any point inside a sphere with perfectly diffusing walls, every part of the interior is equally illuminated.

SUN COMPASS. A device utilizing the direction of the sun for direction or orientation purposes. The sun compass operates on much the same principle as that of the sun dial. In the sun dial, the gnomon for casting the shadow is set accurately parallel to the earth's axis of rotation, and the direction of the shadow indicates local apparent time. In the sun compass, the dial is set for local apparent time, and the direction of the shadow is used in connection with a compass card. The instrument is quite complicated, for it must be set for terrestrial latitude, longitude, and local apparent time. It has been of great service in connection with flights in the polar regions of the earth, where the weakness and uncertainty of the horizontal component of the earth's magnetic field render the use of the magnetic compass most unreliable.

SUNDIAL. It is logical to suppose that from the earliest times, mankind has used the apparently moving sun as a means for reckoning time. As the sun appears to move across the heavens during the day, the position and length of the shadow cast by an opaque rod will continually change. The positions of lengths of this shadow may be used for the purpose of subdividing the period between sunrise and sunset. Any device that utilizes the shadow cast by the sun for the purpose of subdividing the day into equal parts is known as a sun dial.

It is difficult to say just when the first sun dial was constructed. The earliest written record is found in Isaiah 38:8, which was written approximately 700 years before the Christian era. The earliest instrument still existing is one built in Egypt, for which the exact date of construction is unknown. Sun dials came into general use during the thirteenth century, and the different types were then rapidly developed. By the time that mechanical clocks and watches made their appearance in the fifteenth century, a multitude of types of sun dials had been constructed, and many volumes had been written regarding the theory of the various devices.

There are two fundamental types of sun dials: fixed and portable. The most common fixed type marks the divisions of the day by means of the shadow thrown by the sun. The dial itself may be set at any desired angle, but generally, the plate is horizontal, and the style, which casts the shadow, is so placed as to be parallel to the axis of rotation of the earth. The portable dial makes use of the fact that the length of the shadow of the sun varies throughout the day, being the shortest at noon and the longest at sunrise and sunset. The great difficulty with this type is that because of the change in declination of the sun with season, it is necessary to have different scales of time for different periods of the year.

A multitude of ingenious and beautiful types of sun dials have been used in the past for the purpose of keeping time and are in use at present as ornaments or items of curiosity. In adjusting the horizontal type of sun dial, such as may be purchased from a number of dealers in garden supplies or curios, it is important to remember that the style should be parallel to the axis of the earth. That is, it should lie exactly in the true north-south plane, and the north end should be so elevated that the angle which the style makes with the horizontal plate is equal to the latitude of the observer. When properly adjusted, the sun dial will read local apparent time. This time will differ from ordinary clock time by the longitude difference between the position of the dial and the standard time meridian, and also by the equation of time.

SUNDOGS. A sundog (or sun dog) is a relatively common atmospheric optical phenomenon associated with the reflection/refraction of sunlight by the numerous small ice crystals that make up cirrus or cirrostratus clouds. Sundogs typically appear as bright spots of light seen on both sides of the Sun. See Fig. 1. They are also called *halos* or *parhelia*. The best time to see sundogs is in the late afternoon, when the Sun is close to the horizon and can be blocked by trees or buildings. Winter seems to be the best season, because the atmosphere tends to be dry and cold, but sundogs are visible throughout the year and around the world when conditions are right. The two bright spots are 22-23 degrees from the Sun, about the distance covered by your outstretched hand held at arms' length. A line though the sundogs and Sun is parallel to the horizon.

Fig. 1. Image of a halo with sundogs taken by Grant W. Goodge. (*image courtesy of NOAA Photo Library*).

Sundogs are a type of ice crystal halo. Scientists had to understand the size, shape, and motion of ice crystals in the Earth's atmosphere to understand how halos are produced.

Sundogs are caused by sunlight passing through flat, 6-sided ice crystals high in the troposphere. The crystals fall through the atmosphere like leaves, flat side more or less down and slowly rocking back and forth. Because all of the crystals face down, light from the Sun is refracted into definite patterns. If the crystals tumbled as they fell then sundogs would not be produced.

Other halos are possible. Each has a name that describes its location in the display around the Sun and possibly the name of the person who first recorded that halo. A circle of light 22 degrees from the Sun (passing through the sundogs) is fairly common. It is caused by column crystals. They are 6-sided, but have grown long enough to fall in a random pattern. This 22-degree halo can also be seen around a bright moon and may be an indicator of possible snow.

The crystals must be small (between 0.05 and 1 mm) in size to produce halos. They are found at many altitudes but have to be in clouds 5-10 km above the ground to form halos. If the crystals grow in cold, dry air, they grow slowly and give the best displays.

Sundogs are not a type of rainbow. Sundogs and halos are seen when looking toward the Sun. Rainbows are caused by sunlight reflecting from raindrops. To see a rainbow you must stand with the Sun behind you. Both sundogs and rainbows use the Sun to study the water cycle in our atmosphere.

SUNFISHES *(Osteichthyes)*. Of the suborder *Percoidea*, family *Centrarchidae*, various species of sunfishes are among the favorite food and sporting fishes, particularly in North American fresh waters. The largemouth black bass, crappie, and bluegill are members of this family. Although initially American fishes, a number of species have been introduced elsewhere, notably Europe. The largest of the species is *Micropterus salmoides* (largemouth black bass) which measures up to about 30 inches (76 centimeters) and weighs up to 25 pounds (11 kilograms). The *Micropterus dolomieui* (smallmouth) is somewhat smaller, ranging up to 27 inches (69 centimeters) and weighing up to 12 pounds (5.4 kilograms). The *Lepomis macrochirus* (common bluegill) is frequently used as a small forage fish when stocking the larger species. Capable of attaining a length of about 15 inches (38 centimeters) and weight of nearly 5 pounds (2.3 kilograms), the average adult bluegill usually does not exceed about 4 inches (10 centimeters). Crappies are popular with sportsmen and have been distributed widely throughout North America. The *Pomoxis annularis* (white crappie) prefers muddy and turbid waters. In contrast, the *Pomoxis nigromaculatus* (black crappie) normally is found in clear waters. Records indicate that crappies up to 21 inches (53 centimeters) in length and 5 pounds (2.3 kilograms) have been caught. Archoplites interruptus (Sacramento perch), attaining a length of about 12 inches (30 centimeters), is found in the San Joaquin and Sacramento basins of California.

SUNFLOWER OIL. See **Vegetable Oils (Edible)**.

SUNLIGHT. Light from the sun; also called sunshine. The majority of the energy from the sun is divided into three parts: ultraviolet radiation, wavelengths less than about 0.4 μm visible radiation, wavelengths between about 0.4 and 0.7 μm; infrared radiation, wavelengths greater than about 0.7 μm. There are conflicting conventions as to whether all three regions are referred to as light, or whether that term should only be applied to the visible portion of the spectrum. The ultraviolet radiation is sometimes called short waves and the infrared region, long waves.

SUN PILLARS. They are narrow columns of light *apparently* beaming directly up and sometimes downwards from the sun. They can be 5 –10° tall and occasionally even higher. Most sun pillars are formed by plate-like crystals. See Fig. 1.

Fig. 1. A sun pillar observed near Harpers Ferry, West Virginia. This pillar was visible in Silver Spring, Maryland, about 50 miles to the southeast at approximately the same time. (*image courtesy of Janet Ward, NOAA HPCC*).

Optical perfection is unnecessary. Often pillars are the only halo in the sky because crystal faults like side faces blocked by growths or internal defects prevent other arcs from forming.

Upper pillars are created by rays reflected downwards from the *lower* faces of tilted crystals. In plate crystals of good quality, a significant number of pillar forming rays enter a side face, undergo total internal reflection an odd number of times from the upper and lower basal faces and then leave through the opposite side face. The refraction at the two faces is equal and so the pillar is not colored. However, pillars adopt the colors of the incident sunlight which may be highly reddened. Lower pillars form when light is reflected upwards from the *topmost* crystal face.

Most halos are at their finest when crystals are well aligned. In contrast, sun pillars need crystals with large tilts. The larger the tilts the taller is the pillar.

Pillars are not actually vertical rays, they are instead the collective glints of millions of ice crystals.

Pillars take on the colors of the sun and clouds, they can appear white and at other times shades of yellow, red or purple.

Sometimes they appear as several vertically strung patches of light depending on the locations of the cloud crystals.

Pillars often lengthen and brighten after sunset. Watch them creeping northwards (southwards in the Southern Hemisphere), following the sun's movement below the horizon, for up to 30 to 60 minutes after it has set at ground level.

See also **Atmospheric Optical Phenomena**.

SUN SYNCHRONOUS ORBITS. These are polar orbits which are synchronous with the Sun. A satellite in a sun synchronous orbit would usually be at an altitude of between 600 to 800 km (373 to 497 miles). Generally these orbits are used for Earth observation, solar study, weather forecasting and reconnaissance, as ground observation is improved if the surface is always illuminated by the Sun at the same angle when viewed from the satellite.

See also **Earth-Orbiting Satellites (Data Receiving And Handling Facilities)**; **Orbit (Astronomy)**; **Satellites (Communications and Navigation)**; and **Satellites (Scientific and Reconnaissance)**.

SUN (The). The sun is a self-luminous body; it is our nearest star, 93,000,000 miles (~150 million kilometers) from the Earth, from which we receive light and heat to generate and maintain all life processes on the Earth. The sun is 109 times the Earth's diameter and 300,000 times its mass, but when we compare it to other stars for size, mass, and brightness we find that it falls in the middle of their range. It is a typical dwarf star of spectral class G2. Its energy output in the form of light and heat, generated by nuclear processes, appears to be remarkably constant and to have been so over hundreds of millions of years, and is expected to be so for many billions of years into the future. Being the closest star, we can examine its surface in great detail. As such it serves as a testing ground for astrophysical theories. The sun's atmosphere consists of the visible surface or photosphere and two higher-temperature envelopes, the chromosphere and corona. Telescopic views show the surface of the sun to be in great turmoil, covered by a granular pattern of convection cells and punctuated with sunspots, great magnetic storms in the sun's atmosphere. Magnetism plays the dominant role in the sun's variability; in addition to sunspots it is fundamental to flares, with their X-ray and radio bursts, it controls the motions and behavior of prominences, governs the solar wind streaming past the Earth, and indirectly produces a wide variety of solar-terrestrial events: auroras, magnetic storms, radio fadeouts and possible changes in the climate. Physical data for the sun are given in Table 1.

Modern solar astronomy can be roughly divided into three major subdivisions:

1. **Velocity Fields** Solar rotation, granulation and supergranulation, solar oscillations.
2. **Magnetic Fields** General field of the sun, sunspots, flares, prominences.
3. **Composition** Interior structure, chemical composition, energy output.

These will be discussed in the following sections of this entry.

The Photosphere

The visible surface of the sun is called the photosphere — literally, light sphere. If the surface of the sun is examined carefully through a telescope of 4 inches (~10.2 centimeters) aperture or larger, at the times of best viewing the surface is seen to be mottled, a structure referred to as *granulation*. Figure 1 shows granules in a photograph taken on very high contrast film. Also clearly visible, even in a small telescope, and sometimes with the naked eye, are *sunspots*, dark only in contrast to their brilliant surroundings.

TABLE 1. DIMENSIONS AND PHYSICAL DATA FOR THE SUN

Diameter	864,000 miles (1,390,180 kilometers); 110 × diameter of the earth
Volume	1.412×10^{33} cm^3 (1.3 million times the volume of the Earth)
Mass	1.989×10^{33} gm (330,000 times mass of the Earth)
Mean density	1.41 gm cm^{-3} (1/4 the earth's mean density)
Central density	148 gm cm^{-3}
Force of gravity of surface	Nearly 28 times that at earth's surface (A mass weighing 100 pounds on Earth would weigh nearly 1.4 tons on the sun)
Mean distance from Earth	92,955,807 miles (149,597,870 kilometers = 1.0 astronomical unit)
Time for light to travel from sun to Earth	499 seconds (slightly over 8 minutes)
Velocity in space	About 12.4 miles per second (20 kilometers per second) toward a direction in space not far from the star Vega
Solar constant (rate at which solar radiation is received outside the Earth's atmosphere on a surface normal to the incident radiation and at the Earth's mean distance from the sun)	1.94 calories per square centimeter per minute
Candle power of sun	2.4×10^{27} candles
Average illumination of sun at zenith	100,000 meter-candles

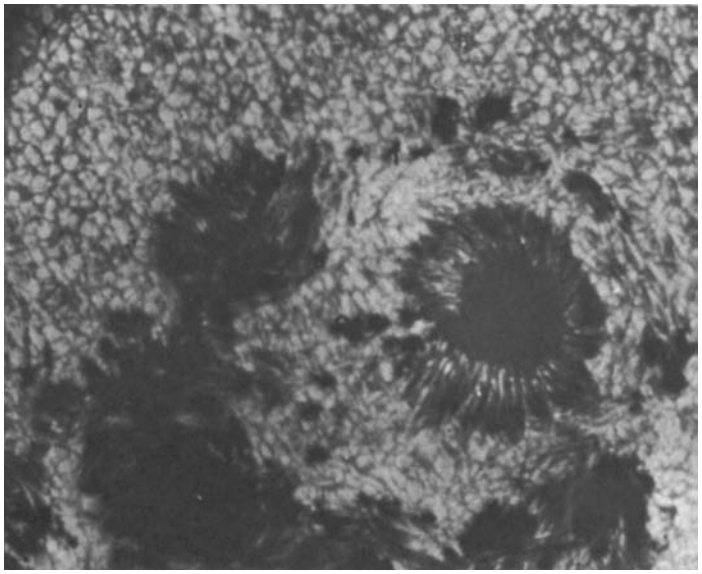

Fig. 1. Portion of sun's disk photographed from a balloon at an altitude of about 24 kilometers (80,000 feet). (*Princeton University*.)

Three to four million granules, each about the size of an American state (200–1000 miles; 322–1609 kilometers across), cover the surface of the sun. Similar to the convection in a boiling pot of cereal, granulation is one of the ways energy is brought to the surface from the deeper, hotter layers. Time lapse photography reveals the 5–10 minute life history of a granule: each starts out as a small bright area that grows in several minutes to about 1000 miles (1610 kilometers) diameter, divides into several smaller units, which may coalesce with other granules or they fade and then are replaced by a new granule. A spectrum of the photosphere shows Doppler shifts of the spectrum lines indicating that each granule rises in the atmosphere with an average velocity of $\frac{1}{3}$ mile (~0.5 kilometer) per second. As the granule cools and dissipates the gas returns to the sun in the darker intergranular spaces. Groups of granules appear to be in a constant up and down oscillation with a 5-minute period.

The photospheric layer is about 500 miles (805 kilometers) thick — hot ter (10,000 °K), denser, and more opaque at the bottom, cooler (4200 °K), much less dense, and quite transparent at the top. The energy radiated from the photosphere can be characterized by a continuous spectrum with a temperature of 5740 °K — the effective temperature of the sun. In appearance the surface is brilliant white, brighter at the center of the disk, where we see to the deeper hotter layers, and darker at the limb of the sun, where we see only the outermost, cooler layers of emitting gas. The variation in brightness, center to limb, is known as the solar *limb darkening* (visible also in spectrum lines, i.e., Ha of Fig. 2).

The amount of limb darkening varies with wavelength. In the red and infrared there is very little variation between center and limb, whereas in the violet the intensity falls rapidly away from disk center to about 10% of the central value. From the observed limb darkening we can derive from an integral equation the temperature variation with depth in the sun's atmosphere.

The Chromosphere

A layer of the sun's atmosphere about 6200 miles (10,000 kilometers) thick just above the photosphere was named the chromosphere by eclipse observers. At eclipse time, when the moon has covered the bright photosphere, it is revealed for a few seconds before and after totality, as a thin crescent colored bright pink (from the hydrogen Ha spectrum line). Examined through a telescope the top of the layer is resolved into a great multitude of small, short-lived (5–15 minutes), geyser-like jets called *spicules*, each about 310 miles (500 kilometers) diameter and 3100–6200 miles (5000–10,000 kilometers) tall, projecting outward at all angles to the sun's surface.

Spicules are not randomly distributed over the sun's surface. High-resolution spectroheliograms show that they are arranged in a "network" pattern that covers the entire sun. Piled up at the network boundaries by

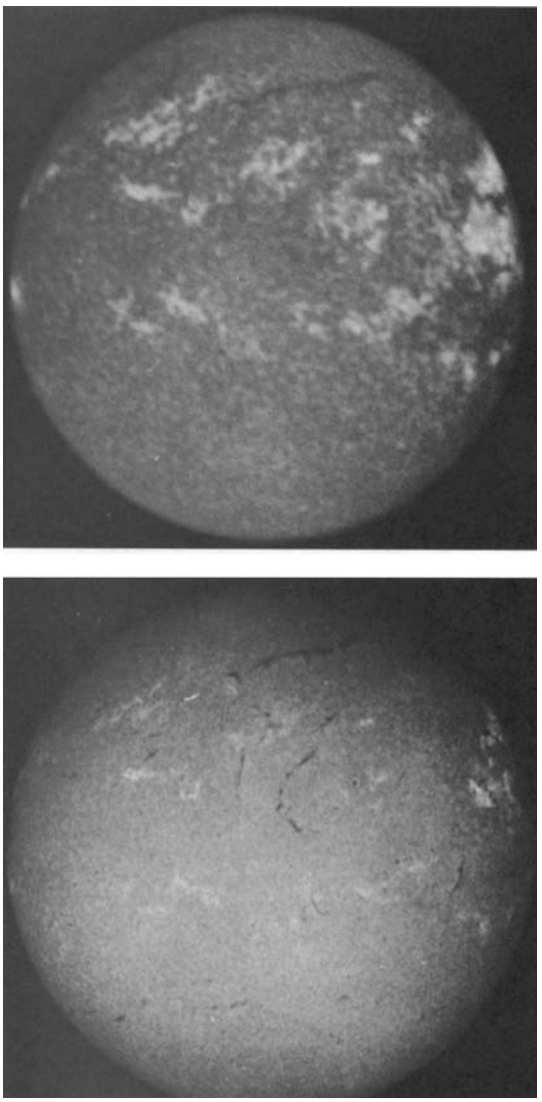

Fig. 2. Photographs of sun taken in the K line of Ca II. (*Top*) Calcium plages are indicated. (*Bottom*) Simultaneous photograph in the Balmer H alpha line. (*U.S. Navy*.)

slow, outward directed motion, each element of the net is a giant convection cell, typically 18,600 miles (30,000 kilometers) across, in which material flows up and outward from the center carrying with it the chromospheric magnetic fields concentrated in the spicules, to the cell boundary, and then descends. The motion is slow, horizontally about $\frac{1}{3}$ mile ($\frac{1}{2}$ kilometer) per second. The lifetime of a cell is about a day.

The disk of the sun when viewed in the light of Hα through a spectrohelioscope or monochromatic filter presents a totally different view from its white light photospheric image. Prominences, bright at the limb show very black on the disk. See Fig. 2. Bright areas appearing around sunspots, given the French name for beach, are called *plages*. In the central regions of the disk we see a composite of very small, overlapping, worm-like prominence structures referred to as chromosphericmottling. Near sunspots these structures are drawn out into long threads and filaments which often exhibit a spiral structure tracing out magnetic fields emerging from the spot.

The gases of the chromosphere are transparent. When viewed at the extreme limb, and not projected onto the bright underlying photosphere, the chromospheric spectrum consists of emission lines which in the last crescent phase of an eclipse momentarily flash into view, i.e., the *flash spectrum*. See Fig. 3. From the temperature minimum (4200 °K) at the top of the photosphere the temperature rises to a plateau of 6000 °K for the layers 620–1240 miles (1000–2000 kilometers) high then rises very rapidly to 30,000 °K at 1550 miles (2500 kilometers) and then to coronal values. The lower pressure and higher temperature of the chromosphere

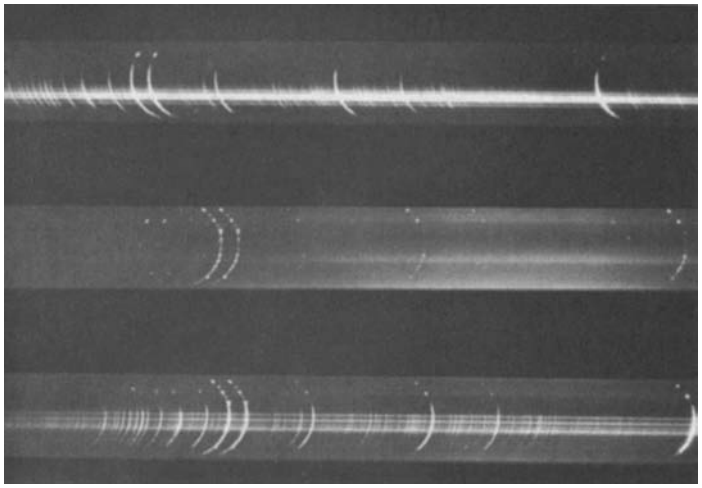

Fig. 3. Solar flash spectrum. (*Top*) Just before second contact; (*Center*) Bailey's — beads light passing through valleys in the moon's limb form two rings that are the violet lines of ionized calcium; (*Bottom*) Just after third contact. (*Mount Wilson and Palomar Observatories*.)

results in greater ionization and excitation than in the photosphere, thus the spectrum consists of many lines from singly ionized elements.

Corona

At the time of a total solar eclipse a pearly white radiance, called the corona, can be seen around the sun. See Fig. 4. The corona is composed of three parts, labeled L, K and F. The L-corona refers to a low level portion, the light from which is emitted by highly ionized atoms. The light of the K-corona, one hundred times brighter than L, is sunlight scattered by fast moving free electrons. The F component is produced by sunlight scattered by interplanetary dust particles; it is an extension of zodical light inward to the sun. Only the L and K components represent the true coronal atmosphere of the sun. Though the inner corona can be studied with a very specialized telescope called a Coronagraph or from space, its beauty can only be seen and appreciated at the time of a total eclipse, when one can discern outward streaming rays, arches, filaments, and brilliant red prominences, apparently projected on the corona. At sunspot maximum short streamers extending outward in all directions give the corona a globular shape; at sunspot minimum there may be only a few long equatorial streamers together with a polar plume or crown composed of fine rays curving outward from the north and south poles like iron filings at the poles of a magnet.

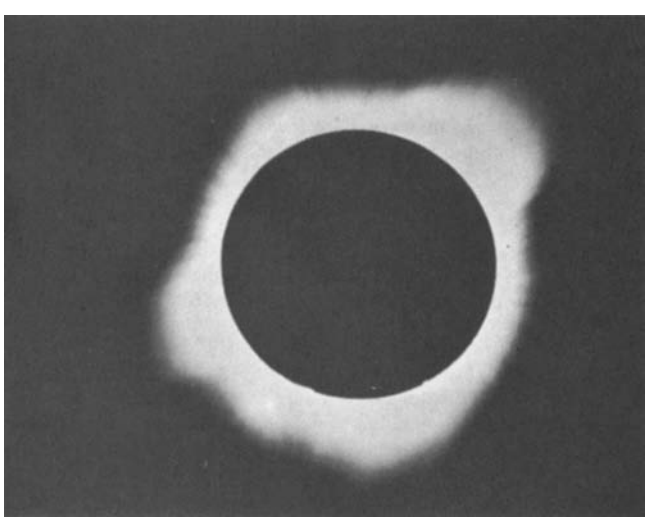

Fig. 4. The corona shown at time of total eclipse of the sun.

Though normally visible only at the limb of the sun, when the bright surface is occulted, the corona can also be seen projected on the disk, if photographed from space in X-ray wavelengths. The Japanese YOHKOH satellite, launched at the peak of the 1991 sunspot cycle, aimed in X-rays at the million-degree corona and yielded spectacular motion pictures of intense, active regions in the sun's corona, visible in these wavelengths both on the sun's disk and off the sun's limb. The hope is to solve the puzzle of the flare mechanism. Photographs from Skylab revealed a complex structure of bright points surrounded by rays and arch structures. Between them large dark irregular areas appear, *coronal holes*. These are low-density regions from which magnetic lines of force lead out into interplanetary space, allowing the plasma to escape. Moving with a velocity of about 400 km/sec near the earth, this plasma is called the solar wind. This represents a steady mass flow from the sun of 10^{-14} solar masses/year. Coronal transients, outwardly expanding loops or clouds, contribute another 5%. Parenthetically this is a very small fraction of the loss shown by many early-type hot stars and cool giants and supergiants.

The spectrum of the corona, first observed in 1869, exhibited many unidentified spectrum lines. Not duplicated in the laboratory, the composition of the corona remained a mystery for many years, leading the suggestion of a light hypothetical gas, "coronium," as their source. W. Grotrian and B. Edlen (1939–1942) found the clue and showed that the spectrum was that of common elements — iron, calcium, nickel, etc. — which had lost 10 to 15 electrons, thus indicating a temperature of several million degrees for the corona. As yet no satisfactory theory accounts for the temperature rise from about 4200 °K at the top of the photosphere to 2,000,000 °K in the corona.

Spectrum Analysis

The latter half of the nineteenth century saw not only great advances in the observations of the solar spectrum, but also the beginnings of the theory by which those observations could be understood. The first breakthrough occurred when Gustav Kirchoff (1859) noted that incandescent solids or liquids gave off continuous spectra of all colors, while hot gases emitted light in bright lines, their color or wavelength being characteristic of the chemical composition of the gas. If the continuous spectrum of an incandescent solid was passed through a cooler gas, dark lines would appear in the spectrum at exactly the same positions as the bright lines displayed by the incandescent gas when viewed alone. This fact formed the basis for the analysis of the solar spectrum. Kirchoff applied his results to derive a model of the sun as a hot liquid sphere covered by an atmosphere of gases, which produced the dark lines in the spectrum. We now know that a dense gas may also produce a continuous spectrum and that the sun is totally gaseous, but for the 1860s Kirchoff's ideas were quite reasonable.

Since each gaseous element produces a characteristic pattern of spectral lines it was possible to analyze the chemical composition of the sun, a task first undertaken by Kirchoff together with a Heidelberg Professor of Chemistry, R. Bunsen. The solar spectrum was set beside the spectrum produced by a laboratory sample (usually heated to an incandescent vapor in a spark discharge or an arc source) and visually noting the coincidences of the lines; in the later years of the nineteenth century a photographic comparison was made with far greater precision. Kirchoff and Bunsen identified solar spectrum lines from the following elements: sodium, calcium, barium, strontium, magnesium, copper, iron, chromium, nickel, cobalt, zinc, and gold. Later workers such as Angstrom extended this list to include hydrogen, which we now know to be the major constituent of the sun. To date most (about 65) of the naturally occurring nonradioactive elements have been found to be present in the solar atmosphere. At the time of the total solar eclipse of 1869, Lockyer and Frankland observed in the flash spectrum a bright yellow line which had never before been seen in laboratory spectra. The element producing this line was not known on the earth and was named helium (after *helios* — the Greek word for sun). It was not until 1895 that helium was first detected on the earth. Despite its rarity on Earth, helium is the second most abundant gas in the sun (after hydrogen).

Cosmology deals with the chemical formation and evolution of the universe. The chemical composition of the sun, Earth, and meteorites serve as standards of comparison; hence a great deal of effort has been expended in their determination. Solar abundances can only be determined for the

sun's atmosphere, but with few exceptions, the sun is considered to have the same composition throughout.

Solar (and stellar) atomic and molecular abundances can be determined from spectrum analysis, i.e., by knowing the atomic parameters from laboratory determinations and by comparing the observed intensity of Fraunhofer lines with theory. As the abundance increases a Fraunhofer line becomes darker in the center until black, i.e., saturated, then slowly broadens, finally developing resonance wings — the so-called *curve of growth*. On the theoretical side the strength of a line is determined by: (1) the abundance of the element, (2) the number of atoms of the element in a state able to produce the line — determined by the pressure and temperature of the gas — and (3) the atomic transition probability between the atomic levels connected with the line. A plot of the theoretical intensity vs. observed intensity yields the atomic abundance of the element. Hydrogen and helium make up 99.9% by volume of the sun. For every 1,000,000 atoms of hydrogen there are 63,000 of He, 690 of O, 32 of Fe, 3 of Al, 2 of Na, etc.

Sunspots

The discovery and first scientific study of sunspots was carried out telescopically by Galileo Galilei in 1610. Many of his contemporaries to whom he showed them refused to believe their eyes for they considered the sun to be immaculate and hence they had to be objects in front of the telescope. However, Galileo noted their daily westward movement, their motion in parallel lines, and their slower apparent motion near the limb, from which he concluded that the sun was a sphere rotating in about 27 days and that the spots were on its surface.

When examined through a telescope a large sunspot is seen to consist of two distinct parts: a dark central *umbra* surrounded by a less dark *penumbra*. On birth, one sees several small round pores each about 2000 miles (3220 kilometers) in diameter separated by tens of thousands of miles. If their development continues — most small sunspots last less than a day — the leader and follower grow rapidly in size and separate, resulting in two large spots having umbra and penumbra together with a number of smaller spots forming a complex group. Old age sets in after a week or two; one of the large spots disintegrates, as it becomes covered by light bridges, leaving a single spot which over several days diminishes in size until gone. On occasion exceptionally large, complex groups develop, exhibiting great variety of shape, often covered by brilliant "bridges" of light, giving the impression of great turmoil. Such spots, which may extend over 100,000 miles (160,000 kilometers) of the sun's surface, are easily visible to the naked eye when the sun's light is reduced by fog or by absorption of the earth's atmosphere at sunset. Russian records of naked eye sunspots describe them as looking like nail heads. Chinese annals, some before Christ, record many objects (sunspots) on the sun and describe them as like a flight of birds or as having the appearance of pigeon eggs.

Sunspots are dark only in contrast to the photosphere. Brighter than an electric arc, examined spectroscopically one finds atomic and molecular lines from which a temperature of about 3800 °K is obtained. George Ellery Hale (1914) found that some of the atomic lines were divided and polarized in the sunspot spectrum (the Zeeman effect), demonstrating the strong magnetic field associated with sunspots. Further work showed that pairs of spots were of opposite polarity, that the leader spot in the Northern Hemisphere had a magnetic polarity opposite that of the leader in the Southern Hemisphere, and that the polarity in each hemisphere reversed every 11 years.

Telescopic records for 400 years and scattered naked eye observations for 2000 years show that the number of sunspots varies with an average period of 11.2 years. Wolf, of Zurich, introduced the term *sunspot number*, $R = f + 10g$, as a measure of solar activity, where f is the total number of individual sunspots and g is the number of spot regions, either groups or spots. This number is quite arbitrary, but in practice serves very well to define solar activity. See Fig. 5. The last maximum occurred in 1979, at which time as many as 100 spots were visible on the sun's surface. At minimum, months may pass without a single record of a sunspot. The cause of this periodicity is not known. It has been suggested that Jupiter, which revolves around the sun with a period of 11.8 years and has a mass $\frac{1}{1000}$ that of the sun, could introduce tidal action and sunspots. Other suggestions, such as swarms of meteors striking the surface, have been made — all without success.

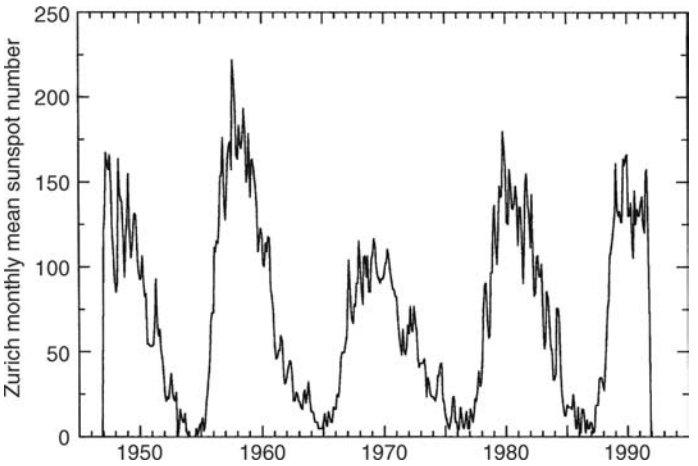

Fig. 5. Sunspot cycle.

We should here remark that the sun rotates not like the earth, as a rigid body, but rather nonuniformly. Being gaseous throughout, it rotates once in 25 days in the equatorial regions, whereas the polar regions require 35 days. This nonuniform rotation results in deep-seated stirring of the interior. The sun is a magnet like the earth. According to a recent theory due to Babcock, its nonuniform rotation causes the magnetic lines of force to wind up like string on a top. As the magnetic lines deep in the interior become drawn out parallel to the equator and get tighter and closer together, magnetic buoyancy and turbulent motion carries a kink in the lines to the surface. The visible manifestation at the surface then is a pair of spots of opposite magnetic polarity with a field strength of 1000 to 3000 gauss, a field equal to that in a modern power-plant generator but distinguished from it by the fact that it extends over an area larger than the size of the Earth. The time required for the windup of the magnetic lines of force is 3–4 years. The time required for them to appear at the surface is 6–7 years; hence, the 11-year cyclic period. Each solar cycle begins with appearance of spots in two zones north and south about 30° from the equator. During the cycle the zone of spots drifts equatorward, ending at ±5°.

Strangely, the cycle of sunspot activity died out for about 75 years in the late seventeenth century. Indirect evidence of solar activity before the invention of the telescope in 1610, from isotopic carbon 14 found in tree rings, suggests that even longer periods of quiescence have occurred. Eddy has noted that the periods of low solar activity coincides with climatic lows in European temperatures and thus a connection between solar activity and climate.

Prominences

Prominences first seen at solar total eclipses stand as cloud-like forms above the sun's surface. See Fig. 6. They are classified by appearance and formation into the following types: quiescent, coronal, eruptive, sunspot, and tornado. A typical quiescent prominence is a large, thin, caterpillar-like form with several of its feet attached to the sun's surface; some may extend over 125,000 miles (201,125 kilometers) in length; 30,000 miles (48,270 kilometers) in height by 5,000 miles (8,045 kilometers) thick. They generally develop in the sunspot zone, then drift north or south to the polar regions; drawn out by differential solar rotation they may last for several years as a polar crown. Coronal forms appear to condense from the hot coronal gas and stand free of the sun's surface. Active prominences are generally associated with underlying or nearby sunspots.

Though formerly viewed at an eclipse or spectroscopically, today prominences are more easily seen and studied through a narrow passband interference filter (5 angstroms or less) or through a Lyot-Ohman polarizing filter (0.2–1.0 Angstrom passband) centered on Hα — the red line of hydrogen, $lambda = 6563$ angstroms. Time-lapse motion pictures of active prominences show the strong control exerted by magnetic fields on their support and behavior. Often appearing as great inverted funnels, condensing from the corona, there is a general downward flow of prominence material along curved arcs into neighboring sunspots. Over a sunspot region, particularly after a flare, multiple arches may appear,

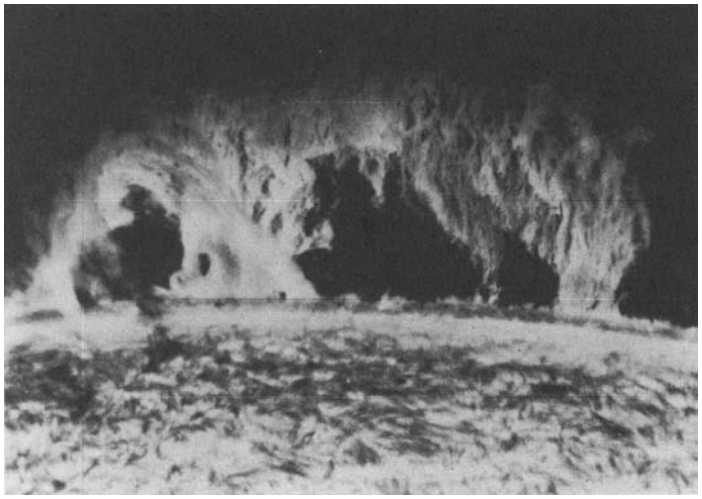

Fig. 6. Hedge-row prominence. (*Big Bear Solar Observatory*.)

condensing at several apices, the material flowing downward along curved lines of magnetic force with velocities of 12–24 miles (20–40 kilometers) per second. Greatly enhanced activity is often triggered by a nearby solar flare that destroys the equilibrium of the magnetic field structure; the whole or a portion of a prominence may erupt from the sun with great acceleration reaching velocities of several hundreds of miles/second.

Spectroscopic studies of prominences show that they may be divided into cool, quiescent (8000–10,000 °K) forms and hot, active arch-prominences with temperatures up to 100,000 °K. The same elements that appear in the sun's atmosphere exist in the prominence, their appearance modified only by its temperature and pressure.

Flares

A flare is a short-lived brightening of a small area of the sun comprising an evolving bipolar magnetic structure. Optically, except for the very rare and outstanding flares visible in white light, most flares are seen through the spectrohelioscope or filter as intense bursts in the Ha light of hydrogen; they are one of the most spectacular sights connected with the sun. Flares are chromospheric phenomena. They are by no means uncommon; at the peak of the sunspot cycle there are about 20–30 flares per year of class 3, having a duration 2–4 hours, and a thousand of class 1 lasting on the average 25 minutes. Preflare activity is often noted in quiescent prominences which takes the form of enhanced internal motions, a slow rise into the corona, and when the flare starts sudden acceleration and complete disappearance, sometimes to reappear with hours or days in nearly the same shape and position. The flare phenomenon often includes the ejection of material: surges from small flares take place along lines of magnetic force, generally at an angle to the sun's surface, the material returning to the sun along the same path. Great flares are accompanied by sprays of explosively ejected material with velocities as high as 930 miles (1500 kilometers)/second.

The flare phenomenon is exceedingly complex. We will describe some of the events in a great flare. Typically, individual brightenings merge along the sides of a disappearing quiescent prominence to form two ribbons, or starting as a bright single ribbon in a young active region it divides into two which initially separate with speeds up to 62 miles (100 kilometers)/second, but soon stop. See Fig. 7. The flare starts with a very rapid increase of temperature to 5–10 million degrees Kelvin high in the corona, accompanied by a soft X-ray burst, followed by a slow exponential decrease. Next the flare energy moves down into the chromosphere, heating a thin layer to 10,000 °K and becoming visible as ribbons in Ha. In the flash phase, within the first 10 minutes, electrons accelerated to 10–100 keV produce hard X-rays, impulsive radio, and far-ultraviolet bursts. Streams of electrons moving outward at 100,000 km/sec produce intense radio frequency bursts and can be tracked at low radio frequencies to the vicinity of the earth and recorded by spacecraft. In some large flares a blast wave originates, accelerating electrons and protons to hundreds of millions of

Fig. 7. An intense two-ribbon flare with associated magnetic arches. (*Big Bear Solar Observatory*.)

electron volts which, in turn, when bombarding the photosphere, produce nuclear reactions and associated gamma rays.

Among the many terrestrial effects of a flare is the short-wave radio fadeout (SWF). Hard X-rays emitted at the onset of large flare illuminate the sunlight side of the earth, causing an SWF for all transmission paths over this hemispherical cap. The X-rays ionize the lower layers of the earth's atmosphere (60 km), freeing electrons which, excited to oscillation by radio waves, quickly lose their energy of oscillation by collisions with abundant air molecules. The loss of signal by absorption of the radio waves may last for several hours. Very large flares have been known to produce marked changes in the earth's geomagnetic field, which in turn induce electric currents in long-distance transmission lines strong enough to trip circuit breakers and to stop telegraph communication.

On March 10, 1989, a great flare occurred in a large sunspot region on the sun. Protons and electrons arriving at the earth two days later produced brilliant auroras over Canada and the United States. Transformers tied to the Hydro-Quebec power grid and to the United States saturated, overheated, and were destroyed from induced, nearly DC, earth-surface potentials of 1–10 V per kilometer of transmission line. The cost of outages and loss of transformers exceeded tens of millions of dollars from this one event.

The Solar Constant

The solar constant is defined as the quantity of solar energy received at normal incidence outside the earth's atmosphere at the earth's mean distance from the sun. It is expressed in calories per square centimeter per minute or kilowatts per square meter. The latest measurements give 1.968 cal cm^{-2} min^{-1} or 1.373 kW m^{-2}.

Variations in the solar output in X-ray, far infrared, and radio wavelengths are well known, but very little energy comes from these wavelengths (less than 1.0%), hence the larger question of any appreciable variation in the total luminosity of the sun over long periods of time goes begging. The evidence from paleontology suggests that it has been nearly constant (less than 10–15% variation) over several billion years. Today a variation of 0.5% or less is of interest to climatologists. For decades, C.G. Abbot with instruments of his own devising made a long series of

measurements from mountains located in arid lands, particularly the Atacama desert of Northern Chile. He observed variations of up to 1.5%, which he attempted to correlate with rainfall. Recent measures from satellites show variations up to ±0.04%.

Solar Energy Generation — The Neutrino Puzzle

Mass can be converted into energy. Substituting the energy output of the sun (3.86×10^{33} ergs/sec) into Einstein's famous formula $E = mc^2$, we find that m, the mass loss, amounts to 4,700,000 tons per second. Large as this is, it is only 10^{-11} of the solar mass per year. In the sun's core, between center and one-tenth of the solar radius, the most important fusion process is the proton-proton reaction in which hydrogen nuclei, called protons, are converted into a stable helium nucleus. The reaction is:

$$2 \times \begin{cases} H^1 + H^1 \longrightarrow e^+ + v \\ H^2 + H^1 \longrightarrow He^3 + \gamma \\ He^3 + He^3 \longrightarrow He^4 + H^1 + H^1 \end{cases}$$

In this chain reaction, two protons fuse giving deuterium, a positron, and a neutrino. The neutrino escapes the sun at the velocity of light, carrying a small amount of energy with it. The positron collides with an electron and both are annihilated, with the release of gamma rays. The fusion of the deuterium nucleus with another abundant proton results in the light isotope of helium, with two protons and one neutron, and the emission of more gamma rays. Finally, two helium-3 atoms combine to make a stable helium nucleus plus two nuclei of hydrogen. With a loss of six hydrogens and two electrons we gain one helium and two hydrogens, additionally two neutrinos and 5 gamma rays are released in the process. From the known weights of He^4 and H^1 one calculates that 4.3×10^{-5} ergs is released for every He^4 nucleus formed.

Ninety percent of the sun's energy is produced through this reaction. Another reaction chain of the proton-proton cycle gives beryllium and boron with the emission of gamma rays, a positron, and a high energy (14 MeV) neutrino. It is this neutrino that can be detected by its absorption in a chlorine 37 nucleus, giving a radioactive argon 37 atom. The experiment performed by Davis uses 100,000 gallons (3785 hectoliters) of perchloroethylene enclosed in a sealed tank situated in a deep gold mine in South Dakota. One atom per day of radioactive argon is observed. This rate falls short by a factor of 3 from the rate calculated from the standard model of the sun, that is, its temperature, pressure, energy output, and chemical composition. The discrepancy can be equated either to a lack of knowledge of the sun's interior, or to a lack of knowledge of the neutrino's properties. This experiment has stimulated a great deal of theoretical work in solar and neutrino physics.

Low-energy neutrinos from the proton-proton fusion reaction, which contributes most of the neutrinos, can be detected through a nuclear transmutation of gallium, by neutrino capture, giving radioactive germanium. At the earth's distance from the sun, there are 1000 billion of these neutrinos passing through our bodies every second. A neutrino, moving with the velocity of light and having passed from the sun's core to its surface (and through the Earth if the sun is on the other side and we are in darkness), spends very little time in the neighborhood of a gallium atom. The chance of capture is very, very small. Thirty tons of gallium in solution sits in a laboratory under a high peak in the Italian Apennines, and in another experiment 57 tons of gallium metal is deep under a mountain in the Caucasus. Thirty tons of gallium should yield 1.2 atoms of germanium per day. From 300 days of collection, the number of captures was 63% of that predicted. Further tests are under way.

Solar Seismology

Like the earth, the sun also oscillates with a variety of shapes and frequencies. Though such oscillation is extremely difficult to detect from 93 million miles (~150 million kilometers) away, from precise measurements of its shape and from Doppler measurements of the up and down motion of its surface we can now probe the sun's interior. The 5-minute oscillation, discovered in the 1960s, of large groups of solar granules covering areas 2480–9300 miles (4000–15,000 kilometers) across, represents a standing pattern of sound waves trapped within the convection zone. Globally the entire convection zone (124,000 miles; 200,000 kilometers deep) is oscillating, with several nodes around the sun's circumference and with a number of nodes between the surface and the bottom of the zone. See Fig. 8. The observations are interpreted in terms of spherical harmonics of low-angular (l) and high-radial ($n \sim 15$) overtones with an amplitude of 10–100 cm/sec. l-values of 0, 1, 2, 3, 4 have been observed in a 5-day Doppler-shift measurement recorded in Antarctica at the South Pole during its summer, where the sun may be seen continuously for long periods of time. Because of the global coherence in space and time, it has been possible to derive the depth of the convection zone and the solar rotation rate down to the bottom of the zone, where it is found that the sun rotates 5% faster than at the surface. In addition to the well established 5-minute oscillation, work in Crimea, the United Kingdom, and the United States has yielded a 160-minute period of oscillation.

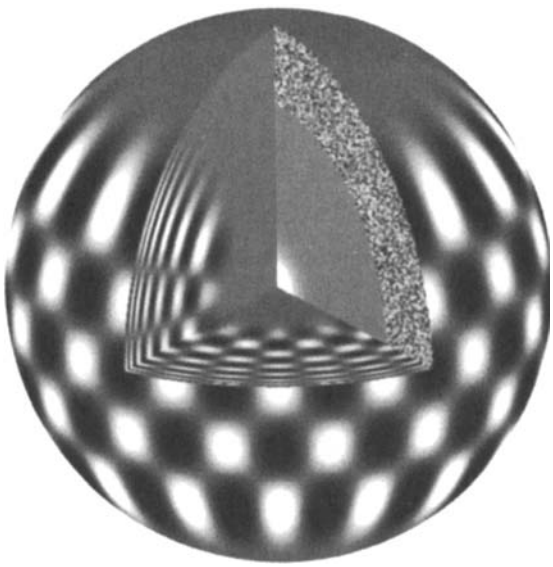

Fig. 8. The up-down motions (solar oscillations) of one of the 10 million modes of the solar surface. This mode has an angular degree $l = 20$, an azimuthal order $m = 16$, a radial order $n = 15$, and a frequency corresponding to a period of 5 minutes. (*Global Oscillation Network Group, National Solar Observatories*.)

The Sun's Motion in Space

Our sun, together with the stars in its immediate neighborhood, slowly orbits around the galactic center, located 33,000 light years away in the direction of the Milky Way constellation of Sagittarius, moving with a velocity of 155 miles (250 kilometers) per second. The "cosmic year" or period of rotation is 2400 million years. Additionally the sun has its own motion within the local group of naked eye stars. A study of radial velocities and proper motions places the direction in which the sun is moving near the summer constellation of Lyra. From the radial velocities its speed toward the solar apex is found to be approximately 12.1 miles (19.5 kilometers) per second.

Solar Telescopes and Instrumentation

Because of the enormous light and heat of the sun, and because the full surface of the star can be examined, unusual telescopes and instruments have evolved. The size of the sun's image in a camera or telescope is $\frac{1}{108}$th of the focal length. Thus, in the common 35-millimeter camera of 50 millimeters focal length, the sun's image on the film is only $\frac{1}{2}$ millimeter $\frac{1}{50}$th inch). The McMath-Pierce Solar Telescope Facility at Kitt Peak, Arizona, with a 300-foot (91.4-meter) focal length, yields an image 3 feet (0.9 meter) in diameter. Like most solar telescopes, the McMath-Pierce instrument is not pointed to the sun, but is fixed in direction. Sunlight goes 500 feet (152 meters) down the south polar axis at an angle of 32°. The heliostat mounting is driven to follow the sun during the course of the day. The beam, focused by a 60-inch (152-centimeter) concave mirror, is returned slightly below the incoming light to a 48-inch (122-centimeter) flat that directs the image vertically downward to spectrographs and other instrumentation located in the observing room. Great care has been taken to eliminate thermal disturbances, which distort the image.

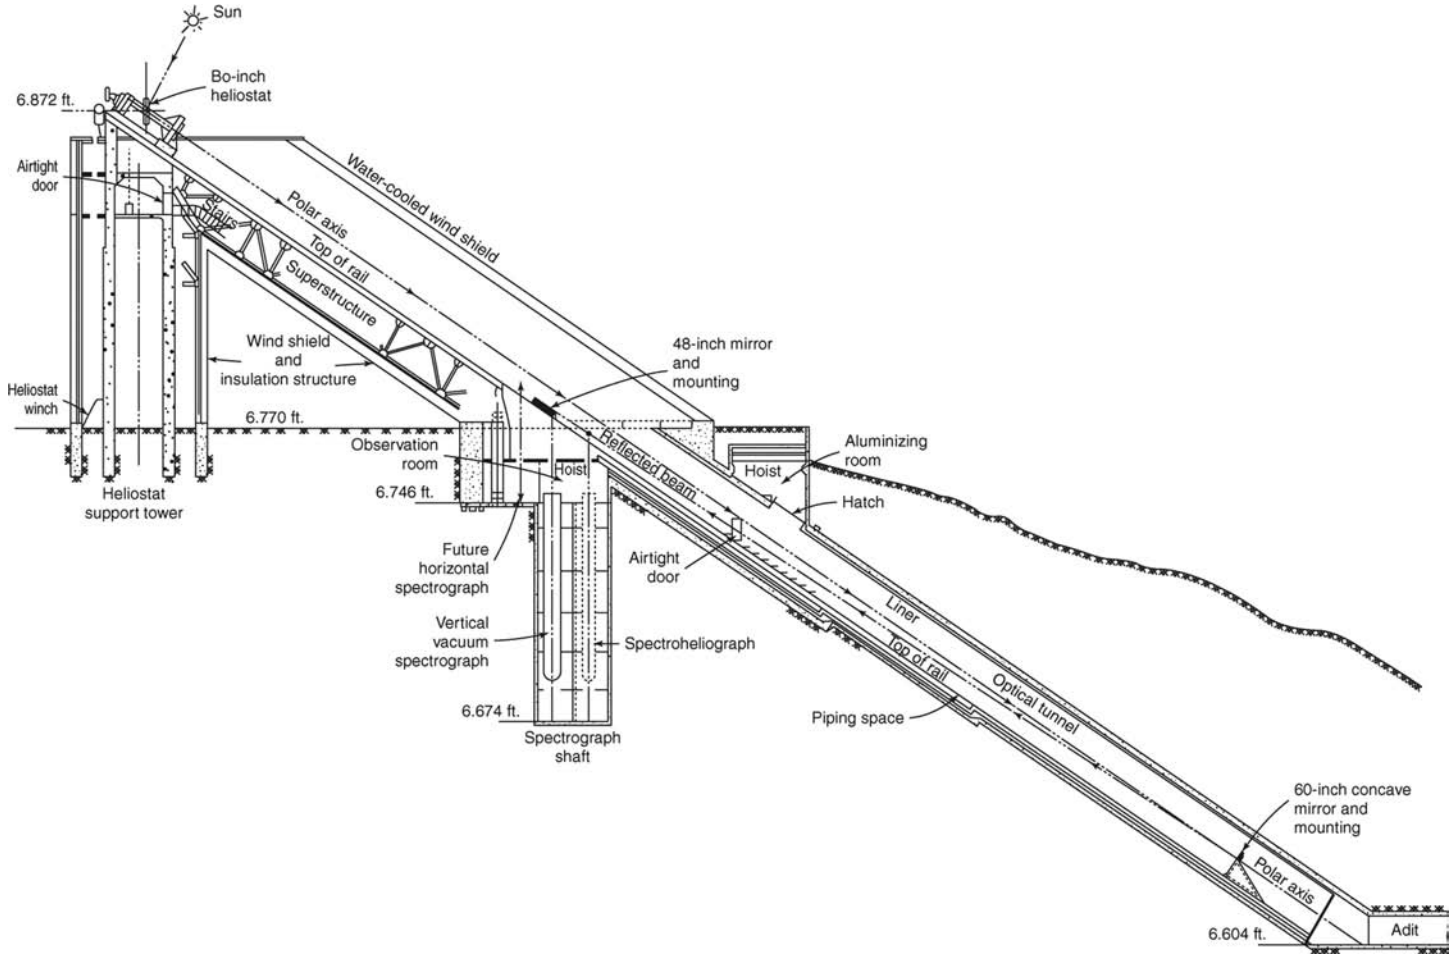

Fig. 9. Sectional view of the McMath-Pierce solar telescope located at Kitt Peak, Arizona. (*Kitt Peak National Observatory*.)

Thus, the 80-inch (203-centimeter) mirror is located 100 feet (30.5 meters) above the local terrain to eliminate ground effects. Additionally, the whole telescope, two-thirds of it underground, is cooled to ambient air temperature. The problem of internal seeing in solar telescopes is so great that the bold step of evacuating the whole telescope has recently been taken. The newer 30-inch (76.2-centimeter), 180-foot (54.9-meter) focal length tower at Sacramento Peak in New Mexico, and the 24-inch (61-centimeter) Cassegrain instrument located at San Fernando, California are good examples of vacuum telescopes.

The McMath-Pierce solar telescope is illustrated in the diagram of Fig. 9. An overall external view of the telescope is shown in Fig. 10. An image is shown in Fig. 11.

Coronagraph. A telescope for observing the corona surrounding the sun, at times other than at a solar eclipse, is called a *coronagraph*. An artificial eclipse of the sun is produced by placing an opaque circular disk slightly larger than the image of the sun at the focus of the telescope. Light from the corona passing the edge of the occulting disk is re-imaged by a lens onto a photographic plate or other detector. Suitable diaphragms capture the diffracted light from the objective. The brightness of the corona is one millionth that of the sun, hence, the success of the instrument depends upon the great care in selecting the glass for the singlet objective, free of bubbles and stria, and in polishing the surfaces free of all scratches. Furthermore, great pains must be taken to avoid dust on the objective. To minimize the atmospheric scattering, coronagraphs are mounted at high elevation sites (10,000 feet; 3050 meters).

The appearance of strong emission lines in the spectrum of the corona permits the instrument to be used monochromatically with narrow band polarizing filters or with a spectrograph.

Spectroheliograph. Essentially the instrument consists of a high-dispersion spectrograph with a second slit placed directly in front of the photographic plate so that the radiation from only one spectral line is received on the plate. If the instrument is so placed that the first slit is in the principal focus of a telescope directed toward the sun, a narrow strip of the sun's image will be admitted by the first slit and an image of that narrow section of the sun will be formed on the photographic plate in the particular radiation for which the second slit is adjusted. The instrument is

Fig. 10. Heliostat support tower and part of water-cooled wind shield of the McMath-Pierce solar telescope. (*Kitt Peak National Observatory*.)

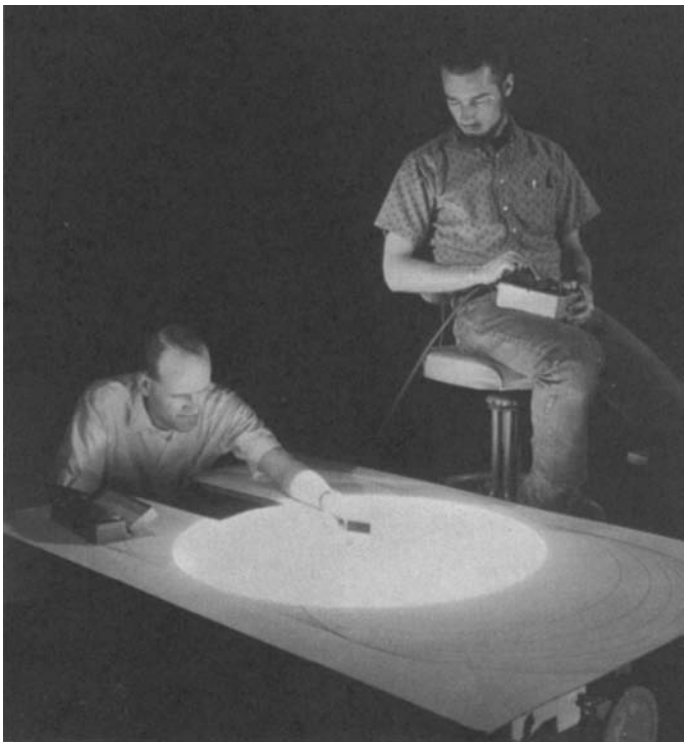

Fig. 11. Inspection of solar image. (*Kitt Peak National Observatory*.)

so constructed that the first slit may be moved across the image and at the same time the second slit will move across the photographic plate at the same rate. Hence, it is possible to obtain a photograph of the sun in the almost monochromatic radiation of any particular element, say calcium.

Birefringent Filters. B. Lyot (1933) investigated the transmission of a series of crystalline plates in polarized light. Independently in 1937, Y. Ohman built such a filter capable of isolating the Hα line of hydrogen and was able to photograph prominences through it. The filter consists of a series of quartz plates in which each plate has a thickness of one-half the preceding plate. Polaroid is sandwiched between each plate. By suitable design, a narrow passband (0.25–5Å) can be obtained anywhere within the spectrum. With their use, the whole sun can be examined in the light of one element, usually hydrogen. These filters have been widely used particularly in cinematography of solar phenomena.

Solar Experiments in Space

The selective absorption of ozone, carbon dioxide, and water vapor in the Earth's atmosphere effectively blocks the ultraviolet solar spectrum short of 2900 angstroms and in bands beyond 7000 angstroms in the infrared. The earliest (1946) rockets carrying small spectrographs above 70 kilometers (43 miles) extended the solar spectrum from the ultraviolet ozone cut off at 2900 angstroms to 2100 angstroms. These unstabilized instruments were soon superseded by high resolution spectrographs on stabilized platforms capable of guiding to a fraction of a second of arc. The *Skylab* manned mission of 1973 mounted a complex of instruments designed to obtain high resolution direct photographs of the sun, prominences and flares in X-ray and far UV wavelengths. The disk of the sun was observed to be covered with thousands of X-ray bright points bringing magnetic fields to the surface. *Skylab*'s white light coronagraph observed for the first time huge blast waves — coronal transients — moving outward through the corona at speeds of 600 km (375 mi) per second, set in motion by an underlying flare.

The solar maximum mission of 1980 carried seven instruments into space: a gamma ray spectrometer, several X-ray spectrometers, a coronagraph, and an active cavity radiometer for measuring the solar irradiance. This instrument is still (1987) providing data. Future programs look to high resolution imaging of the solar granulation.

The Six Basic Problems of Solar Physics

Giovanelli has listed five problems of solar physics to which we add a sixth, i.e., the neutrino puzzle: (1) the cause of the sunspot cycle, (2) the structure of the convection zone comprising the outer 200,000 km (125,000 mi) of the sun's radius, (3) differential rotation with latitude and depth in the sun's atmosphere, (4) the cause of flares, and (5) the heating mechanism of the chromosphere and corona.

SUPERACIDS. See **Acids and Bases**.

SUPERCELL. See **Meteorology**.

SUPERCHARGER. The performance of an internal combustion engine is indicated, among other things, by the brake horsepower output. A review of the factors affecting power indicates that atmospheric conditions have a significant effect. A naturally aspirated (unsupercharged) engine is able to draw into the cylinders on suction strokes only from 70–85% of the fuel charge which it is theoretically capable of inducing. Consequently, the mean effective pressures are not as large as they might be, and power output per cubic inch of piston displacement does not reach its maximum possible value. Compression of the incoming air, or air-fuel mixture, somewhat above ambient pressure is a natural way of increasing output at sea level or of regaining it at altitudes. A compressor used for this purpose is designated a *supercharger*.

In recent years in connection with automotive engines, there has been considerable emphasis on the use of a turbocharger boost device to increase downsized engine power while increasing fuel economy and, in essence, retaining packaging advantages.

The Society of Automotive Engineers observed that recently there has been a high level of activity involving the use of the mechanically driven supercharger as a boost device. The supercharger can provide improved engine torque response at low engine speeds as compared to the turbocharger. The latest production turbochargers using variable geometry housings and ceramic turbines still take four times as long as a positive displacement, mechanically driven supercharger to produce maximum boost. In addition, the turbocompressor does not reach its maximum efficiency range until high speeds and airflows are achieved later in the vehicle acceleration event. This contrasts with the almost immediate boost response of the supercharger, which takes approximately 0.4 second to produce 50 kPa boost. The supercharger is continuously driven at full boost speed for the given rpm, and as soon as the bypass valve can be closed, the intake system is pressurized. There is no need to accelerate a mechanical device to high rotational speeds prior to production of boost pressure.

In testing commercially available vehicles, some equipped with turbochargers and others with superchargers, the researchers found that in attempting to accelerate from a stop in a turbocharged car resulted in a sluggish feel until 2 seconds after pressing the accelerator pedal. Then, the power rapidly climbed making it necessary to readjust the pedal position. Usually, the lack of turbocharger response at low engine speeds resulted in a large throttle opening and rich fuel during the first 3 seconds of acceleration then a gradual throttle closing. Fuel economy suffered and a high level of driver interaction was required to maintain vehicle control.

When driving a supercharged car, much less throttle modulation was needed to set the desired level of vehicle acceleration. The engine torque level increased almost immediately upon application of the throttle and did not suddenly change seconds later as with the turbocharged vehicles. This reduced the amount of driver interaction needed to maintain control of the vehicle and gave the same feel as a much larger, naturally aspirated engine under the same conditions.

SUPERCONDUCTIVITY. A property of a material that is characterized by zero electric resistivity and, ideally, zero permeability. The phenomenon of superconductivity was discovered in 1911 by Heike Kamerlingh Onnes (University of Leiden) as the outcome of a remarkable achievement in those years — the liquefaction of helium for the first time. Helium condenses at atmospheric pressure at 4.2 K. Onnes, using the newly available very low temperature substance, proceeded to investigate the electrical resistance of various metals at low temperatures. Even prior to quantum mechanics, it had been predicted that if absolute zero could be achieved in a metal having a perfectly regular interatomic structure, the electrical resistance of the metal would be zero. Onnes found that the resistance of a mercury wire suddenly dropped to zero at 4.2 K, which indeed is a very low temperature, but still well above absolute zero. Onnes and other investigators at Leiden researched superconductivity in other metals, such as lead, which was found to become superconductive at 7.2 K. It should be mentioned at this point that scientists of that period were biased in their thinking of conductivity and superconductivity in terms of metals. The first stable conducting organic material was not synthesized until 1960 and it was not until 1979 that a superconducting organic material was isolated. The so-called "hottest" superconductor was announced in mid-1993 by a research team at Eidgenossische Technische Hochschule in Zurich. The new material, considered toxic, is made of two distinct compounds that commence to be superconductive at 133 K. Prior record was claimed for $Tl_2Ca_2Ba_2Cu_3O_{10}$ at 127 K.

Rediscovery. The topic and potential of superconductivity essentially was rediscovered in the late 1970s and early 1980s, during which period the research activity safely can be described as zealous. This was fueled by the scores of probable applications of superconductors, but which to date largely remain as promises. Research continues at a good pace, and the topic is much better understood as compared with a decade ago. As pointed out later in this article, much excellent technological fallout has occurred from many millions of dollars invested in research. The search for the ultimately practical superconductor, although still elusive, has reinforced the multidisciplinary sciences involved, notably physics and chemistry.

Application Targets. Among the ultimately practical applications for superconductivity, especially those of significant future commercial values, are: (1) magnetic shielding, (2) magnetic resonance imaging magnets for medicine and research, (3) electric utility transmission lines and load-leveling storage coils, (4) magnetic separators for materials processing, (5) higher-speed (10×) switching and signal transmission for computers, (6) more compact electronics with finer interconnect lines, (7) extremely compact electric motors and actuators, (8) no-loss portable electrical storage "batteries," and (9) noncontact bearings and magnetically levitated vehicles. Special areas of interest by the military in superconductors include (1) infrared optical detector elements, (2) high-speed millimeter and submillimeter-wave electronics for advanced radar countermeasures, (3) magnetic anomaly detection of submarines, and (4) free-electron laser components.

Considerable research of a contemplative or assumptive nature continues to go forward — that is, studying how the "ideal" superconductor can be applied, once developed. Examples of progress are shown in Figs. 1, 2, and 3.

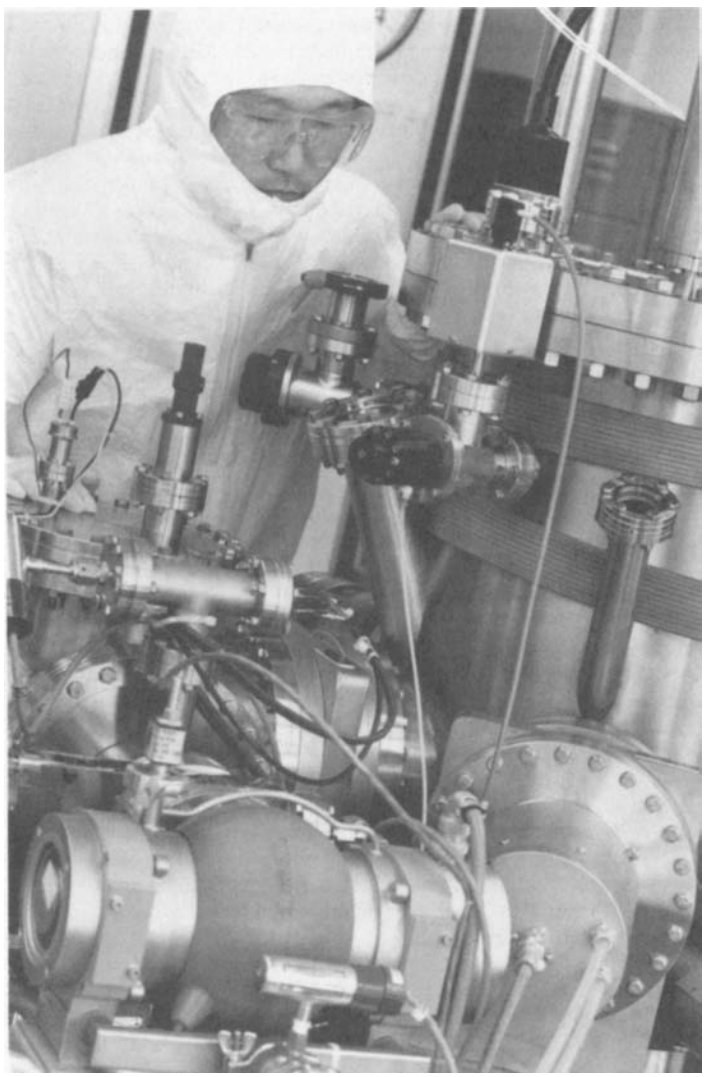

Fig. 1. Special equipment required to fabricate low-temperature superconducting junctions. Josephson junctions are comprised of aluminum oxide sandwiched between layers of niobium. These trilayer devices are considered vital to the very-high-speed signal processing demands of next-generation computers, radar, and communication systems. Shown in illustration is scientist Dr. Joonhee Kang. (*Westinghouse Electric Corporation.*)

Fundamental Research Findings

For several years following the previously mentioned work of the Louden scholars, investigators concentrated principally on metallic elements and alloys, including indium, tin, vanadium, molybdenum, niobium-zirconium, and niobium-tin, among many others. A number of basic discoveries were

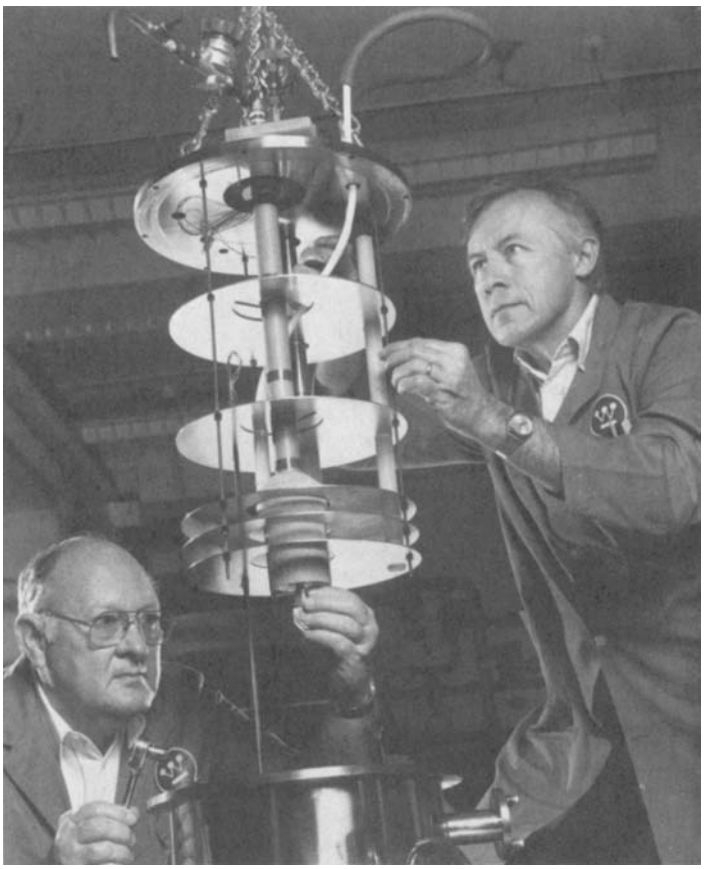

Fig. 2. Electrical lead comprised of a high-temperature superconductor can carry a current of 2000 amperes. A variety of uses include magnetic resonance imaging and superconducting magnetic energy storage. (*Westinghouse Electric Corporation*.)

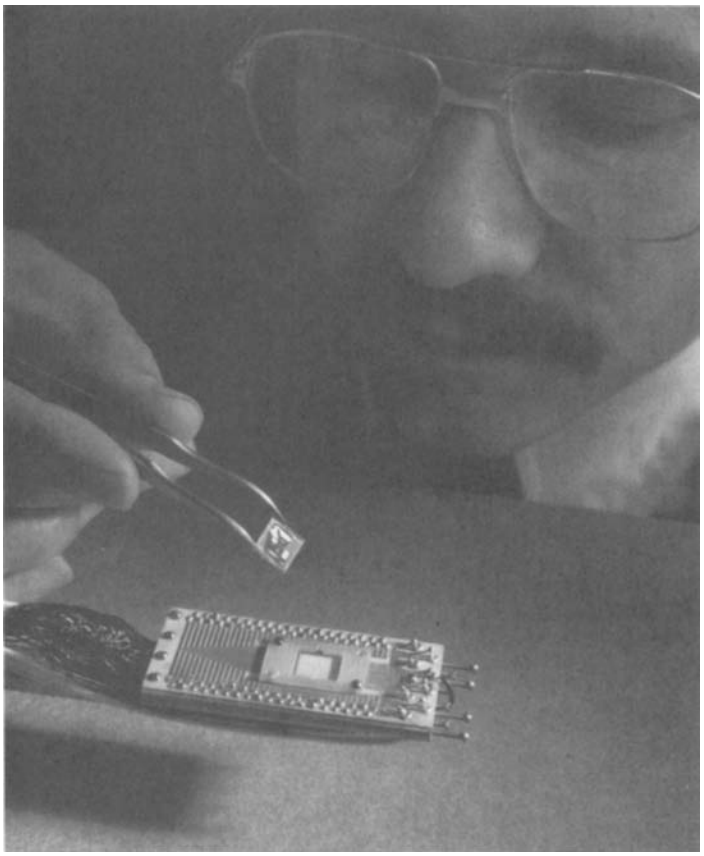

Fig. 3. Scientist Donald L. Miller holds an integrated circuit chip comprising a high-resolution superconducting analog-to-digital converter. The one-square-centimeter chip, known as a counting converter, holds promise as an unprecedented combination of high resolution and low power consumption, as needed in future air traffic control radar and infrared space-tracking applications. The 12-bit circuit (Josephson junction) has a resolution of 1 part in 4000. (*Westinghouse Electric Corporation*.)

made. For example, finding that the property of superconductivity could be destroyed by the application of a magnetic field equal to or greater than a critical field H_c. This H_c, for a given superconductor, is a function of the temperature given approximately by

$$H_c = H_0(1 - T^2/T_c^2) \tag{1}$$

where H_0, the critical field at 0K, is in general different for different superconductors and has values from a few gauss to a couple of thousand gauss. For applied magnetic fields less than H_c, the flux is excluded from the bulk of the superconducting sample, penetrating only to a small depth λ into the surface. The value of λ (called the penetration depth) is in the range 10^{-5} to 10^{-6} centimeter. Thus the magnetization curve for a superconductor is

$$B \text{ (inside)} = 0 \qquad \text{for } H < H_c$$
$$B \text{ (inside)} = B \text{ (outside)} \qquad \text{for } H > H_c$$

This magnetization behavior is reversible and cannot therefore be explained entirely on the basis of the zero resistance. The reversible magnetization behavior is called the Meissner effect.

The existence of the penetration depth λ suggests that a sample having at least one dimension less than λ should have unusual superconducting properties, and such is indeed the case. Thin superconducting films, of thickness d less than λ, have critical fields higher than the bulk critical field, approximately in the ratio of λ to d. This result follows qualitatively from the thermodynamics of the Meissner effect: the metal in the superconducting state has a lower free energy than in the normal state, and the transition to the normal state occurs when the energy needed to keep the flux out becomes equal to this free energy difference. But in the case of a thin film with $d < \lambda$, there is partial penetration of the flux into the film, and thus one must go to a higher applied field before the free energy difference is compensated by the magnetic energy.

It is clear that the existence of the critical field also implies the existence of a critical transport electrical current in a superconducting wire, i.e., that current I_c, which produces the critical field H_c at the surface of the wire. For example, in a cylindrical wire of radius r, $I_c = \frac{1}{2} r H_c$. This result is called the Silsbee rule.

All of the above properties distinguish superconductors from "normal" metals. There is another very important distinction, which contains a clue to understanding some of the properties of superconductors. In a normal metal at 0 K, the electrons, which obey Fermi statistics, occupy all available states of energy below a certain maximum energy called the Fermi energy ζ. Raising the temperature of the metal causes electrons to be singly excited to states just above the Fermi energy. There is for all practical purposes a continuum of such excited energy states available above the Fermi energy. The situation is quite different in a superconductor; it turns out that in a superconductor, the lowest excited state for an electron is separated by an energy gap ε from the ground state. The existence of this gap in the excitation spectrum has been confirmed by a wide range of measurements: electronic heat capacity, thermal conductivity, ultrasonic attenuation, far infrared and microwave absorption, and tunneling. The energy gap is a monotonically decreasing function of temperature, having a value $\sim 3.5\ kT_c$ at 0 K (where k is the Boltzmann constant) and vanishing at T_c.

The superconducting state has a lower entropy than the normal state, and therefore one concludes that superconducting electrons are in a more ordered state. Without, for the present, inquiring more deeply into the nature of this ordering, one can state that a spatial change in this order produced say by a magnetic field will occur, not discontinuously, but over a finite distance ζ, which is called the *coherence length*. The coherence

length represents the range of order in the superconducting state and is typically about 10^{-4} centimeter, though we shall see later that it can in some superconductors take much lower values and lead to some remarkable properties.

Measurements of the transition temperature on different isotopes of the same superconductor showed that T_c is proportional to $M^{-1/2}$, where M is the isotopic mass. This isotope effect suggests that the mechanism underlying superconductivity must involve the properties of the lattice, in addition to those of the electrons. Another indication of this is given by the behavior of allotropic modifications of the same element: white tin is superconducting, while grey tin is not, and the hexagonal and face-centered cubic phases of lanthanum have different transition temperatures. A third, and most striking, indication is that the current vs voltage characteristic of a superconducting tunneling junction shows a structure which is intimately related to the phonon spectrum of the superconductor.

The superconducting properties of alloys present a bewildering variety of phenomena. They show a great deal of magnetic hysteresis, with little indication of a perfect Meissner effect. The Silsbee rule is inapplicable, and the resistive transition occurs at fields generally very much higher than in pure superconductors. For example, a wire of Nb_3Sn can carry a current of 10^5 amperes/cubic centimeter in an applied field of 100 kilogauss, while a similar wire of lead would carry about 10^3 amperes/cubic centimeter in a field of only 100 gauss. When experiments are done using well-annealed (preferably single-crystal) alloys, it is found that the critical currents drop considerably, and the magnetic behavior becomes reversible but still quite unlike that of pure superconductors. The flux is excluded from the interior of the sample up to a well-defined field H_{c1}. When the applied field is raised further, flux begins to penetrate, even though the resistance remains zero, until a second critical field H_{c2} is reached, at which the flux penetration is complete, and normal resistance is abruptly restored.

Superconductivity Theory

The theory of superconductivity has developed along two lines, the phenomenological and the microscopic. The phenomenological treatment was initiated by F. London, who modified the Maxwell electromagnetic equations so as to allow for the Meissner effect. His theory explained the existence and order of magnitude of the penetration depth, and gave a qualitative account of some of the electrodynamic properties. The treatment was extended by V.L. Ginzburg and L.D. Landau, and by A.B. Pippard, who in particular emphasized the concept of the range of coherence. A.A. Abrikosov used these ideas to develop a model for alloy superconductors. He showed that if the electronic structure of the superconductor were such that the coherence length ζ becomes smaller than the penetration depth λ, one would get magnetic behavior similar to that observed in alloys, with two critical fields H_{c1} and H_{c2}. The problem of high critical currents in unannealed (or otherwise metallurgically imperfect) alloys and compounds is more complicated because it involves the interaction between the microscopic metallurgical structure and the superconducting properties. This is an area of great research activity because of the technological implication to be mentioned later.

The microscopic theory of superconductivity was initiated by H. Fröhlich, who first recognized the importance of the interactions of electrons with lattice vibrations and in fact predicted the isotope effect before its experimental observation. The detailed microscopic theory was developed by J. Bardeen, L.N. Cooper and J.R. Schrieffer in 1957, and represents one of the outstanding landmarks in the modern theory of solids. The BCS theory, as it is called, considers a system of electrons interacting with the phonons, which are the quantized vibrations of the lattice. There is a screened coulomb repulsion between pairs of electrons, but in addition there is also an attraction between them via the electron-phonon interaction. If the net effect of these two interactions is attractive, then the lowest energy state of the electron system has a strong correlation between pairs of electrons with equal and opposite momenta and opposite spin and having energies within the range $k\theta$ (where θ is the Debye temperature) about the Fermi energy. This correlation causes a lowering of the energy of each of these Cooper pairs (named after L.N. Cooper who first pointed out their existence on the basis of some general arguments) by an amount ε relative to the Fermi energy. The energy ε may be regarded as the binding energy of the pair, and is therefore the minimum energy which must be supplied in order to raise an electron to an excited state. We see thus that the experimentally observed energy gap follows from the theory. The magnitude ε_0 of the gap at 0K is

$$\varepsilon_0 \approx 4k\theta \exp\left(-\frac{1}{NV}\right)$$

where N is the density of electronic states at the Fermi energy and V is the net electron-electron interaction energy. The superconducting transition temperature T_c is given by

$$3.5kT_c \approx \varepsilon_0$$

It has been shown that the BCS theory does lead to the phenomenological equations of London, Pippard and Ginzburg and Landau, and one may therefore state that the basic phenomena of superconductivity are now understood from a microscopic point of view, i.e., in terms of the atomic and electronic structure of solids. It is true, however, that we cannot yet, *ab initio*, calculate V for a given metal and therefore predict whether it will be superconducting or not. The difficulty here is our ignorance of the exact wave functions to be used in describing the electrons and phonons in a specific metal, and their interactions. However, we believe that the problem is soluble in principle at least.

The range of coherence follows naturally from the BCS theory, and we see now why it becomes short in alloys. The electron mean free path is much shorter in an alloy than in a pure metal, and electron scattering tends to break up the correlated pairs, so that for very short mean free paths one would expect the coherence length to become comparable to the mean free path. Then the ratio $\kappa \approx \lambda/\zeta$ (called the Ginzburg-Landau order parameter) becomes greater than unity, and the observed magnetic properties of alloy superconductors can be derived. The two kinds of superconductors, namely those with $\kappa < 1/\sqrt{(2)}$ and those with $\kappa > 1/\sqrt{(2)}$ (the inequalities follow from the detailed theory) are called respectively type I and type II superconductors.

Challenges to Established Theories. It is interesting to note that some theoreticians struggle with describing how superconductivity occurs at high temperatures in the newer, ceramic superconductors. This is understandable because the classic theory of superconductivity is tied to metals. Most ceramic superconductors discovered to date incorporate distinctive layers of copper and oxygen atoms. One question posed by some researchers, "Is the mechanism of high-temperature superconductivity the same in hole superconductors as it is in electron superconductors?"

Researchers at the Brookhaven National Laboratory, in applying X-ray techniques to a cerium-doped electron superconductor developed at the University of Tokyo, found that the holes of a hole superconductor are linked to oxygen atoms in the copper-oxygen layers, whereas in an electron superconductor the electrons are associated with copper atoms. This is exemplary of how easy it is for former theories to become outdated when new material combinations are tested for their superconductivity.

Superconductivity Research

In 1962, B. Josephson recognized the implications of the complex order parameter for the dynamics of the superconductor, and in particular when one considers a system consisting of two bulk conductors connected by a "weak link." This research led to the development of a series of weak link devices commonly called Josephson junctions. See also **Josephson Junctions**. These devices hold much promise for achieving ultra high-speed computers where switching time is of the order of 10^{-11} second.

Good success also has been achieved in the use of certain type II superconductors, such as Nb-Zr and Nb-Ti alloys, and Nb_3Sn, in making electromagnets. In a conventional electromagnet employing normal conductors, the entire electric power applied to the magnet is consumed as Joule heating. For a magnet to produce 100 kilogauss in a reasonable volume, the power requirement can run into megawatts. In striking contrast, a superconducting magnet develops no Joule heat because its resistance is zero. Indeed, if such a magnet has a superconducting shunt placed across it after it is energized, the external power supply can be removed, and the current continues to flow indefinitely through the magnet and shunt, maintaining the field constant. Superconducting magnets have been constructed producing very strong fields in usable volumes. There is a natural

upper limit to the critical field possible in such superconductors, given by the paramagnetic energy of the electrons (due to their spin moment) in the normal state becoming equal to the condensation energy of the Cooper pairs in the superconducting state. This leads to a limit of about 360 kilogauss for a superconductor with a T_c of 20 K.

As investigators accumulated data upon data, many emphasized the practical as well as theoretical aspects of superconductors. The ultimate superconductor, of course, would be one that operated at room temperature or above. The materials must be manufacturable in a useful form, such as strong ductile wires for high-field magnets, electrical machinery, and power transmission lines, situations which could be even more important in commercial and industrial application than their value to science per se. (Traditionally, superconducting materials have been hard, brittle, and difficult to process.) Although superconductors that would operate at room temperature and above present a long-range target, lesser targets, including practical ways to cool them with liquid nitrogen instead of liquid helium and possibly, even better, operate them within a closed-cycle refrigeration system is the goal in the shortrange. Useful superconductors in large-scale applications must retain their properties not only at high temperatures, but also in the presence of high magnetic fields and while carrying large electrical currents. Praveen Chaudhari (IBM) has observed that new superconductors will enter the marketplace rapidly when intensive materials engineering produces easily cooled, mechanically robust conductor configurations that can handle high current densities (100,000+ A/cm^2) under powerful magnetic fields (10+ T), while maintaining stable superconductivity.

Johannes Georg Bednorz and Karl Alexander Mueller (IBM Zurich Research Laboratory) after several years devoted to a study of oxide compounds (not in terms of superconductivity) proceeded with the working hypothesis that an increase in the density of charge carriers in a material (either as electrons or as positively charged "holes") possibly would lead to a rise in transition temperature. They commenced a search for nickel- and copper-containing oxides. Early in 1986, they found a certain form of barium lanthanum copper oxide that evidenced the onset of superconductivity at temperatures as high as 35 K (12 degrees over the previous record). They encountered skepticism, because the facts did not square with accepted theory that limits the phenomenon to well below 35 K. Shortly thereafter, however, researchers at the University of Tokyo, the University of Houston, and AT&T Bell Laboratories confirmed the Bednorz-Mueller findings. On October 14, 1987, the Nobel prize in physics was awarded to these two researchers and a speaker for the Royal Swedish Academy of Sciences observed that their work inspired "the explosive development in which hundreds of laboratories the world over commenced work on similar material." [It should be observed that Ching-Wu Chu and colleagues (University of Houston) did announce in February 1987 that a related class of ceramics (a certain form of yttrium barium copper oxide) remained superconducting up to 94 K, proclaiming that to be the first superconductor which could be cooled by liquid nitrogen (bp = 77 K) instead of requiring helium.] That announcement in itself also precipitated a "rush" of researchers to the ceramics.

Technological Fallout of Superconductivity Research

While in the course of finding viable superconductors for commercial applications, researchers have produced valuable ancillary information.

Quantization of Energy. In a scholarly paper, D.G. McDonald (U.S. National Institute of Standards and Technology, Boulder, Colorado) observes, "Ideas about quantized energy levels originated in atomic physics, but research in superconductivity has led to unparalleled precision in the measurement of energy levels. Microscopic things can be identical; macroscopic things cannot. This proposition is so imbued in the minds of physicists that it is interesting to see that it is false in the following sense. In the past, physicists believed that only atoms and molecules could have identical states of energy, but recent experiments have shown that much larger bodies, superconductors in macroscopic quantum states, have equally well-defined energies." In the paper, McDonald uses the novelty of the Josephson effect to illustrate the primary point of the technical paper. See McDonald reference listed.

Structural Chemistry. In an enlightening paper, R.J. Cava (AT&T Bell Laboratories) asserts, "The discovery of high-temperature superconductivity in oxides based on copper and rare and alkaline earths at first caught the solid-state physics and materials science communities completely by surprise. Since the earliest 30 to 40 K superconductors based on $La_{2-x}(Ca,Sr,Ba)_xCuO_4$, many new superconducting copper oxides have been discovered, with ever-increasing chemical and structural complexity. The current record transition temperature is held[1] by $T1^2Ba^2Ca^2Cu^3O^{10}$, a material whose processing requires the stoichiometric control of five elements, each with considerably different chemical characteristics." In the Cava paper, the crystal structures of the known copper oxide superconductors are described, with particular emphasis on the manner in which they fall into structural families. The local charge picture — a framework for understanding the influence of chemical composition, stoichiometry, and doping on the electrical properties of complex structures — is also described.

This probing of complex and previously unattended solid materials typifies technical fallout from superconductor research.

Impact on Materials Processing and Chemical Engineering. In an interesting paper, R. Kumar (Indian Institute of Science, Bangalore) points out how processing considerations for achieving high-temperature superconductors has introduced new process engineering problems not contemplated heretofore. In a paper (reference listed), Kumar observes that processes involve multicomponent solid-solid reactions; mixing of fine powders; simultaneous precipitation of many ions from solutions, emulsions, microemulsions, and liquid membranes; the flow of cohesive powders with and without binders; the flow of thin films over partially wetted particles; grain boundary growth and composition; quick evaporation using pulsed lasers; mixing of molecules during their flight paths and the influence of oxygen jets; deposition of particles on substrates; and other relatively unfamiliar processing techniques.

SUPERCOOLING. The reduction of temperature of any liquid below the melting point of that substance's solid phase; that is, cooling beyond its nominal freezing point. Also called *subcooling* or *undercooling*; see note below. See also **Freezing Point**; and **Melting Point**.

A liquid may be supercooled to varying degrees, depending upon the relative lack of freezing nuclei or solid boundary irregularities within its environment, and freedom from agitation. See also **Freezing Nucleus**. This supercoolability of a substance with a crystalline solid form (as opposed to amorphous matter) stems from the unique energy transformations necessary for the formation of the first crystal nucleus, whereafter all adjacent liquid immediately becomes solid unless or until the latent heat released elevates the system's temperature sufficiently to arrest the process. It should be noted that the reverse process is not possible; a crystalline solid cannot be "superheated"; therefore, a substance's melting point is very conservative, only slightly dependent upon pressure. Supercooled clouds are quite common. In extreme cases, they have been observed at temperatures as low as $-40\,^{\circ}\mathrm{C}$ ($-40\,^{\circ}\mathrm{F}$). The smaller and purer the water droplets, the more likely is supercooling.

Note: The choice of terminology for this concept has been variable and controversial for many years, largely based on conceptual views of the prefixes super, sub, and under. Supercooling remains, however, the most frequently utilized term.

AMS

SUPERELEVATION. When the plane of a roadway is tilted on a curve (commonly known as banked), it is said to be superelevated. The purpose of superelevation is to permit a vehicle to round a curve on a roadway at high speed without danger of overturning or skidding. See Fig. 1. The superelevation can be made so that the resultant of dead weight and centrifugal force passes through the vertical plane of symmetry of the vehicle. In this condition, no side sway would be felt by the occupants. However, the superelevation necessary to accomplish this is different for each vehicle speed, so that it is apparent that the superelevation of a highway presupposes an average vehicle speed. The same is true of railways, although the variation of speeds with which the trains round curves is less than in the case of highway traffic.

To illustrate how the superelevation depends upon vehicle speed, let it be assumed that an automobile approaches a curve on a highway at a speed of V (feet per second). If the radius of the turn is r, the centrifugal

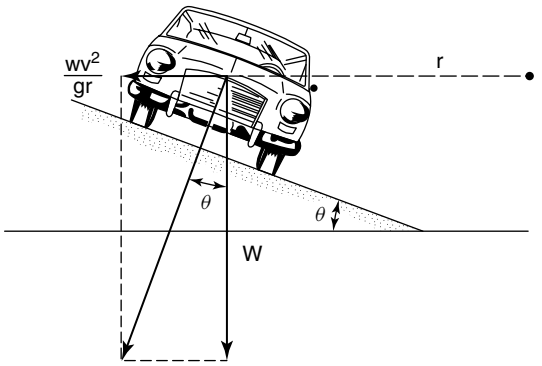

Fig. 1. Demonstration of superelevation principle applied to highway.

acceleration is V^2/r. Furthermore, assume that the weight is W pounds. While negotiating the curve, the car is subject to two forces, one, the weight vertically downward, the other, centrifugal force acting horizontally away from the center of curvature, and having a magnitude WV^2/gr. The surface of the road must be perpendicular to the resultant for no "side sway." If superelevation is given as the angle of bank (see figure), the angle of superelevation θ has a tangent equal to centrifugal force divided by weight. This tangent is V^2/gr, demonstrating that the superelevation must be made with respect to the radius of curvature and the velocity of the vehicle. It is independent of the dimensions and weight of the vehicle.

See also **Spiral Curve**.

SUPERFINISHING. An abrasive process for removing smear metal, scratches and ridges produced by machining and grinding operations, and other surface irregularities from parts that are to have a highly finished surface. The process resembles lapping in that a lubricated abrasive stone is applied to the surface at comparatively low speeds and light pressures. A superfinishing head whose base is attached to the cross-slide of an engine lathe may be used. The base supports two vertical cylindrical guides on which the head proper may be manually adjusted to the work by a hand-operated lever. The abrasive stone is carried in a vertical slide, which is subjected to the action of a spring for applying pressure to the stone. The stone pressure may be regulated to suit the requirements of the work by turning the screw at the top of the slideway.

SUPERFLUIDITY. The term used to describe a property of condensed matter in which a resistance-less flow of current occurs. The mass-four isotope of helium in the liquid state, plus over 20 metallic elements, are known to exhibit this phenomenon. In the case of liquid helium, these currents are hydrodynamic. For the metallic elements, they consist of electron streams. The effect occurs only at very low temperatures in the vicinity of the absolute zero ($-273.16\,^{\circ}\mathrm{C}$ or 0 K). In the case of helium, the maximum temperature at which the effect occurs is about 2.2 K. For metals, the highest temperature is in the vicinity of 20 K.

If one of the metals (commonly referred to as superconductors) is cast in the form of a ring and an external magnetic field is applied perpendicularly to its plane and then removed, a current will flow round the ring induced by Faraday induction. This current will produce a magnetic field, proportional to the current, and the size of the current may be observed by measuring this field. Were the ring (e.g., one made of lead) at a temperature above 7.2 K, this current and field would decay to zero in a fraction of a second. But with the metal at a temperature below 7.2 K before the external field is removed, this current shows no sign of decay even when observations extend over a period of a year. As a result of such measurements, it has been estimated that it would require 10^{99} years for the supercurrent to decay. Such persistent or "frictionless" currents in superconductors were observed in the early 1900s — hence they are not a recent discovery.

In the case of liquid helium, these currents are hydrodynamic, i.e., they consist of streams of neutral (uncharged) helium atoms flowing in rings. Since, unlike electrons, the helium atoms carry no charge, there is no resulting magnetic field. This makes such currents much more difficult to create and detect. Nevertheless, as a result of research carried out in

England and the United States during the late 1950s and early 1960s, the existence of supercurrents in liquid helium has been established.

SUPERIMPOSED RIVER VALLEY. A river valley that is independent of present structural control may be described as either superimposed or antecedent. In the former case it is implied that the river has been able to maintain its course across resistant structures such as ridges, because it started as a consequent stream and has been "let down" on the underlying or nonconformable structure.

SUPERIOR MIRAGE. A mirage in which the image or images are displaced upward from the position of the object. If only a single image of distant objects is seen, then the term *looming* is often applied: A horizontal surface appears to curve upward with increasing distance and terminate in a relatively distant optical horizon. The looming might be accompanied by either *stooping* or *towering*. The superior mirage is most striking when it exhibits three or more images. The upper and lower images are always erect, while a single middle image will be inverted. No matter the number, images will alternate between erect and inverted, although sometimes a pair will appear back to back and might be interpreted as a single image. Although textbooks sometimes suggest that what is seen is an object and an even number of images, all are images, and have positions and magnifications that differ from that of the object. What is seen is dependent upon both the distance to objects and the height of the eye. A change of either can produce markedly different image characteristics. Superior mirages occur over a surface when (molecular number) density decreases with height, but are always most striking when temperature increases with height. Then, what is seen (for a particular distance and observing height) depends critically on the shape of the temperature (and thus, the refractive index) profile. Everything from stooping to towering to multiple images is a possible result of fairly simple profiles. A common profile, a lifted temperature inversion, can not only produce the three-image mirage but, since internal gravity waves often occur on such an inversion, the resulting periodic horizontal inhomogeneity can also produce a higher number of images. Such lifted inversions are common over, but hardly confined to, enclosed bodies of water on warm afternoons when the warmer air from the surrounding land flows over the colder water. See also **Inferior Mirage**; **Looming**; **Mirage**; **Sinking**; **Stooping**; and **Towering**.

SUPERMOLECULAR CHEMISTRY. See **Molecular Recognition**.

SUPERNOVA 1987A AND 1993J. What is there about an event that occurred 160,000 years ago that so fires the imagination and excites scientists into a veritable frenzy of observation? Supernovae are the results of violent explosions and are perhaps the most spectacular outbursts of energy we can ever see. A nova is an explosive variable star that brightens by a factor of thousands within hours or days and then fades to its previous brightness within months. The name "nova" is shortened from "stella nova," the Latin for "new star." It was once believed that these were really new stars, but we now know that they are actually old stars which suddenly explode and become much brighter. If the star was too faint to see before the explosive brightening, then it appeared as if it were a "new" star. Observations show that novae occur in close binary systems, one of whose components is a white dwarf star. White dwarf stars represent a final stage in the life history of a star, when it has consumed its nuclear fuel and has shrunk to the dimensions of the earth. In such a close binary system, mass transfer onto the white dwarf can occur when the companion star begins to expand as a result of its evolution. Detailed numerical calculations (in lieu of experiments!) show that when a critical amount of mass has been dumped onto the white dwarf star, explosive nuclear fusion occurs and the outer layer of accumulated matter is blown off.

A supernova is superficially similar to a nova in that it suddenly increases in brightness. A supernova, however, increases in brightness by factors of many millions. Hence the name *super nova*. Careful searches through historical records of visual observations from around the world suggest that supernovae were observed in AD 185, 393, 1006, 1054, 1181, 1572 and 1604.

The 1054 AD event left a spectacular remnant, widely known today as the Crab Nebula, and an associated pulsar. The events of 1572 AD and 1604 AD were observed by the famous astronomers Tycho Brahe and Johannes Kepler respectively and occurred before the invention of the telescope. No new supernova has been observed in our Milky Way since 1604 AD and thus our knowledge is almost entirely based on observations of supernovae in external galaxies. Because most external galaxies are so distant, supernovae in them appear quite faint to us, in spite of their intrinsic brightness, which at maximum light can rival that of billions of stars. Astronomers have long hoped for a bright, nearby supernova that would permit more detailed observations.

Additional information on novas and supernovas can be found in article on **Nova and Supernova**.

Supernova 1987A

On the night of 23/24 February 1987, Ian Shelton, working at the University of Toronto Las Campanas Station in northern Chile, discovered the brightest supernova seen since 1604. See Fig. 1. Not surprisingly, several other people, in Australia, Chile and New Zealand, saw it that same night, when it had a visual magnitude of about five. The official designation is Supernova 1987A (the letter A indicating that it is the first supernova discovered in 1987) in the Large Magellanic Cloud, because it appears to belong to this nearby companion galaxy to our own Milky Way. The Large and Small Magellanic Clouds are the nearest external galaxies and are named after the famous Portuguese navigator Ferdinand Magellen who traveled around the world in the early 1500s. The Magellanic Clouds are visible only from the Earth's Southern Hemisphere and appear to the unaided eyes as illuminated clouds. "Nearby" is a relative concept, of course. The Large Magellanic Cloud is approximately 160,000 light years away, which means that what Shelton saw that night actually happened some 160,000 years ago.

Within hours, astronomers all over the world were notified of Shelton's discovery. Astronomy is not an experimental science, and so astronomers must make the most of opportunities offered by unscheduled "experiments" which occur in the universe around us. For this purpose, the International Astronomical Union operates a Central Bureau for Astronomical Telegrams which sends out telegrams and circulars (which are distributed via postal and electronic mail services). All the suitably located telescopes were thus able to join quickly in gathering data about this serendipitous discovery, thus ensuring that Shelton's supernova already had become the best observed supernova ever. See accompanying illustration.

EDITOR'S NOTES: At the end of 1987, Supernova 1987A continued to attract scientific attention. By December 1987, the object had faded at a steady 0.01 magnitude rate per day and was by then observable only instrumentally. It is regarded as the closest (160,000 light-years from Earth) and the most studied supernova in nearly 400 years (and, in fact, in history because of the unavailability of adequate instrumentation centuries ago). For quite some time after the event, observations, including the detection of neutrinos and the long-term falloff in luminosity aided in authenticating some theoretical predictions. During the investigation, a few intriguing problems surfaced, one of these being the blue color of the progenitor star, which was dimmer by a factor of 10 than what had been predicted. As one scientist observed, "We started out looking at the most dramatic event in the universe, and now we're arguing about what seemed like the most pedestrian thing — hydrogen burning and stellar evolution." Indeed, the event triggered a detailed reexamination of the former knowledge of stars.

Traditional theory provides the following approximate scenario for Sandu-leak — the star, losing sufficient thermonuclear fusion to prevent collapse, could no longer support its own weight and lost to "gravity." Hydrogen was converted to helium; the temperature and pressure in the core of the star progressively increased. The most tightly bound elements, oxygen, silicon, and ultimately iron, were involved, in a situation about to turn critical. The steadily growing core passed a threshold of about 1.5 solar masses; a multibillion-degree iron plasma underwent a phase transition. Thence, the iron nuclei commenced to "boil," disintegrating into helium nuclei, thus eliminating the supporting core. The core gave away and a supernova event occurred.

The gravitational potential energy of the collapsing core radiated neutrinos. The gravitational potential energy given up by the collapse is estimated at 3×10^{53} ergs (equivalent to about that required to convert about 10% of the mass of the sun into energy). Astronomers detected a neutrino pulse from the object at the large proton-decay detector near

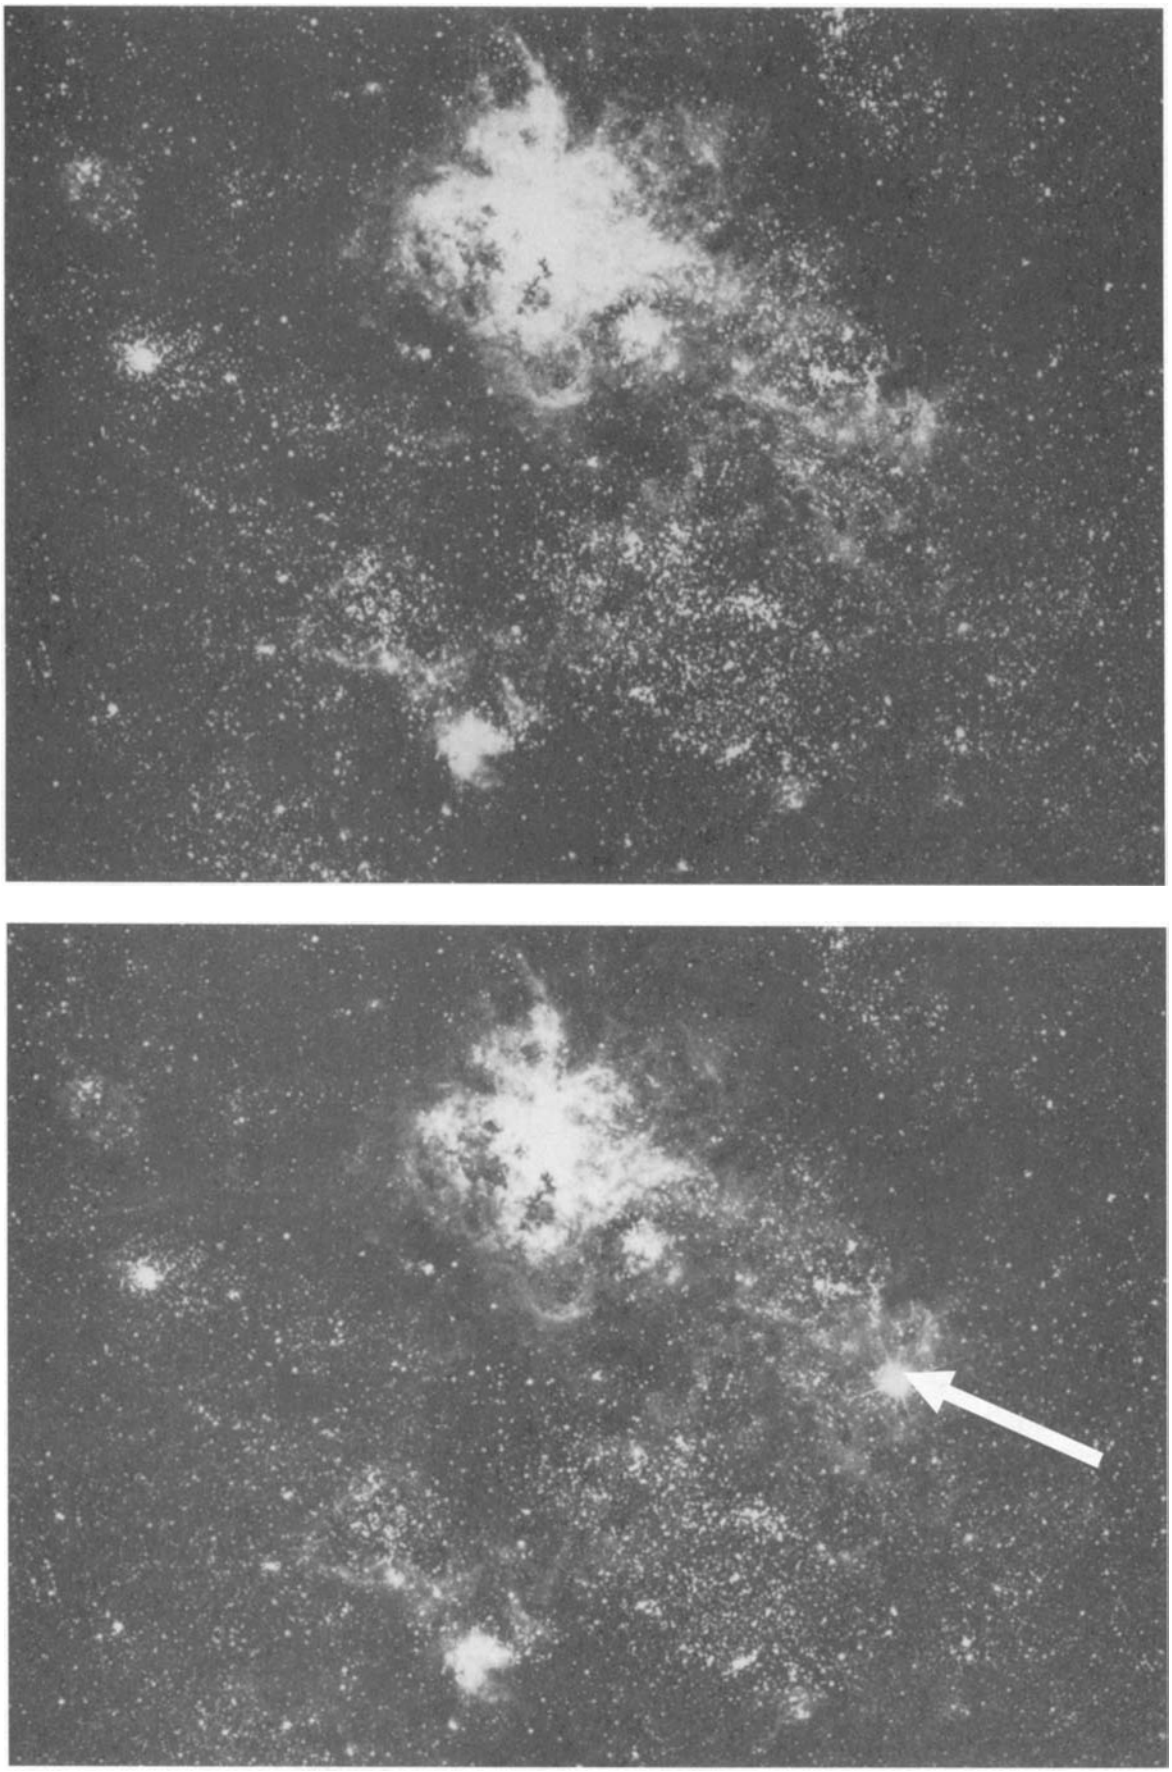

Fig. 1. Supernova 1987A: (*Top*) Large Magellanic Cloud taken with a 1.5 meter telescope at NOAO's Cerro Tololo (Chile) Inter-American Observatory in 1969 by Dr. Victor Blanco, former observatory director. (*Bottom*) Image of same area of sky made with the Cerro Tololo's Schmidt telescope on February 26, 1987 by Dr. Wendy Borbers of the Harvard-Smithsonian Center for Astrophysics. Bright image at right-center of photo shows the supernova detected in this nearby galaxy. (*National Optical Astronomy Observatories.*)

Cleveland, Ohio, as well as by a similar detector in Japan. (A prior burst of neutrino events observed at the Mount Blanc proton decay detector in Europe about 4 hours earlier is now believed to be spurious.)

Stanford Woosley (University of California at Santa Cruz) has observed that the emergence of cobalt-56 is yet another confirmation of standard theory. The resemblance to radioactive decay is no accident. Since June 1987, the supernova has been shining by the light of cobalt-56.

In February 1989, astronomers (University of California, Berkeley) suggested that they caught a glimpse of the ultra dense object at its heart, namely, a pulsar spinning furiously, almost 2000 times per second — so fast that it actually had broken apart. See Waldrop reference. However, also as reported by Waldrop, in late March 1989, the pulsar no longer was in view. As pointed out by one investigator, "Extensive computer analysis of the data showed that, on the night of 18 January (1989), the supernova was flickering ever so faintly at 1968.629 times per second, or more than twice as fast as any other pulsar ever seen. The rate gently rose and fell as though the pulsar were being tugged back and forth by the gravity of some kind of companion object." The foregoing frenzy of observations was disproved by a team at the Cerro Tololo Inter-American Observatory in Chile when it was announced that "the pulsar-like signals actually came from a television camera used to transmit images from the telescope to a monitor."

Supernova 1993J

An amateur astronomer, Francisco Garcia (Lugo, Spain), first reported this supernova on the night of March 28, 1993. On the following night, astronomers at the University of California, Berkeley, confirmed that Garcia had discovered a new supernova and, in fact, the brightest to shine in the Northern Hemisphere since 1937. Although supernova 1987A was far brighter, it could be seen only from the Southern Hemisphere. Professional astronomers consider 1993J to be in the same class as 1987A. The suspect object is believed to be a red supergiant, a larger and cooler star than the blue supergiant that exploded in 1987A. The object now is the target of numerous astronomical instruments.

SUPERPOSITION (Law of). The fundamental law in stratigraphy and historical geology stating that underlying strata are older than overlying strata unless the formations have been inverted by folding or by low-angle thrusts.

SUPERPOSITION (Nernst Principle of). The potential difference between junctions in similar pairs of solutions which have the same ratio of concentrations are the same even if the absolute concentrations are different, e.g., the same potential difference exists between normal solutions of HCl and KCl as exists between tenth-normal solutions of HCl and KCl.

SUPERPOSITION (Principle of). If a physical system is acted on by a number of independent influences, the resultant influence is the sum (vector or algebraic as circumstances dictate) of the individual influences. The principle takes on many specific forms depending on the nature of the system and the influence in question. For example, when two forces act simultaneously on a particle the resultant force is the vector sum of the two. Another example is provided by the small oscillations of a system about a state of equilibrium. Thus the total displacement of a vibrating string is the algebraic sum of all its various harmonic modes of oscillation which add without interfering with each other. The principle is validated in this case by the fact that the wave equation governing the oscillations is linear. Superposition does not apply to nonlinear systems.

The principle can also be applied to quantum mechanics. Here it is exemplified by the postulate that any state function of a given quantum mechanical system corresponding to a given observable (e.g., the energy) can be expressed as a linear expansion of the eigenstates of the system for the same observable.

SUPERSATURATED VAPOR. A vapor that remains dry, although its heat content is less than that of dry and saturated vapor at the pressure. Supersaturation is an unstable condition, and is found in the steam emerging from the nozzles of a steam turbine See also **Supercooling**. The abnormality of the phenomenon is similar to that of supercooling. Supersaturation of the steam probably results from the very rapid expansion of steam in the nozzle, permitting the traverse of a short distance before the condensation of moisture is completed. At a certain definite point, however, known as the Williams limit, the supersaturation vanishes, and the steam regains the wet state which would be normal in view of the pressure and the heat content. Supersaturation of vapor is impossible in the presence of numerous charged ions or dust particles.

SUPERSATURATION (Chemical). The condition existing in a solution when it contains more solute than is needed to cause saturation. Thermodynamically, this type of supersaturation is closely allied to supersaturation of a vapor, since the solute cannot crystallize out in solutions free from impurities or seed crystals of the solute. See also **Supersaturated Vapor**.

SUPERSATURATION (Meteorology). The condition existing in a given portion of the atmosphere (or other space) when the relative humidity is greater than 100%, that is, when it contains more water vapor than is needed to produce saturation with respect to a plane surface of pure water or pure ice. Such supersaturation does develop because frequently there is no "plane surface of pure water (or ice)" available. In the absence of water surfaces and in the absence of condensation nuclei or any wettable surfaces, phase change from vapor to liquid cannot occur due to the free energy barrier imposed by the surface free energy of the embryonic droplets that would then have to form by spontaneous nucleation. Humid air, purified of all foreign nuclei, can be expanded in cloud chambers to relative humidities of the order of 400% without any condensation taking place. Cloud condensation occurs in our atmosphere at relative humidities near 100% only because nature provides an abundance of condensation nuclei.

SUPERSONIC AERODYNAMICS. In the entry on **Aerodynamics and Aerostatics**, the topic is generally covered from the standpoint of subsonic flows. World War II fighters were the first aircraft to attain speeds

which produced, on critical points of the airplane, local flow velocities of Mach 1.0 and higher, although the airplane speed was less than the speed of sound. Only in the last couple of decades has aerodynamic experience passed beyond a limited theoretical knowledge. But since the early 1950s, a considerable bank of knowledge on supersonic flight has been collected.

For flight at low speeds, below about 300 miles per hour, air acts as an incompressible fluid. However, as velocity increases, air density changes about the airplane, and this effect becomes increasingly important as speeds are increased. When flow velocities reach sonic speeds at some point on an airplane, the airplane's drag begins to increase at a rate much greater than that indicated by subsonic aerodynamic theory. Subsonic flow principles are invalid at all speeds above this point.

Certain new definitions and concepts are necessary in dealing with air as a compressible fluid and with supersonic speeds:

Mach number is the ratio of the speed of motion to the speed of sound in air. The term comes from an Austrian physicist, Ernst Mach. An airplane traveling at the speed of sound is traveling at Mach 1.0.

A *shock wave* (compression wave) occurs in supersonic flow when the air must enter a volume smaller than the volume it has been occupying.

An *expansion wave* occurs in supersonic flow when the air is entering a larger volume than it has been occupying.

Supersonic Flow Characteristics. When an airplane flies at subsonic speeds, the air ahead is "warned" of the airplane's approach by a pressure change transmitted ahead of the airplane at the speed of sound. Because of this warning, the air begins to move aside before the airplane arrives and is prepared to let it pass easily. If the airplane travels at supersonic speeds, the air ahead receives no advance warning of the airplane's approach because the airplane is outspeeding its own pressure waves. Sound pressure changes are felt only within a cone-shaped region behind the nose of the airplane. Since the air is unprepared for the airplane's arrival, it must move to one side abruptly to let the airplane pass. This sudden displacement of the air is accomplished through a "shock wave." See Fig. 1.

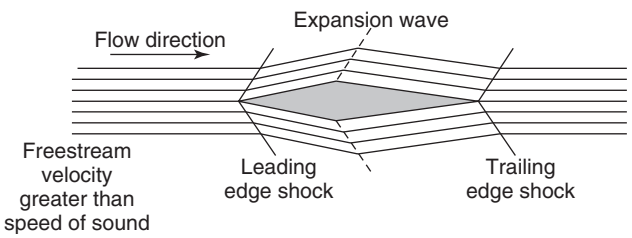

Fig. 1. Typical supersonic flow pattern.

The water-wave analogy furnishes a good physical picture of the subsonic "warning" system and supersonic "shock" formation. If one drops pebbles into a smooth pond of water, one each second, from the same point, each pebble will produce a water-wave moving outward with constantly increasing radius, as shown in Fig. 2. This is similar to the pattern of sound waves produced by an airplane sitting on the runway before take-off. Even though one cannot see the airplane, its presence is signaled by these outward rolling waves of engine noise.

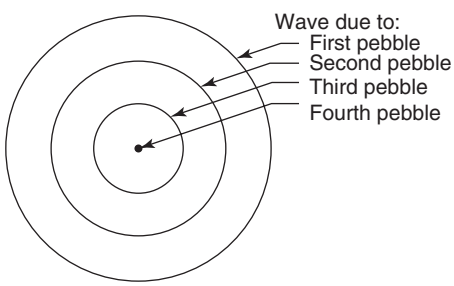

Fig. 2. Supersonic aerodynamics.

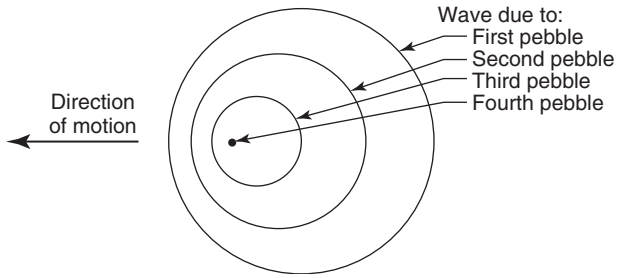

Fig. 3. Waves for motion at subsonic speed.

Now suppose we move slowly over the pond dropping pebbles at regular intervals. The picture of the waves is changed to that shown in Fig. 3. Each pebble still produces a circular wave, but the circles are crowded together on the side toward which we are moving; the center of each succeeding circle is displaced from the preceding one by a distance proportional to the speed at which we are traveling over the water. The wave pattern is identical to the pattern of sound waves around an airplane flying at subsonic speeds. The air ahead of the airplane is warned of the imminent arrival of the airplane and the warning time decreases with increasing airplane speed. The warning time is zero when the airplane is flying at exactly sonic speed. The corresponding water wave pattern is shown in Fig. 4. If we move across the water more rapidly than the water-wave speed, the wave pattern is markedly different from the previously illustrated patterns. The smaller circles are no longer completely inside the next larger ones. Now all the circles are included within a wedge-shaped region as shown in Fig. 5. This is similar to the sound wave pattern for an airplane flying at supersonic speed. The airplane is, in fact, a continuous disturbance in the air rather than an intermittent one, such as the pebbles falling regularly into the pond. Therefore, instead of several circles, there is an envelope surface of countless circles. The wedge on the surface of the pond looks like a section through the cone formed by an airplane in the air. Figure 5

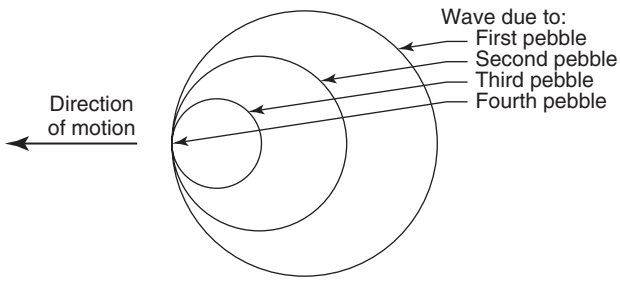

Fig. 4. Waves simulating Mach 1.0 motion.

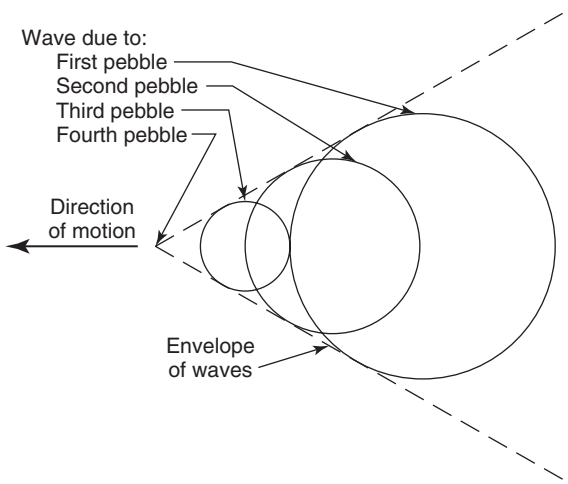

Fig. 5. Waves simulating supersonic motion.

indicates that there is considerable overrunning and interference between the wave circles; we might suspect from this that such interference will change the envelope shape for an actual airplane. This is, in fact, the case.

If the airplane is very streamlined and has a long, sharply pointed nose, then the air is not required to move a great distance suddenly in allowing the airplane to pass. In this case, the interference between sound waves is slight; the envelope is defined by the Mach angle, μ. Figure 6 shows that the Mach angle is the angle whose sine is the speed of sound divided by body velocity, or $1/V$. Thus, the Mach angle is 90° at a Mach number of 1.0; 30° at a Mach number of 2.0; and 10° at a Mach number of 5.75, for example. This envelope is called a Mach line in two dimensions or a Mach cone in three dimensions.

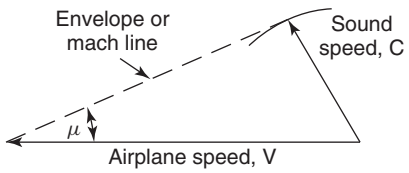

Fig. 6. Mach angle.

Types of Supersonic Waves. It is now apparent that waves are formed about any disturbance in a supersonic stream of air. The type of wave formed depends upon the nature of the disturbing influence. In our case, an airplane is the disturbing influence; its shape determines the location and characteristics of the waves formed. A wave of some type will exist whenever the air is required to change direction. The wave caused by a slight disturbance was defined as a Mach line. Air passing through a Mach line undergoes an infinitesimally small amount of temperature increase, pressure increase, and decrease in velocity. The Mach line envelope due to a long, slender, sharply-pointed body is conical in shape and is called a Mach cone. See Fig. 7. The envelope for a very thin wing is a wedge at center span bounded by a Mach cone at each tip, as shown in Fig. 8. The apex angle of these wedges and cones is the Mach angle, μ.

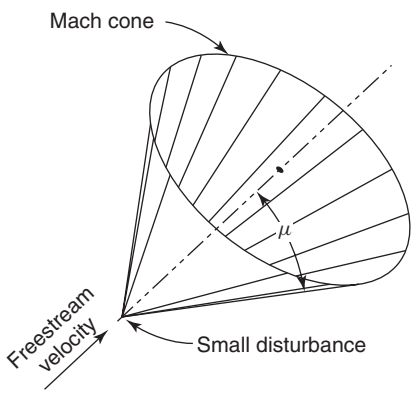

Fig. 7. Conical shock wave.

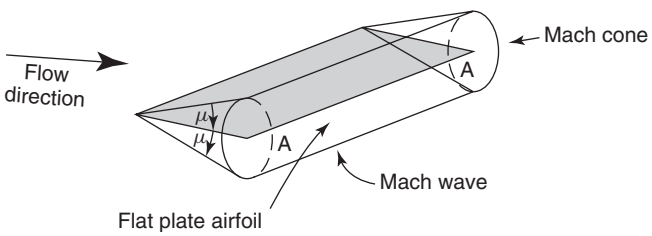

Fig. 8. Shock wave and Mach cones.

Mach waves are associated only with very small or gradual changes in the flow direction of the passing air. The bodies small enough to produce Mach waves are too slender to be incorporated on an actual airplane. To be practical, an airplane must be too blunt and thick for Mach waves to form; instead, a blunt body causes shock waves, called shocks.

These shocks are formed by the interference of sound waves mentioned earlier in the water wave discussion. Shocks are like Mach lines in that the pressure and temperature of the air passing through are abruptly increased and the air velocity is decreased. However, the magnitude of these changes through a shock is many times greater than the magnitude of these changes through a Mach line.

The difference in the magnitude of these changes is the essential difference between a Mach line and a shock wave. Since the drag of an object is dependent upon the pressure on its surface, the drag caused by a shock is very high compared to that caused by a Mach wave on the same body. Fundamentally, a Mach wave may be thought of as a shock of negligible strength, a shock through which air undergoes the smallest pressure, temperature, and velocity changes. The magnitude of the changes in these properties is used to measure the strength of a shock. The strength of a shock is dependent upon its angle with the freestream and the freestream Mach number. Strong shocks are associated with high drag. The strongest shocks are normal shocks, so-called because they stand at right angles to the freestream. All shocks standing at an angle of less than 90° to the freestream are called oblique shocks. Figure 9 shows examples of these two general cases.

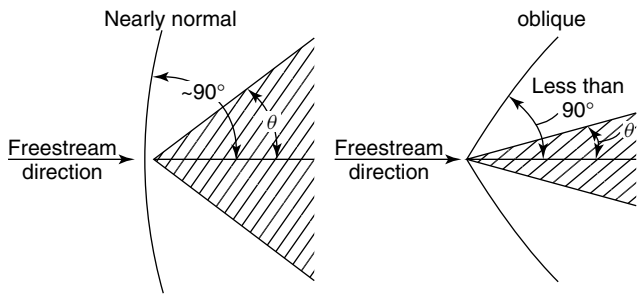

Fig. 9. Types of shock waves.

The Mach line and shock wave are compression waves. There is also the expansion wave or fan, which has characteristics opposite to the compression wave. In passing through an expansion wave, air velocity increases, while temperature and pressure are reduced. Expansion waves occur where bodies begin to narrow, making more space available for the passing air to occupy. Figure 10 illustrates a typical expansion wave. Since compression and expansion waves are opposite in nature, they tend to cancel each other when they intersect, and the shock's strength is reduced accordingly. Figure 11 shows a complete wave pattern on a double-wedge airfoil. The airfoil is at zero angle of attack. Shocks are formed at the leading and trailing edges while expansion fans occur at the surface angles or discontinuities. To obtain lift, the airfoil would have to have some finite angle of attack; the resultant wave pattern is shown in Fig. 12.

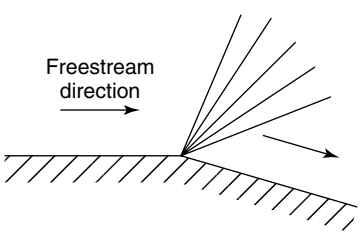

Fig. 10. Expansion wave.

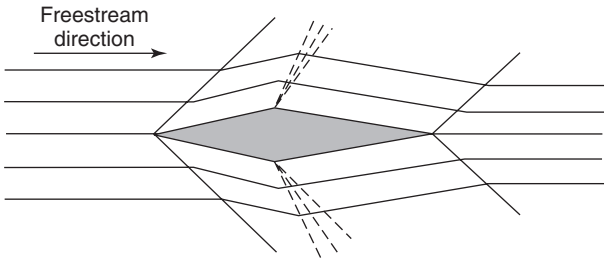

Fig. 11. Wave pattern on double-wedge airfoil where angle of attack is zero degrees.

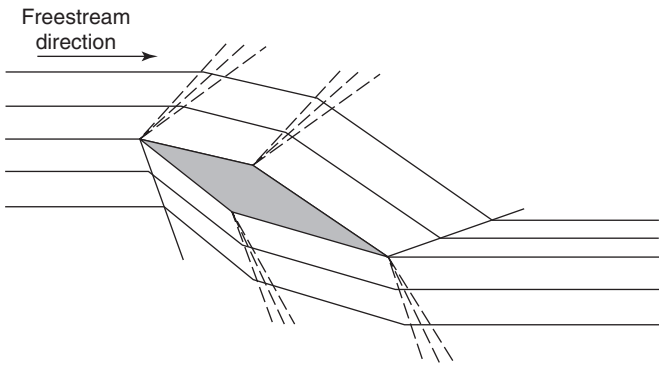

Fig. 12. Wave pattern on a double-wedge airfoil at angle of attack.

The oblique shocks at the upper surface of the nose and lower surface of the rail are replaced by expansion fans in Fig. 12. This is a graphic illustration of the effect of slope change on wave formation. In one case, the air is pushed away to allow the airfoil to pass; in the other, the air has room to expand after passing over the airfoil nose, but undergoes high compression at the lower surface nose.

Airfoil Characteristics. The double-wedge airfoil used to illustrate wave patterns is convenient to study because the flow changes in direction only at four definite points. Another typical airfoil section might be as shown in Fig. 13. Here there are leading- and trailing-edge shocks, but the expansion is continuous over the entire surface between. The expansion waves intersect the leading-edge shock and progressively weaken it, thus making it a curved shock. The local pressure coefficient along the chord is plotted as a part of Fig. 13. The pressure coefficient is proportional to the local slope. The local slope is influenced by airfoil shape and angle of attack as well as by freestream Mach number. The upper and lower surfaces produce about equal amounts of lifting pressure. This represents a departure from the subsonic case where most of the lifting pressure comes from the upper surface.

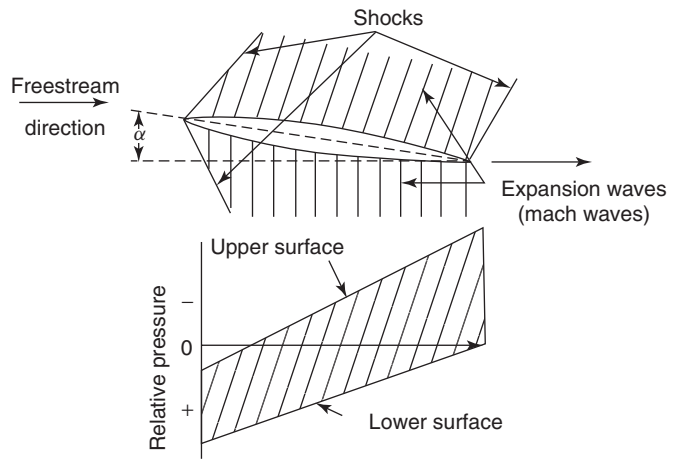

Fig. 13. Pressure distribution of an airfoil.

For supersonic airfoils, the center of pressure is very close to the half-chord point. This is a marked departure from the quarter-chord location of the center of pressure in subsonic flight.

The lift coefficient for supersonic airfoils of infinite span at moderate angle of attack and Mach number is

$$C_L = \frac{4\alpha}{\sqrt{M^2 - 1}}$$

where C_L = lift coeffieient
α = wing angle of attack, radians
M = freestream Mach number

The expression for lift $(C_L(\rho V^2/2)S)$ is still applicable, and

$$L = \left(\frac{4\alpha}{\sqrt{M^2 - 1}}\right)\left(\frac{\rho V^2}{2}S\right) = \frac{2\alpha\rho V^2 S}{\sqrt{M^2 - 1}}$$

where V = velocity, feet per second.
S = wing area, square feet.
$\frac{\rho V^2}{2}$ = dynamic pressure, pounds per square foot (ρ = air density in slugs per cubic foot).

The drag coefficient of airfoils in supersonic flight is composed of several equally important parts. These are pressure drag, friction drag, and drag due to lift. Pressure drag is the drag due to pressure distribution over the wing at the angle of zero lift and does not vary appreciably. It is also referred to as wave drag, and is similar to subsonic form drag. The approximately pressure drag coefficient is

$$C_D = \frac{5.33(t/c)}{\sqrt{M^2 - 1}}$$

where C_D = drag coefficient
t/c = thickness ratio

The pressure drag coefficient increases with increasing wing thickness and decreases with increasing Mach number. Consequently, supersonic airfoils are thin sections.

Friction drag results from the viscosity of the air. This tendency of the air to cling to a surface and to itself is felt with supersonic flow just as with subsonic.

Drag due to lift is the component of the resultant pressure force, which acts in the drag direction. It too has an exact counterpart in subsonic flow. Drag due to lift is

$$C_D = \frac{4\alpha^2}{\sqrt{M^2 - 1}}$$

The term induced drag used for subsonic flow is not applied to supersonic drags. Induced drag in the subsonic case is due to tip losses. Tip losses occur in supersonic flow, but not in the same proportions as in subsonic flow.

Wing (Finite Span) Characteristics. It should be recalled that in subsonic flow, a wing of finite span experiences a three-dimensional flow which includes tip vortices, a downwash field, and induced velocities locally along the wing surface. See also **Aerodynamics and Aerostatics**. This is not true in supersonic flow. In Fig. 14, note that the pressure along the wing between the tip Mach cones is the same as for an airfoil of infinite length. Vortices produced within the tip Mach cones reduce the pressure from the airfoil value to zero at the tip, with the average lifting pressure in the tip region one-half the airfoil value. With a low aspect ratio, the absence of any airfoil circulation, as in subsonic flow, results in a marked decrease in wing average lifting pressure, and lift coefficient.

The supersonic drag due to lift depends upon the airfoil and angle of attack, while the subsonic induced drag is a function of lift coefficient and aspect ratio.

If a wing with a planform other than rectangular is used, tip losses can be eliminated. The delta, or triangular, wing planform accomplishes this and can be illustrated by the two possible pressure patterns over a delta

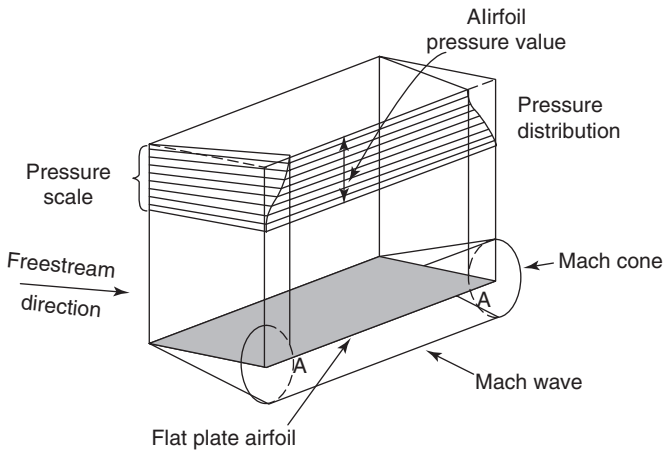

Fig. 14. Supersonic pressure distribution on a rectangular wing.

wing, depending on the relationship between freestream Mach number and wing leading-edge sweep.

In this case (Fig. 15), the components of velocity perpendicular to the leading edge are subsonic, even though the freestream flow is supersonic. The lifting pressure is maximum along the leading edge and decreases rapidly toward the center of the wing. The average lift coefficient is less than would be obtained by a similar airfoil in subsonic flow.

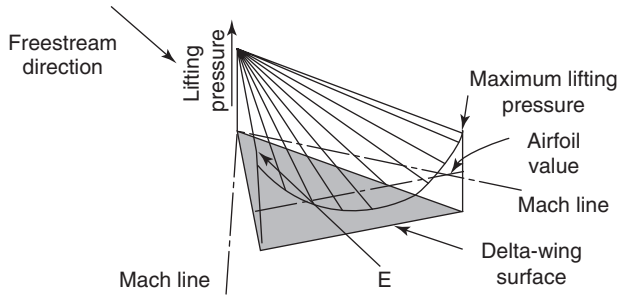

Fig. 15. Pressure distribution on a delta wing (leading edge inside the Mach line).

In the other pattern, the wing leading edge lies ahead of the tip Mach cone. Figure 16 illustrates that the highest lifting pressure still exists along the wing leading edge. In this case, however, the lifting pressure remains constant at this peak value in the region between the leading edge and the Mach cone. Inside the Mach cone, the lifting pressure again decreases, but the wing's average lift coefficient is as high as can be obtained with an airfoil of a similar cross section. When the leading edge is outside, the pressure drag coefficient is lower than airfoil pressure drag. Wing pressure drag reaches a maximum when the Mach cone lies along the leading edge.

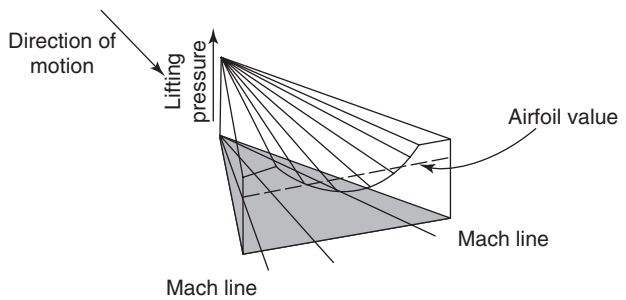

Fig. 16. Pressure distribution on a delta wing (leading edge outside the Mach line).

Consider the effects of modifying the delta planform. If area is added at the trailing edge to make a diamond planform, it is being added where the local lift coefficient is low. In this case, the average wing lift coefficient is less than that obtainable with a delta planform. Conversely, cutting out area to given an arrow planform will increase the average lift coefficient.

Body Characteristics. This discussion pertains only to bodies of revolution. A body of revolution is one whose cross section perpendicular to its longitudinal axis is always circular (Fig. 17). Airplane fuselages are generally as near circular in cross section as volume requirements will permit. Studies and tests indicate that a parabolic longitudinal shape is desirable. The pressure distribution on a body of revolution at zero angle of attack shows a positive value at the nose lower than for an airfoil of the same "seminose angle." See Fig. 17. Following this, the air finds more room in which to expand than in the case of the airfoil; it can fill the "ring" all around the body. The pressure drops so rapidly that the pressure coefficient returns to zero before the body slope has returned to zero, i.e., before the body contour becomes parallel to the longitudinal axis of the body.

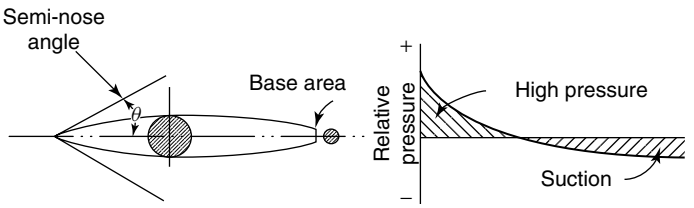

Fig. 17. Pressure distribution on a body of revolution.

The expansion continues over the aft part of the body and the pressure coefficient becomes more negative. However, the largest negative value of the pressure coefficient is limited by the occurrences of a complete expansion to a vacuum. Usually, the positive pressure coefficient at the nose is larger than this maximum negative value.

The pressure drag of bodies of revolution depends upon their shape, angle of attack, and flight Mach number. Angles of attack other than zero usually do not cause a large drag increase, nor will they cause the body to produce much lift. Drag force increases with increasing Mach number just as does wing lift force. Body shape has a strong influence on body drag. The longitudinal lines should be parabolic; the exact equation of the lines is a function of Mach number. A good fineness ratio for low drag is a length to maximum diameter ratio of 8 to 12. Many bodies are designed so that the pressure drag coefficient reaches its peak at very low supersonic Mach numbers, then drops rapidly until it begins to approach a minimum value at about Mach 2. The center of pressure of such bodies will be close to the half-length point if the tail is pointed. As base area increases, the center of pressure moves forward.

Wing-Body Combinations. In consideration of subsonic drag, it is apparent that a factor is interference drag, resulting from the effect of angles between surfaces, such as wing and fuselage. This drag is reduced by the use of smooth fairings, thus avoiding sharp corners — in effect it is corrected "locally" at the point it occurs.

In supersonic airplanes, the interference problem is much more critical and cannot be solved locally. It has been stated that the ideal streamline shape is a body of revolution having a longitudinal parabolic curve, that is, if the cross-sectional areas of the ideal body, taken at even increments along its axis, were plotted, the result would be a parabolic curve. Studies in the supersonic area indicate that in supersonic aircraft, the parabolic cross-sectional area distribution from nose to tail must be based on the complete airplane cross section, not just the fuselage cross section. The so-called "Coke-bottle" shape of the fuselage of some supersonic airplanes is the result of the application of this principle.

Supersonic Stability and Control. The analysis of the stability and control characteristics of an airplane capable of flight at supersonic speeds is essentially the same as that used for subsonic aircraft. A supersonic airplane must be statically and dynamically stable; it must have a control system that gives the pilot accurate, safe control of the airplane throughout its flight regime. However, the magnitude of control forces and moments

and the changes in these forces and moments resulting from a displacement of the airplane about one or more of the stability axes are much greater at supersonic speeds than at subsonic speeds. Consequently, supersonic airplanes have power control systems to enable the pilot to move the control surfaces. The power control systems used on these aircraft can be designed so that the pilot has the same stick feel for a maneuver of given severity at all speeds despite the variation of control force with speed changes. In general, these airplanes also need 3-axis stability-augmentation systems to provide satisfactory dynamic stability.

Aerodynamic Heating. This results from the conversion of kinetic energy to thermal energy. At the surface of an aircraft, the air is slowed to zero velocity. This means that freestream kinetic energy has been converted to thermal energy. The resultant stagnation temperature is a function of freestream temperature and Mach number. Most of the aircraft surface does not reach this stagnation temperature because the conversion of kinetic energy to thermal energy is not 100% efficient. The maximum resultant skin temperature, known as adiabatic wall temperature, is 85 to 95% as high as the stagnation temperature. Radiation reduces skin temperature to less than adiabatic wall temperature; this effect increases as altitude and Mach number increase. Adiabatic wall temperature minus heat loss to radiation gives equilibrium temperature; this is the temperature to which an aircraft is designed. Typical stagnation temperatures are about 260 °F (127 °C) at Mach 2.0; and 1,550 °F (843 °C) at Mach 5. These temperatures serve to explain the structural and airconditioning problems involved in the design of supersonic airplanes.

Noise and Supersonic "Boom." The high-thrust jet engines used to power modern aircraft produce a sound level that tends to exceed human tolerance. Users of these aircraft equip their ground crews and mechanics with ear plugs to prevent physical and mental damage due to this noise. In addition to their effect on people, these sounds, or pressure waves, must be considered in the design of any part of the aircraft on which they impinge.

Supersonic flight is sufficiently commonplace to the public, but an associated phenomenon, known as the sonic boom or supersonic bang, has not met with the same public acceptance. A boom will occur whenever a shock wave (pressure wave) emanating from an aircraft flying supersonically reaches an observer. According to the water-wave analogy given earlier, a supersonic boom is similar to a water wave moving past a floating leaf and causing the leaf to bob up and down.

There are many shocks emanating from an aircraft flying supersonically, but these usually interact and coalesce to form two main shocks — one from the nose and one from the aft end of the aircraft. For this reason, the shape of an aircraft has little or no influence on the number of shocks reaching an observer. The bow and tail shock waves gradually diverge as they extend outward from the aircraft. This divergence is due to a slight difference in propagation velocities of the two waves. The observer will hear two bangs or booms if the time interval between the passing of the two waves is of the order of 0.10 second or greater. If this time interval is much less than this figure, as would be experienced during a low-level pass of a small aircraft, the ear could not discriminate between the two shock waves and would hear only one.

The loudness of the boom is a function of the distance between airplane flight path and observer, Mach number, aircraft size and shape, atmospheric pressure, temperature, and winds. The factor having the strongest influence on loudness is the distance between observer and airplane flight path. The loudness, as an increase in pressure above atmospheric, is inversely proportional to the three-quarter power of this distance.

Atmospheric temperature and wind gradients cause a bending or refraction of shock waves. Other atmospheric conditions, such as clouds, cause a diffusion of the waves. Hence in some cases the shockwave pattern from the airplane may become so distorted and attenuated that the bang is not even heard on the ground. Prediction of these effects under actual flight conditions is extremely difficult, though by precise control of airplane speed and flight path, shock waves may be focused at a point in space or on the ground. Such conditions can produce a supersonic boom on the order of ten times the normal intensity.

Several means of avoiding sonic boom from all causes have been tested. One, based on extremely accurate prediction of temperature and wind at the time of take-off, would adjust the angle of climb for subsonic speed. A two-degree error in temperature prediction, however, could negate a good plan and possibly the resultant noise would be worse than were no effort made to control it. Changing the climb angle, of course, also could adversely affect engine performance and fuel consumption. Another method advocates deceleration to subsonic speed before descent from cruise level, solving only one phase of the problem. Another plan embraces routing supersonic aircraft over unpopulated areas. Flying at greater altitudes is an alternative. However, the result of higher altitudes might decrease the intensity of the shock wave at the ground, but it would also spread the area affected. As of the early 1980s, the best approach appears to be a combination of very careful operational control at low altitudes and cruise altitudes sufficiently high to prevent or reduce the intensity effect of shock waves reaching the ground.

SUPERVISORY CONTROL. In control system terminology, a control action in which the control loops operate independently, subject to intermittent corrective action, e.g., setpoint changes from an external source. Generally, a supervisory control system is assumed to incorporate a computer that provides broad, possibly relatively infrequent commands to a control system. The latter continues to perform its usual control functions during those periods between commands provided by the supervisory computer. In this sense, supervisory control is superimposed over the fundamental, second-to-second control system. A supervisory control computer thus replaces or assists the human operator in making periodic adjustments to a control system in an effort to better realize process objectives. The computer in a supervisory control system decides according to the information it receives, assisted by certain programmed calculations or logic procedures, what adjustments in the control system should be made. Where the computer is completely *off-time*, the human operator will make the control adjustments manually based upon the computer inputs he receives. In other configurations, the computer may be interconnected with the process control system on a periodic or continuous basis. There are several shades of difference between a purely off-line and a purely on-line situation.

SUPPLY CURRENT. The electrical current in the atmosphere that is required to balance the observed air-earth current of fair-weather regions by transporting positive charge upward or negative charge downward. Accounting for the supply current has been for many years a key problem of the field of atmospheric electricity and has received much attention. A quasi-steady current of about 1800 A for the earth as a whole is estimated to be required to balance the air–earth current. Wilson (1920) suggested that the thunderstorms present in widely scattered regions of the earth at any one time might be responsible for the supply current. Although this suggestion has not been fully confirmed, there is growing conviction that this is correct. When one considers an average over many storms, thunderstorm lightning transports negative charge downward to earth, as does point discharge in the regions below thunderstorms. Also, positive ions flow upward above active thunderstorms. See also **Air-Earth Conduction Current**; **Fronts and Storms**; and **Point Discharge Current**.

SUPPRESSOR (Electrical Noise). An element or device used in electric or electronic components or circuits to prevent or reduce undesired actions or currents. See also **Static and Noise**.

SUPPURATION. The formation and/or discharge of pus (leukocytes, serum, microorganisms, and necrotic debris) — as from a pustule (abscess, bubo, pimple, or other type of sore).

SURFACE. The locus of points satisfying an equation in three variables $f(x, y, z) = 0$. If u, v are parameters, the equation $x = \phi_1(u, v)$, $y = \phi_2(u, v)$, $z = \phi_3(u, v)$ are often useful. Figures which lie on the surface of a plane are studied in plane geometry. They include triangles, quadrilaterals, polygons, and circles. The differential properties of surfaces are a generalization of those that occur for plane and space curves but they become fairly complicated. They can be studied by means of differential calculus and differential geometry but tensor methods are especially suitable. A ruled surface is one that can be generated by the motion of a straight line called the generatrix. Any quadric surface can be produced in this way but the generatrix is real only for the cone, cylinder, hyperboloid of one sheet, and the hyperbolic paraboloid. In the other possible cases, the generatrix is imaginary. A surface of revolution results when a plane curve is revolved about a line lying in its plane. Special cases of each of the quadric surfaces may also be produced in this way.

Properly one should distinguish between a surface and a solid but often, for example, a sphere and a spherical surface are considered to be the same mathematical concept.

SURFACE CHART. See **Meteorology**.

SURFACE CHEMISTRY. This article deals with the behavior of matter, where such behavior is determined largely by forces acting at surfaces. Since only condensed phases, i.e., liquids and solids, have surfaces, studies in surface chemistry require that at least one condensed phase be present in the system under consideration. The condensed phase may be of any size ranging from colloidal dimensions to a mass as large as an ocean. Interactions between solids, immiscible liquids, liquids and solids, gases and liquids, gases and solids, and different gases on a surface fall within the province of surface chemistry.

Surface forces determine whether one material will wet and spread on a substrate, e.g., whether a liquid will wet a solid and spread into crevices and pores to displace air. This seemingly simple phenomenon is of cardinal importance in determining the strength of adhesive joints and of reinforced plastics; it establishes the printing and writing qualities of inks; lubricants will wet and spread over entire surfaces or be confined to limited working areas depending upon built-in wetting or nonwetting properties; ores are floated if the surrounding liquid is readily displaced by air bubbles; the dispersion of pigments in paints depends upon wetting of the individual particles by the liquid; the action of a foam breaker frequently depends upon its ability to spread on the foam; secondary oil recovery often involves displacement of oil from sand by water; wetting is also a factor in detergency; water and soil repellancy depend upon nonwetting.

Wetting or nonwetting often depends upon the adsorption of a solute at a surface or interface. The bulk liquid phase either advances or recedes, depending upon the nature of the solute and the condensed phase. However, there are many phenomena where adsorption is essential to the process but wetting is not a factor. For example, toxic gases and cigarette tars are removed by adsorption on suitable substrates; color bodies are removed from vegetable oils by adsorption on activated clays; heterogeneous catalysis requires the adsorption of reactants on the catalytic surface; dyeing of fabrics is an adsorption process; dispersions and emulsions are stabilized by the adsorption of suitable solutes and flocculated by the adsorption of other solutes; foaming depends upon adsorption; chromatography is a preferential adsorption process; the action of many corrosion inhibitors depends upon their adsorption on metal surfaces.

The spreading of an insoluble monolayer is a process analogous to adsorption with a number of specialized applications. Thus, cetyl alcohol is spread as a monoloayer on reservoirs to retard the evaporation of water. Some antifoaming agents act by spreading as monolayers.

Because of the widespread applications of surface chemistry, practically all industries, knowingly or otherwise, make use of the principles of surface chemistry.

Surface forces are merely an extension of the forces acting within the body of a material. A molecule in the center of a liquid drop is attracted equally from all sides, while at the surface the attractive forces acting between adjacent molecules results in a net attraction into the bulk phase in a direction normal to the surface. Because of unbalanced attraction at the surface, the tendency is for these molecules to be pulled from the surface into the interior, and for the surface to shrink to the smallest area that can enclose the liquid. The work required to expand a surface by 1 sq cm in opposition to these attractive forces is called the surface tension.

This concept applies equally well to solids. Molecules in a solid surface are also in an unbalanced attractive field and possess a surface tension or surface free energy. While the surface tension of a liquid is easily measured, this is much more difficult to do for a solid, since to increase the surface extraneous work must be done to deform the solid.

In the case of solid or liquid solutions it is frequently observed that one component of the solution is present at a greater concentration in the surface region than in the bulk of the solution. Thus, for an ethanol-water system, the surface region will contain an excess of ethanol. The concentration of water will be higher at the surface than in the bulk, if the solute is sulfuric acid. Molybdenum oxide dissolved in glass will concentrate at the surface of the glass. The concentrating of solute molecules at a surface is called adsorption.

If a clean solid is exposed to the atmosphere, molecules of one or more species present in the atmosphere will deposit on the surface. If the clean solid is immersed in a solution, molecules of one or another species present in the solution will be apt to concentrate at the solid-liquid interface. These phenomena are also referred to as *adsorption*.

All adsorption processes result from the attraction between like and unlike molecules. For the ethanol-water example given above, the attraction between water molecules is greater than between molecules of water and ethanol. As a consequence, there is a tendency for the ethanol molecules to be expelled from the bulk of the solution and to concentrate at the surface. This tendency increases with the hydrocarbon chain-length of the alcohol. Gas molecules adsorb on a solid surface because of the attraction between unlike molecules. The attraction between like and unlike molecules arises from a variety of intermolecular forces. London dispersion forces exist in all types of matter and always act as an attractive force between adjacent atoms and molecules, no matter how dissimilar they are. Many other attractive forces depend upon the specific chemical nature of the neighboring molecules. These include dipole interactions, the hydrogen bond and the metallic bond.

There is an additional explanation for the tendency of a solute such as ethanol to concentrate at the surface of a liquid, which originates with Langmuir. According to his "principle of independent surface action" each portion of a molecule behaves independently of other portions of the molecule in its attraction to other molecules or functional groups on a molecule. The attraction between the CH_3CH_2 portion of the ethanol molecule and water arises from relatively weak London dispersion forces, as compared with the additional attraction of strong hydrogen-bonding forces acting between the hydroxyl group of the alcohol and water. Hydrogen bonding is also responsible for the strong attraction between water molecules. As a consequence, not only is the alcohol concentrated at the surface, it is also oriented with the hydroxyl group toward the water and the hydrocarbon chain directed outward. Since the attraction between adjacent hydrocarbon molecules is less than that between adjacent water molecules, hydrocarbon liquids have lower surface tensions than water, and the surface tension of an aqueous alcohol solution is intermediate between that of liquid hydrocarbons and water.

As noted earlier, the phenomenon of adsorption is encountered in diverse applications. Medical applications are often the most complex and the least understood. For example, replacement hearts and kidney machines require plastics that can be kept in contact with human blood for long periods of time. However, foreign material in contact with blood results in clotting. The material first becomes coated with adsorbed protein. Some time later the clotting process begins, apparently due to activation of the Hageman factor, one of the proteins in blood, at the blood-material interface. The activation initiates a chain reaction that results in the conversion of

fibrinogen to fibrin. It has been suggested that the Hageman factor is helical in form and that adsorption results in an unfolding of the protein helix with exposure of certain active sites which then initiate the clotting of blood. Other proteins are also adsorbed and their biological function may be altered, but little is known about this.

The ideal surface for contact with human blood is the surface of blood vessels, and the immediate surface contains heparinoid complexes. Heparin, a negatively charged polysaccharide, has been bonded to silicon rubber and other polymers. In one procedure, a quaternary ammonium compound is first adsorbed on the polymer substrate and heparin is in turn adsorbed on the positively charged surface. Chemical bonding of heparin has also been achieved. Such surfaces do not cause clotting of contacted blood.

As noted earlier, the phenomenon of adsorption is encountered in such diverse applications as the separation of components in chromatography, the removal of toxic gases by activated charcoal, heterogeneous catalytic reactions and the dyeing of fabrics. The surface area of solids is most commonly determined by the adsorption of nitrogen on the surface of the solid at $-915\,^{\circ}\mathrm{C}$. Nitrogen is assigned an area of 16.2 $\mathrm{\AA}^2$ per molecule. The method is due to Brunauer, Emmett and Teller and is referred to as the BET method for determining surface area.

The fundamental adsorption equation is due to Gibbs. In the case of a solution containing a single solute,

$$\Gamma = \frac{1}{RT}\left(\frac{\partial \dot{\gamma}}{\partial \ln a}\right)_T$$

where Γ is the excess of solute at the surface as compared with the concentration of solute in the bulk liquid expressed in moles per sq cm, R is the gas constant, T is the absolute temperature γ is the surface tension of the solution, and a is the activity of the solute. Where the solution is sufficiently dilute, the concentration of the solute may be substituted for its activity.

The equation also applies to the adsorption of a gas on a solid. At low gas pressures, p, the equilibrium pressure of the gas can be substituted for a, the activity of the solute. The amount of gas adsorbed v/V is equivalent to the surface excess γ, where v is equal to the volume of gas adsorbed per gram of solid and V is the molar volume of the gas. The total free energy change at constant pressure is $\Sigma\delta\gamma$, where Σ is the area per gram of solid.

When a drop of liquid is placed on the surface of a solid, it may spread to cover the entire surface, or it may remain as a stable drop on the solid. There is a solid-liquid interface between the two phases. In the case of liquids that do not spread on the solid, the bare surface of the solid adsorbs the vapor of the liquid until the fugacity of the adsorbed material is equal to that of the vapor and the liquid.

The equation relating contact angle to surface tension, generally ascribed to Young or Dupre, is

$$\gamma_{\mathrm{Se}} = \gamma_{\mathrm{SL}} + \gamma_{\mathrm{L}}\cos\theta$$

where γ_{Se} is the surface tension of the solid covered with adsorbed vapor, γ_{SL} is the solid-liquid interfacial tension, γ_{L} is the surface tension of the liquid and θ is the contact angle.

As a general rule, organic liquids and aqueous solutions will spread on high-energy surfaces, such as the clean surfaces of metals and oxides. The rule has a number of exceptions. For one, certain organic liquids will deposit a low-energy film by adsorption on higher-energy surfaces over which the bulk liquid will not spread.

Zisman discovered that there is a critical surface tension characteristic of low-energy solids, such as plastics and waxes. Liquids that have a lower surface tension than the solid will spread on that solid, while liquids with a higher surface tension will not spread. Examples of critical surface tension values for plastic solids in dynes per cm are: "Teflon," 18; polyethylene, 31; polyethylene terephthalate, 43; and nylon, 42–46. As one indication of the way this information can be used in practical applications, one can consider the bonding of nylon to polyethylene. If nylon were applied as a melt to polyethylene, it would not wet the lower-energy polyethylene surface and adhesion would be poor. However, molten polyethylene would spread readily over solid nylon to provide a strong bond.

There are a large number of materials that exhibit a pronounced tendency to concentrate at surfaces and interfaces and thus alter the surface properties of matter. These materials are called surface-active agents or surfactants. Depending upon the manner in which they are used or the purpose they serve in specific applications, they may be referred to as detergents, emulsifying agents, foaming agents or foam stabilizers, antibacterial agents, fabric softeners, flotation reagents, antistatic agents, corrosion inhibitors, or by other names. There are two general ways of classifying surfactants. According to solubility, they are classified as water or oil soluble. The other classification is according to change type. Those that do not ionize are called nonionic surfactants. If they ionize and the surface-active ion is anionic, the material is an anionic surfactant. If the surface-active ion carries a positive charge, it is called a cationic surfactant.

Only molecules with certain specific types of configurations exhibit surface activity. In general, these molecules are composed of two segregated portions, one of which has low affinity for the solvent and tends to be rejected by the solvent. The other portion has sufficient affinity for the solvent to bring the entire molecule into solution. Water-soluble soaps are probably the oldest surfactants. The long hydrocarbon chain has a low affinity for water and is referred to as the hydrophobic or nonpolar portion of the molecule. The carboxylate group has a high affinity for water and is called the hydrophilic or polar portion.

SURFACE GRAVITY WAVE. A wave that propagates, typically, on the surface of water under the influence of buoyancy forces. In water of uniform depth H, the dispersion relationship is given by squared frequency

$$\omega^2 = gk\tanh(kH),$$

in which k is the wavenumber and g is the acceleration of gravity. In shallow water, when the wavelength is much larger than the fluid depth, the waves are nondispersive; the dispersion relationship is then

$$\omega = ck,$$

in which phase speed $c = (gH)^{\frac{1}{2}}$. In deep water the waves have the dispersion relationship

$$\omega = \pm(gH)^{1/2}.$$

SURFACE OF CONSTANT PHASE. If a solution to any wave equation has a time-harmonic (sinusoidal) solution (exact or approximate) of the form

$$Ae^{i\phi}$$

where the amplitude A and phase φ are functions of position, the equation

$$\phi(x, y, z) = \text{constant}$$

defines a surface of constant phase.

If A is a scalar, the equation

$$A(x, y, z) = \text{constant}$$

defines a surface of constant amplitude.

SURFACE (of Revolution). A surface which may be generated by rotating a plane curve about an axis in its plane. Sections of the surface perpendicular to the axis are circles called *parallel circles*, or *parallels*, or *lines of latitude*. Sections of the surface by planes containing the axis are called *meridan sections*, or *meridians*, or *lines of longitude*.

See also **Conic Section**.

SURFACE TENSION. Fluid surfaces exhibit certain features resembling the properties of a stretched elastic membrane; hence the term surface tension. Thus, one may lay a needle or a safety-razor blade upon the surface of water, and it will lie at rest in a shallow depression caused by its weight, much as if it were on a rubber air-cushion. A soap bubble, likewise, tends to contract, and actually creates a pressure inside, somewhat after the manner of a rubber balloon. The analogy is imperfect, however, since the tension in the rubber increases with the radius of the balloon, and the pressure inside, which would otherwise decrease, remains approximately constant; while the liquid "film tension" remains constant and the pressure in the bubble falls off as the bubble is blown.

Surface tension results from the tendency of a liquid surface to contract. It is given by the tension σ across a unit length of a line on the surface of the liquid. The surface tension of a liquid depends on the temperature; it diminishes as temperature increases and becomes 0 at the critical temperature. For water σ is 0.073 newtons/meter at 20 °C, and for mercury, it is 0.47 newtons/meter at 18 °C.

Surface tension is intimately connected with capillarity, that is, rise or depression of liquid inside a tube of small bore when the tube is dipped into the liquid. Another factor related to this phenomenon is the angle of contact. If a liquid is in contact with a solid and with air along a line, the angle θ between the solid-liquid interface and the liquid-air interface is called the angle of contact. See Fig. 1. If $\theta = 0$, the liquid is said to wet the tube thoroughly. If θ is less than 90°, the liquid rises in the capillary; and if more than 90°, the liquid does not wet the solid, but is depressed in the tube. For mercury on glass, the angle of contact is 140°, so that mercury is depressed when a glass capillary is dipped into mercury. The rise h of the liquid in the capillary is given by $h = 2\sigma \cos\theta / r\rho g$, where r is the radius of the tube, ρ the density of the liquid, and g is the acceleration due to gravity.

Surface tension can be explained on the basis of molecular theory. If the surface area of liquid is expanded, some of the molecules inside the liquid rise to the surface. Because a molecule inside a mass of liquid is under the forces of the surrounding molecules, while a molecule on the surface is only partly surrounded by other molecules, work is necessary to bring molecules from the inside to the surface. This indicates that force must be applied along the surface in order to increase the area of the surface. This force appears as tension on the surface and when expressed as tension per unit length of a line lying on the surface, it is called the surface tension of the liquid.

The molecular theory of surface tension was dealt with by Laplace (1749–1827). But, as a result of the clarification of the nature of intermolecular forces by quantum mechanics and of the more recent developments in the study of molecular distribution in liquids, the nature and value of surface tension have been better understood from a molecular viewpoint. Surface tension is closely associated with a sudden, but continuous change in the density from the value for bulk liquid to the value for the gaseous state in traversing the surface. See Fig. 2. As a result of this inhomogeneity, the stress across a strip parallel to the boundary — ρ_N per unit area — is different from that across a strip perpendicular to the boundary — ρ_T per unit area. This is in contrast with the case of homogeneous fluid in which the stress across any elementary plane has the same value regardless of the direction of the plane.

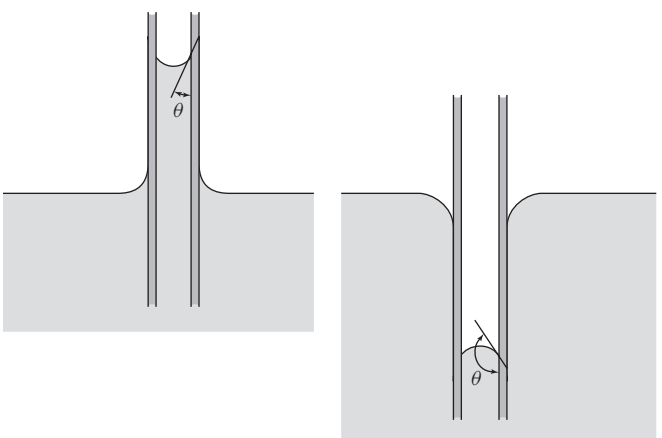

Fig. 1. Interrelationship between surface tension and capillarity: (*Left*) Case where angle theta is less than 90° (water); (*Right*) case where angle theta is greater than 90° (mercury).

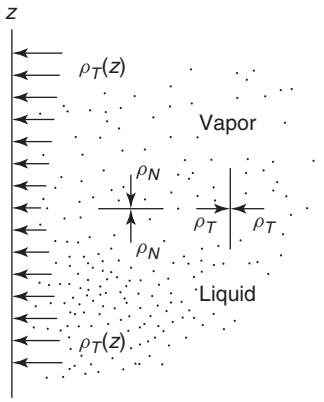

Fig. 2. Stress relationships in surface tension.

The stress ρ_T is a function of the coordinate z, the z-axis being taken normal to the surface and directed from liquid to vapor. The stress ρ_N is constant throughout the liquid and the vapor. Figure 2 shows the stress ρ_N and ρ_T. The stress $\rho_T(z)$ as a function of z is also shown on the left side of the figure.

SURFACE TENSION (Gibbs Formula). The total differential of the surface tension γ in the variables temperature T, and chemical potentials μ, is

$$d\gamma = -s^a\, dT - \sum_i \Gamma_i\, d\mu_i \tag{1}$$

where s^a is the entropy per unit area of the surface phase and Γ_i the adsorption of component i.

This formula is the analog for a surface phase, of the Gibbs-Duhem equation for a bulk phase.

Another basic formula also due to Gibbs, that relates the surface tension to the thermodynamic functions of the surface phase, is

$$\gamma = A^a - \sum_i \Gamma_i \mu_i \tag{2}$$

where A^a is the Helmholtz free energy (see also **Free Energy (2)**) per unit area of the surface phase. This expression is the analog of the relation between the Gibbs free energy and the chemical potentials

$$G = \sum_i n_i \mu_i \tag{3}$$

valid for a bulk phase.

SURFACE WATER SUPPLY INDEX (SWSI). See **Drought Indices**.

SURFACE WAVE. 1. A gravity wave formed on the free surface of a fluid. In classical hydrodynamics, to distinguish surface waves from tidal waves, the condition is imposed that vertical accelerations are not negligible. Dynamically, this wave is similar to that on an interface separating two fluids, becoming identical in the case of zero density in the upper fluid.

2. A wave at the interface of a light and a much heavier fluid, in particular of the air–sea interface.

SURFACE WEATHER OBSERVATION. See **Meteorology**.

SURFACTANTS. The term surfactant, contraction of surface-active agent, is used to describe organic substances having certain characteristics in structure and properties. The term detergent is often used interchangeably with surfactant. As a designation for a substance capable of cleaning, detergent can also encompass inorganic substances when these do in fact perform a cleaning function. More often, however, detergent refers to a combination of surfactants and other substances, organic or inorganic, formulated to enhance functional performance, specifically cleaning, over that of the surfactant alone. It is so used herein.

Surfactants are characterized by the following features. Amphipathic structure: surfactant molecules are composed of groups of opposing solubility tendencies, typically an oil-soluble hydrocarbon chain and a water-soluble ionic group; solubility: a surfactant is soluble in at least one phase of a liquid system; adsorption at interfaces: at equilibrium, the concentration of a surfactant solute at a phase interface is greater than its concentration in the bulk of the solution; orientation at interfaces: surfactant molecules and ions form oriented monolayers at phase interfaces; micelle formation: surfactants form aggregates of molecules or ions called micelles when the concentration of the surfactant solute in the bulk of the solution exceeds a limiting value, the so-called critical micelle concentration (CMC), which is a fundamental characteristic of each solute–solvent system; and functional properties: surfactant solutions exhibit combinations of cleaning (detergency), foaming, wetting, emulsifying, solubilizing, and dispersing properties.

The presence of two structurally dissimilar groups within a single molecule is the most fundamental characteristic of surfactants. The surface behavior (surface activity) of the surfactant molecule is determined by the makeup of the individual groups, solubility properties, relative size, and location within the surfactant molecule.

Different designations describe the opposing groups within the surfactant molecules, e.g., hydrophobic (water hating) and hydrophilic (water liking), lipophobic (fat hating) and lipophilic (fat liking), oleophobic (fat (oil) hating) and oleophilic (fat (oil) liking), and lyophobic (solvent hating) and lyophilic (solvent liking). The terms polar and nonpolar are also used to designate water-soluble and water-insoluble groups, respectively.

Surface activity is not limited to aqueous systems; however, because water is present as the solvent phase in the overwhelming proportion of commercially important surfactant systems, its presence is assumed in much of the common terminology of industry. Thus, the water-soluble amphipathic groups are often referred to as solubilizing groups.

Surfactants are classified depending on the charge of the surface-active moiety. In anionic surfactants, this moiety carries a negative charge. In cationic surfactants, the charge is positive. In nonionic surfactants, there is no charge on the molecule, the solubilizing contribution can be supplied by side groups. Finally, in amphoteric surfactants, solubilization is provided by the presence of positive and negative charges in the molecule. In general, the hydrophobic group consists of a hydrocarbon chain containing ca 10–20 carbon atoms. The chain may be interrupted by oxygen atoms, a benzene ring, amides, esters, other functional groups, and/or double bonds. A propylene oxide hydrophobe can be considered a hydrocarbon chain in which every third methylene group is replaced by an oxygen atom. In some cases, the chain may carry substituents, most often halogens. Siloxane chains have also served as the hydrophobe in some surfactants.

Hydrophilic, solubilizing groups for anionic surfactants include carboxylates, sulfonates, sulfates, and phosphates. Cationics are solubilized by amine and ammonium groups. Ethylene oxide chains and hydroxyl groups are the solubilizing groups in nonionic surfactants. Amphoteric surfactants are solubilized by combinations of anionic and cationic solubilizing groups.

The molecular weight of surfactants may be as low as ca 200 up to the thousands for polymeric structures. A surfactant with a straight-chain C_{12}-hydrophobe and a solubilizing group is generally an effective structure. The optimum can be higher by several carbon atoms or even slightly lower than 12 depending on the nature of the polar group and the desired function of the surfactant.

In the application of surfactants, physical and use properties, precisely specified, are of primary concern. Chemical homogeneity is of little significance in practice. In fact, surfactants are generally polydisperse mixtures, such as the natural fats as precursors of fatty acid-derived surfactant structures; e.g., coconut oil contains glycerol esters of C_6–C_{18} fatty acids. Nonionic surfactants of the alcohol ethoxylate type are polydisperse not only with respect to the hydrophobe but also in the number of ethylene oxide units attached.

Commercial surfactants are complicated mixtures exceedingly difficult to separate into pure molecular species.

The usefulness of surfactants stems from the effects that they exert on the surface, interfacial, and bulk properties of their solutions and the materials their solutions come in contact with.

Anionic Surfactants

Carboxylate, sulfonate, sulfate, and phosphate are the polar, solubilizing groups found in most anionic surfactants. In dilute solutions of soft water, these groups are combined with a 12–15 carbon chain hydrophobe for best surfactant properties. In neutral or acidic media, or in the presence of heavy-metal salts, e.g., Ca, the carboxylate group loses most of its solubilizing power.

Of the cations (counterions) associated with polar groups, sodium and potassium impart water solubility, whereas calcium, barium, and magnesium promote oil solubility. Ammonium and substituted ammonium ions provide both water and oil solubility. Triethanolammonium is a commercially important example. Salts (anionic surfactants) of these ions are often used in emulsification. Higher ionic strength of the medium depresses surfactant solubility. To compensate for the loss of solubility, shorter hydrophobes are used for application in high ionic-strength media.

Nonionic Surfactants

Unlike anionic or cationic surfactants, nonionic surfactants carry no discrete charge when dissolved in aqueous media. Hydrophilicity in nonionic surfactants is provided by hydrogen bonding with water molecules. Oxygen atoms and hydroxyl groups readily form strong hydrogen bonds, whereas ester and amide groups form hydrogen bonds less readily. Hydrogen bonding provides solubilization in neutral and alkaline media. In a strongly acid environment, oxygen atoms are protonated, providing a quasi-cationic character. Each oxygen atom makes a small contribution to water solubility; more than a single oxygen atom is therefore needed to solubilize a nonionic surfactant in water. Nonionic surfactants are compatible with ionic and amphoteric surfactants. Because a polyoxyethylene group can easily be introduced by reaction of ethylene oxide with any organic molecule containing an active hydrogen atom, a wide variety of hydrophobic structures can be solubilized by ethoxylation.

Amphoteric Surfactants

Amphoteric surfactants contain both an acidic and basic hydrophilic group. Ether or hydroxyl groups may also be present to enhance the hydrophilicity of the surfactant molecule. Examples of amphoteric surfactants include amino acids and their derivatives in which the nitrogen atom tends to become protonated with decreasing pH of the solution. Amino acid salts, under these conditions, contain both a positive and a negative charge on the same molecule.

Amphoteric surfactants are generally considered specialty surfactants, however, usage has expanded significantly. They do not irritate skin and eyes, exhibit good surfactant properties over a wide pH range, and are compatible with anionic and cationic surfactants. A basic nitrogen and an acidic carboxylate group are the predominant functional groups.

Uses

Detergency, i.e., cleaning, is the primary function of household and personal products. More recently, a secondary function, such as softening in combination with detergency in laundry detergents or conditioning in combination with detergency in shampoos, has been offered as an additional product benefit. In general, products have tended toward functional specialization (Table 1).

Surfactants are widely used outside the household for a variety of cleaning and other purposes. Often the volume or cost of the surfactant consumed in industrial applications is small compared to benefit. See also **Detergents**; and **Soaps**.

TABLE 1. SURFACTANT USES

Use	Function
Household products	Cleansing, abrasion, softening, antistatic
Detergents, scouring powders, hard-surface cleaners, fabric softeners	
Personal care products	Cleansing, moisturizing, softening
Soaps, shampoos, creams	
Agriculture	
Phosphate fertilizers	Manufacturing cycle shortening and prevention of caking during storage
Spray applications of herbicides, insecticides, fungicides	Wet, disperse, suspend powdered pesticides; emulsification of pesticide solutions; promotion of wet spreading; penetration of toxicant
Building and construction	
Paving	Improve asphalt-to-gravel and sand bond (prevent stripping)
Concrete	Promote air entrainment for density, plasticity, insulating control
Elastomers and plastics	
Emulsion polymerization	Solubilization: monomer and catalyst dissolved, react in surfactant micelles; emulsification of monomers; stabilization of latexes
Foamed polymers	Introduction of air and cell size control
Latex adhesive	Promote wetting and improving bond strength
Plastic articles	Antistatic agents
Plastic coating and laminating	Wetting agents
Food and beverages	
Food-processing plants	Clean and sanitize walls, floors, processing equipment
Fruits and vegetables	Remove pesticide residues and aid in wax coating
Bakery products and ice cream	Solubilize flavor oils, control consistency, retard staling
Beverages	Solubilize flavor oils
Crystallization of sugar	Improve washing and reduce processing time
Cooking fats and oils	Prevent spattering in frying because of superheating and sudden volatization of water
Industrial cleaning	
Janitorial supplies	Detergents and sanitizers for walls, floors, windows
Miscellaneous cleaning	Detergents for railroad cars, trucks, airplanes, tunnel walls, engines, etc
Descaling	Wetting agents and corrosion inhibitors in acid cleaning of boiler tubes and heat exchangers
Soft goods	Detergents for laundry and dry cleaning
Wax strippers	Improve wetting and penetration of old finish
Leather	
Skins	Detergent and emulsifier in degreasing
Tanning	Promote wetting and penetration
Hides	Emulsifiers in fat liquoring
Dyeing	Promote wetting, penetration, level dyeing
Metals	
Concentration of ores	Wetting and foaming, i.e., collectors and frothers in ore flotation
Cutting and forming	Wetting, emulsification, lubrication, corrosion inhibition in rolling oils, cutting oils, drawing lubricants, buffing, grinding compounds
	Mold-release additives
Casting	
Rust and scale removal	Wetting, foaming, corrosion inhibition in pickling (acid cleaning) and electrolytic cleaning
Grease removal	Emulsification and wetting in emulsion cleaning preparations
Plating	Wetting and foaming in electrolytic plating baths
Mining and transporting coal and minerals	Wetting and dedusting
Paper	
Pulp treatment	Deresinification, pitch dispersion, washing
Paper machine	Defoaming, felt washing, color leveling, dispensing
Calender	Wetting and leveling in coating and coloring operations
Towels and pads	Rewetting (improve moisture absorption)
Paints and protective coating	
Pigment preparation	Flushing (promote preferential wetting by paint vehicle); dispersing and wetting of pigment during grinding
Latex paints	Emulsify oil or polymer, disperse pigment, stabilize latex, retard sedimentation and pigment separation, modify wetting and rheological properties
Waxes and polishes	Emulsify waxes, stabilize emulsions, and wet substrates in finishes for floor and automobiles; antistat
Petroleum production and products	
Drilling fluids	Emulsify oils, disperse solids, modify rheological properties of drilling-and-completion fluids for oil and gas wells
Mist drilling	Convert intrusion water to foam in air drilling; emulsify and disperse sludge and sediment in clean-out wells; modify wetting of formation at producing zone
Secondary and tertiary (enhanced) recovery	In flooding operations, release crude oil from formation surface (preferential wetting)
Refined petroleum products	As detergent, sludge dispersant, corrosion inhibitor in fuel oils and turbine oils
Textiles	
Preparation of fibers and filaments	Detergent and emulsifier in raw-wool scouring; dispersant in viscose rayon spin baths; lubricant and antistat in spinning hydrophobic filaments
Gray goods preparations	Wetting and detergency in slashing and sizing formulations; wetting and detergency in kier boiling and bleaching of cotton and carbonizing of wool; detergency in scouring piece goods; emulsification of processing oils
Dyeing and printing	Wetting, penetration, solubilization, emulsification, dye leveling, detergency, dispersion
Finishing textiles	Wetting and emulsification in finishing formulations; softening, lubricating, antistatic additives

SURGE. In electric terminology, a surge is an oscillation of relatively great magnitude set up by an electric discharge in a line or system. In meteorology, a surge is a general change in barometric pressure apparently superposed upon cyclonic and normal diurnal changes.

SURGEONFISHES *(Osteichthyes)*. Of the suborder *Acanthuroidea*, family *Acanthuridae*, the surgeonfishes are well named because of the presence of a sharp, knifelike structure on the sides of the caudal peduncle. This is located just ahead of the tail. The fisherman unless careful can receive a serious cut from this structure. There are some 100 species of herbivorous surgeonfishes, the majority of which do not exceed 20 inches (51 centimeters) in length. They are considered food fishes, but the *Acanthurus triostegus* (Indo-Pacific convict fish) has been implicated in tropical fish poisoning instances. The general food supply of the surgeonfish is algae gathered from rocks and coral. Few of the most commonly seen species (*Ctenochaetus strigosus* and *C. striatus*) do well in aquariums.

SURGE TANK OR VESSEL. A liquid-holding chamber used to adsorb irregularities in flow. A surge tank may be used in a process where the total amount of fluid flowing around the closed cycle is constant, but where the volume passing one point in the cycle varies from that at another.

SURVEYOR LUNAR MISSIONS. See **Lunar Exploration**.

SURVEYOR PROGRAM. See **Lunar Exploration**.

SUSPENSION. A system in which very small particles (solid, semisolid, or liquid) are more or less uniformly dispersed in a liquid or gaseous medium. If the particles are small enough to pass through filter membranes, the system is a colloidal suspension (or solution). Examples of solid-in-liquid suspensions are comminuted wood pulp in water, which becomes paper on filtration; the fat particles in milk; and the red corpuscles in blood. A liquid-in-gas suspension is represented by fog or by an aerosol spray. If the particles are larger than colloidal dimensions they will tend to precipitate if heavier than the suspending medium, or to agglomerate and rise to the surface if lighter. This can be prevented by incorporation of protective colloids. Polymerization is often carried out in suspension, the product being in the form of spheres or beads.

See also **Colloid System**.

SUTURE. 1. The line of union of the adjacent flat bones making up the skull. 2. The surgical sewing-up of a wound or incision. Suture material is generally classified either as absorbable or nonabsorbable. The absorbable type is often made of either plain or chromic catgut. Nonabsorbable material is silk, linen, fine wire, or strands of synthetic composition such as nylon.

A fascial suture is one fashioned of a strip of fascia which is usually removed from the thigh where it covers the external muscles. Such sutures are often described as living sutures as they act similarly to a graft. They are used principally in the repair of large herniae where the tissues are weak.

***SUZAKU* MISSION.** (formerly Astro-E2) See **Space Science Missions: Universe**.

SVEDBERG, THEODOR (1884–1971). A Swedish chemist who won the Nobel Prize in 1926. Author of *Die Methoden zur Herstellung Kolloider Losungen anorganischer Stoffe*. His work included research in colloidal chemistry, molecular size determination, and methods of electrophoresis, as well as the development of the ultracentrifuge, for separation of colloidal particles in solution. His education was in Sweden with later work done at the University of Wisconsin before returning to Uppsalla.

SWALLOW *(Aves, Passeriformes)*. An insect-eating bird with a short wide beak, long and relatively narrow wings, weak feet and legs, and usually a forked tail. The distribution of the swallows is worldwide. They constitute the well-marked family *Hirundinidae*.

The swallows' nests are built in burrows, holes in trees, and about human dwellings, hence some of the species are familiar friends. In North America the purple martin, *Progne subis*, is widely known from the large colonies that nest in bird houses year after year. Among the true swallows of this continent the barn swallow, *Hirundo erythrogaster*, is among the most beautiful and is undoubtedly the most widely known. The bank, *Riparia riparia*, cliff, *Petrochelidon albifrons*, and rough-winged, *Stelgidopteryx ruficollis*, swallows are also widely distributed and locally common, though less beautiful than the tree swallow and the western violet-green swallow, *Tachycineta thalassina*. The glossy blue and green shades of the upper parts of the last two species are very striking, but both species are found in wild areas, and are thus less familiar than those mentioned above.

SWALLOW FLOAT (or Swallow Plinger). An electronic device that can be set to float in the seas at a predetermined depth, from which it emits sounds that can be detected by appropriate devices at distances up to several miles.

SWALLOWTAIL *(Insecta, Lepidoptera)*. A large butterfly, usually with slender tails extending from the hinder angles of the hind wings. The many species of swallowtails belong to the family *Papilionidae*. They are widely distributed in the tropical and temperate zones, especially in the former where some are very beautiful and brilliantly colored. Twenty-one species occur in North America. Most of them are yellow with black markings or vice versa but the common pawpaw swallowtail of the eastern and southern states is greenish-white with black bands and some red marks. Some of our species have metallic blue or green scales on the hind wings. Although some species lack the tails, they are also called swallowtails by association with the typical forms.

SWAMP. Where the flatness of the land, the presence of impervious soils or bedrock, or abnormal amounts of plant material obstruct or entirely prevent the normal drainage of an area, an excess of moisture will accumulate to the point of saturation, and a swamp will come into existence. While most swamps are level, this is not a necessary condition, for hillside swamps are by no means uncommon, due to a constant supply of percolating groundwater which maintains the swampy condition.

Lake basins are occasionally filled with vegetation and sediment, thus becoming swamps; these are frequently referred to as muskegs, a word of American Indian origin. Swamps may be formed on the flood plains of rivers as well as upon their deltas; they are characteristic of the flat ill-drained areas of the Atlantic Coastal Plain, examples of which are the Great Dismal Swamp which covers about 2,000 square miles (5,180 square kilometers) in the states of Virginia and North Carolina, and the Everglades of Florida, covering about 4,000 square miles (10,360 square kilometers).

Coastal saltwater swamps may develop in the zone between high and low tides or extend up river estuaries; examples of these are common along the Atlantic and Gulf coasts of the United States. In certain northern latitudes swamps develop into peat bogs. Peat bogs are an important source of fuel in Northern Europe, and also serve as an interesting illustration of the

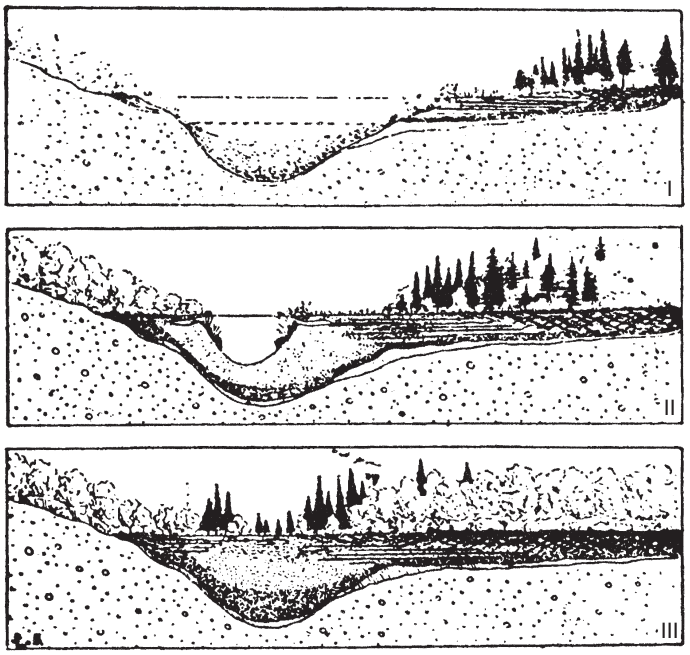

Fig. 1. Origin and development of a peat bog, illustrating the successive stages in filling of a pond by the growth of the peat bog. (*After Dachnowski*.)

origin of coal, as exemplified in the peat, lignite, bituminous coal series. Figure 1 illustrates the formation of a peat bog.

SWARTS REACTION. Fluorination of organic polyhalides with antimony trifluoride (or zinc and mercury fluorides) in the presence of a trace of a pentavalent antimony salt.

SWEEPBACK (Aircraft Wing). The acute angle between a line perpendicular to the plane of symmetry and the locus spanwise of the aerodynamic centers of the airfoils comprising the wing. For airplanes operating at subsonic speeds, sweepback may be employed to obtain the proper relationship between the center of gravity of the airplane and the aerodynamic center of the wing. For designs operating at or above sonic velocities, sweepback is employed to reduce the drag of the wing and the sweepback angle is equal to or greater than the Mach angle.

Sweepback has the same effect as incorporating a positive dihedral angle in the wing design for producing lateral stability. Since the sweepback for very high-speed aircraft is high (30 to 60 degrees) the excess lateral stability due to sweepback has to be counteracted by a negative dihedral, thereby producing a drooping or "tired" look to the wings. See also **Aerodynamics and Aerostatics**; and **Airplane**.

SWEEP CIRCUIT. A circuit utilizing the transient voltage produced in a resistor-capacitor combination which furnishes the voltage or current for deflecting the electron beam in a cathode ray tube (see also **Cathode-Ray Tube**). Figure 1a shows a simple but widely used sweep circuit. The capacitor is charged through the resistance R until the plate to cathode voltage of the thyratron reaches the breakdown value, at which time it begins to conduct and permits the capacitor to discharge very rapidly.

The voltage across the capacitor thus varies between the breakdown and extinction voltages of the thyratron. The transition from the lower to the higher value is along an exponential path determined by R, C, and E_0. The process is then repeated and the resultant voltage output is as shown. Although this circuit is free-running, i.e., does not require an external signal to produce the sweep voltage, the output voltage may be synchronized with another signal by the introduction of a synchronizing signal at the grid. Virtually the same properties are obtained from the circuit of Fig. 2 in which a unijunction transistor is employed. Capacitor C is charged through resistor R until the emitter voltage of the unijunction transistor reaches the peak point value, which results in the emitter junction becoming forward biased, with a corresponding sharp reduction in the dynamic resistance between the emitter and the base connected to the negative side of the battery. Capacitor C then discharges through this low impedance emitter-to-base path until the emitter voltage becomes so low that the emitter junction fails to conduct. At this time, charging of capacitor C resumes and the cycle is repeated. The voltage waveforms are the same as shown in Fig. 1a. The second transistor is an emitter follower used to minimize the effect of the circuit to which the sweep voltage is supplied on the operation of the unijunction transistor circuit.

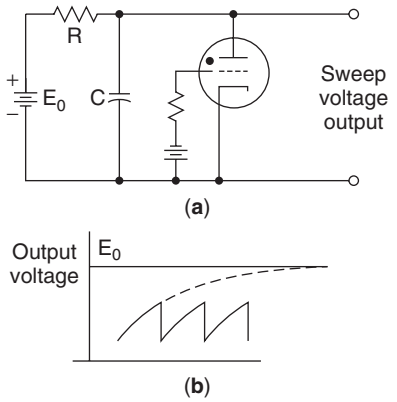

Fig. 1. (**a**) Sweep circuit using thyratron; (**b**) voltage waveform at output of a sweep circuit.

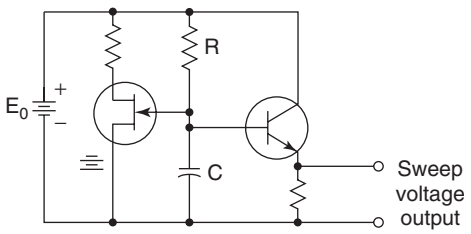

Fig. 2. Sweep circuit using unijunction transistor.

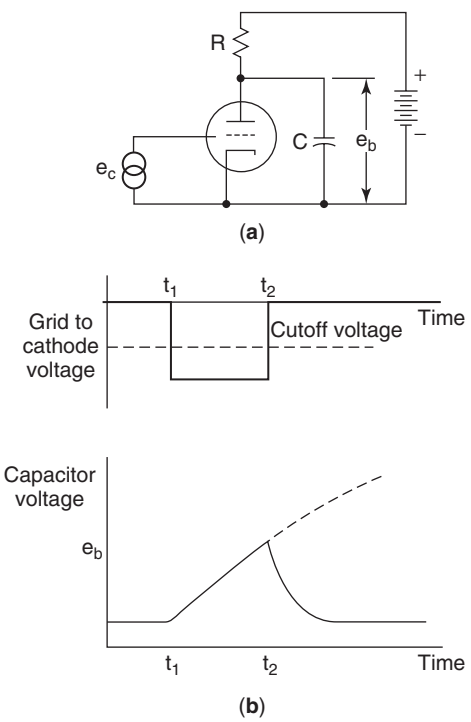

Fig. 3. (**a**) Typical sweep generator circuit; (**b**) input and output voltage waveforms for sweep circuits.

A circuit that provides a single sweep output for each input pulse is shown in Fig. 3a; the associated voltage waveforms are given in Fig. 3b. Prior to time t_1, the triode conducts at zero bias, and the voltage across capacitor C is only a small fraction of the battery voltage because of the voltage drop in the large resistor R. At time t_1, the grid to cathode voltage is made negative enough to cut off the flow of plate current. This condition is maintained until time t_2. During the interval of time that the tube is cut off, the capacitor C is charged from the battery through the resistor R. The voltage across the capacitor increases along the exponential curve associated with the transient in a resistor-capacitor circuit. Ultimately, e_b would become equal to the battery voltage. The exponential rise is not permitted to continue after time t_2, however, for when the tube is returned to zero bias at that time, the capacitor discharges through the tube and its voltage rapidly assumes the value which it had at the start of the charging process. Many refinements, including feedback, may be added to the circuit to increase the degree of linearity of the voltage change between t_1 and t_2.

SWEETENERS. Drawings in Egyptian tombs depicting beekeeping practices and honey production attest that the demand for sweet-tasting substances dates back to 2600 B.C. Sugar consumption varies considerably from one country to the next as shown in Table 1.

TABLE 1. SUGAR CONSUMPTION PER CAPITA PER YEAR[a]

Country	Refined Sugar	
	Pounds	Kilograms
Israel	150	68.0
Bulgaria	130	59.0
Australia	119	54.0
New Zealand	110	49.9
Costa Rica	108	49.0
Cuba	107	48.5
Switzerland	106	48.1
United States	102	46.3
Hungary	99	44.9
Iceland	98	44.9
Poland	95	43.1
Sweden	94	43.1
Austria	92	41.7
Czechoslovakia	92	41.7
European Economic Community	89	40.4
Norway	87	39.5

[a] *Source*: International Sugar Organization.

Sugar [CAS: 57-50-1] (sucrose) imparts a sweet taste that is quick, clean, and short lived. These desirable qualities render sugar the gold standard for sweet taste. Sugar is also an important functional ingredient for preparing attractive foods. It provides the support for bulkiness, texture, preservation, flavor, and color. However, sugar is a nutritive sweetener. It is easily metabolized, yielding an energy of ∼4 kcal/g (16.7 kJ/g), a fact welcome by some people, but disliked by others. See also **Sugar**. Furthermore, metabolism of sugar and other fermentable carbohydrates by the microorganisms in the oral cavity contributes to tooth decay. See also **Carbohydrates**. Thus, for obvious reasons, there is a strong demand for alternative sweeteners that possess all the advantages of sugar, but do not demonstrate the disadvantages. As society's attitude continues to shift toward slimness and increased health, this demand for good alternative sweeteners is expected only to intensify. Sweeteners fall into two general categories — *nutritive* and *nonnutritive*.

As of this writing (∼2006), an ideal alternative sweetener does not exist. There are, however, many sweet compounds in use, which generate less calories than sugar, albeit without all the advantages of sugar. Nonnutritive sweeteners are potently sweet in general and only minute quantities are required for sweetening foods. As such, foods containing nonnutritive sweeteners generate no or negligible calories from the sweeteners themselves, regardless of whether or not these sweeteners are caloric.

Sweetness potency (sucrose potency = 1X) denotes how many times a given compound is more potent than sugar on the same weight basis. When compared to a lower concentration of sugar solution, the sweetness potency is usually much higher than comparing with a high concentration of sugar solution. Therefore, reported sweetness potencies must be interpreted carefully, preferably with the percentage concentration of the matching sucrose solution also indicated. Because sweet beverages commonly employ ∼10% sucrose, sweetness intensity matching this sucrose solution is commonly used. Determination of sweetness potency can be greatly affected by the sensitivity and experience of tasters; other ingredients in the solution, eg, pure water versus flavored beverage; texture of the food; pH; temperature of the samples. Therefore, the published potency should be used only as a guideline and a food technologist should optimize the sweetener level in each product. The potency of major sweeteners denoted throughout this article is reported by the manufacturer, accompanying without indication of the comparative sugar solution concentration.

In addition to being both sweet and safe, a good alternative sweetener should have other qualities similar to those of sucrose. These include stability as a function of temperature and pH, clean sweet taste, quick onset, no lingering aftertaste, compatibility with other food ingredients, high water solubility, high dissolution rate, and ease of handling. It should also be nonhygroscopic, synergistic with other sweeteners, economical (same or cheaper than sugar based on sweetness equivalence), and have a high degree of consumer acceptance, eg, no perceived toxicity. Even an extremely potent sweetener must possess these qualities in order to be developed as a commercial product. Homogeneous distribution of a very potent sweetener in solid products can be a challenge for food technologists.

Nonnutritive sweeteners are highly regulated in United States and abroad. The regulation can be complex. Not only the limits in different food catagories vary, in some countries combination of nonnutritive and nutritive sweeteners is not allowed. Definition for diet, zero calories, low calories, and reduced calories also vary among different countries. Food technologists are advised to check out local sweetener regulations before formulating products for a particular country.

Blending of nonnutritive sweeteners has gained popularity in beverage and the food industry because of better taste and cost savings. A blend of sweeteners tends to impart a more rounded aftertaste with reduced shortcomings of individual sweeteners. This is referred to as qualitative synergy. A combination of sweeteners may also impart a total sweetness higher than the sum of sweetness from the respective sweeteners. This is called quantitative synergy. The most significant example of quantitative synergy is a blend of aspartame and acesulfame-K.

Nutritive Sweeteners

In addition to their sweetening power, nutritive sweeteners are effective preservatives in numerous foods. Sweeteners tie up water, essential for microorganism growth, thus preventing or inhibiting spoilage. Nutritive sweeteners also serve as food for yeasts and other fermenting agents, so important in many processes, including baking. The principal functional properties of sucrose are (1) browning reactions, (2) fermentability, (3) flavor enhancement, (4) freezing-point depression, (5) nutritive solids source, (6) osmotic pressure, (7) sweetness, (8) texture tenderizer, and (9) viscosity/bodying agent.

Among the principal *natural sugars* are fructose, glucose (also called dextrose), honey, invert sugar, lactose, maltose, raffinose and stachyose, sucrose, sugar alcohols, and xylitol.

Dextrose Equivalent. A means for comparing one sugar with another. The total amount of reducing sugars, expressed as dextrose (glucose), that is present in a given sugar syrup is calculated as a percentage of the total dry substance. More technically, the dextrose equivalent (DE) is the number of reducing ends of sugar that will react with copper. The DE can be measured in several ways.

Fructose. [CAS: 7660-25-5]. Also called *levulose* or *fruit sugar*, $C_6H_{12}O_6$. It is the sweetest of the common sugars, being from 1.1 to 2.0 times as sweet as sucrose. Fructose is generally found in fruits and honey. An apple is 4% sucrose, 6% fructose, and 1% glucose (by weight). A grape (*Vitis labrusca*) is about 2% sucrose, 8% fructose, 7% glucose, and 2% maltose (by weight) (Shallenberger). See also **Apple**; and **Grapes and Wines**. Commercially processed fructose is available as white crystals, soluble in water, alcohol, and ether, with a melting point between 103 and

105 °C (217.4 and 221 °F) (decomposition). Fructose can be derived by the hydrolysis of inulin; by the hydrolysis of beet sugar followed by lime separation; and from cornstarch by enzymic or microbial action.

Dry crystalline fructose is reported to have a sweetness level of 180 on a scale in which sucrose is represented at 100 (Andres, 1977). In cool, weak solutions and at lower pH, sweetness value is reported to be 140–150. At neutral pH or higher temperatures, the sweetness level drops, and at 50 °C (122 °F) sweetness equals that of a corresponding sucrose solution. A synergistic sweetness effect is reported between sucrose and fructose. A 40–60% fructose/sucrose mixture in a 100% water solution is sweeter than either component under comparable conditions (Unpublished report, University of Helsinki, 1972).

Glucose. [CAS: 50-99-78]. Also known as *grape sugar* or *dextrose*, this is the main compound into which other sugars and carbohydrates are converted in the human body and thus is the major sugar found in blood. Glucose is naturally present in many fruits and is the basic "repeating" unit of the starches found in many vegetables, such as potato. Purified glucose takes the form of colorless crystals or white granular powder, odorless, with a sweet taste. Soluble in water, slightly soluble in alcohol. Melting point is 146 °C (294.8 °F). Glucose finds many uses — confectionery, infant foods, brewing and winemaking, caramel coloring, baking, and canning. Glucose is derived from the hydrolysis of corn starch with acids or enzymes. Glucose is a component of invert sugar and glucose syrup. Glucose was first obtained (1974) from cellulose by enzyme hydrolysis.

Corn (maize) syrup is a sweetener derived from corn starch by a process that was first commercialized in the 1920s. Corn syrup is composed of glucose and a variety of sugars described as the "maltose series of oligosaccharides." These syrups are not as sweet as sucrose, but are very often used in conjunction with sugar in confections and other food products.

Five types of corn sweeteners are commercially available: (1) *Corn syrup* (glucose syrup), with a DE of 20 or more, is a purified and concentrated aqueous solution of mono-, di-, and oligosaccharides. High fructose corn syrup (HFCS) is prepared by enzymatically converting glucose to fructose with glucose isomerase. (2) *Maltodextrin*, concentrated solutions or dried powders of disaccharides, characterized with a DE of less than 20. The manufacturing process is similar to that of corn syrup except that the conversion process is stopped at an earlier stage. (3) *Dried corn syrup* is a granular, crystalline, or powder product, from which a portion of the water has been removed. (4) *Dextrose monohydrate* is a purified and crystallized form of D-glucose, and contains one molecule of water of crystallization per molecule of D-glucose. (5) *Dextrose anhydrous* is primarily D-glucose with no water of crystallization. See also **Syrups**.

Galactose. [CAS: 59-23-4]. A monosaccharide commonly occurring in milk sugar or lactose. Formula, $C_6H_{12}O_6$.

Honey. A natural syrup which varies in composition and flavor, depending upon the plant source from which the nectar was collected by the honeybee, the amount of processing, and the duration of storage. The principal sugars contained in honey are fructose and glucose, the same components as in table sugar. There are minute amounts of vitamins and minerals in honey, but these are not usually considered in terms of calculating minimum requirements. See also the entry on **Honey**.

Invert Sugar. A mixture of 50% glucose and 50% fructose obtained by the hydrolysis of sucrose. Invert sugar absorbs water readily, and is usually only handled as a syrup. Because of its fructose content, invert sugar is levorotatory in solution, and sweeter than sucrose. Invert sugar is often incorporated in products where loss of water must be minimized. Commercially, invert sugar is obtained from the inversion of a 96% cane sugar solution. This sugar is used in various foods, in the brewing industry, confectionery field, and in tobacco curing.

Lactose. [CAS: 63-42-3]. *Milk sugar* or *saccharum lactis*, $C_{12}H_{22}O_{11} \cdot H_2O$. Purified lactose is a white, hard, crystalline mass or white powder with a sweet taste, odorless. It is stable in air, soluble in water, insoluble in ether and chloroform, very slightly soluble in alcohol. The compound decomposes at 203.5 °C (398.3 °F). Lactose is derived from whey, by concentration and crystallization. Cow's milk contains about 5% lactose. Because of its relative lack of sweetening power, lactose is not considered a sweetener in the usual sense. It is used as a bulking agent in numerous food products. Lactose can be used effectively as a carrier for artificial sweeteners to give a free-flowing powder that is easily handled. There has been interest in the hydrolysis of lactose into glucose and galactose, both enzymatically and chemically. It has been reported that glucose and galactose are known to be sweeter than lactose itself. The relative sweetness of sugars is not a constant relationship, but depends upon many factors, including pH, temperature, and presence of other constituents. Mixtures of sugars can make a different sweetness impression than that of individual sugars alone. Synergistic sweetness often results from a combination of sugars. See also **Milk And Milk Products**.

Maltose. [CAS: 69-79-4]. Also known as *malt sugar*, maltose is a product of the fermentation of starches by enzymes or yeast. Barley malt, which is used as an adjunct in brewing, enhances the flavor and color of beer because of its maltose content. Maltose also is formed by yeast during breadmaking. Maltose is the most common reducing disaccharide, $C_{12}H_{22}O_{11} \cdot H_2O$, composed of two molecules of glucose. It is found in starch and glycogen. Purified maltose takes the form of colorless crystals, melting point, 102–103 °C (215.6–217.4 °F). Soluble in alcohol; insoluble in ether. Combustible. Maltose is used as a nutrient, sweetener, and culture medium.

Raffinose and Stachyose. These are sugars found in significant amounts in some foods, such as beans. These sugars are not digested in the stomach and upper intestine as are other disaccharides. They are fermented by bacteria in the lower digestive tract, producing gases and sometimes causing discomfort from flatulence. Raffinose is a trisaccharide composed of one molecule each of D(+)-galactose, D(+)-glucose, and D(−)-fructose, $C_{18}H_{32}O_{16} \cdot 5H_2O$. Raffinose is sometimes used in the preparation of other saccharides.

Sucrose. Table sugar, also known as *saccharose*. Sucrose is a disaccharide, composed of two simple sugars, glucose and fructose, chemically bound together, $C_{12}H_{22}O_{11}$. Hard, white, dry crystals, lumps, or powder. Sweet taste, odorless. Soluble in water; slightly soluble in alcohol. Solutions are neutral to litmus. Decomposes in range of 160–186 °C (320–366.8 °F). Combustible. Optical rotation = +33.6°. Derived from sugarcane or sugar beets and also obtainable from sorghum. Sucrose is the most abundant free sugar in the plant kingdom and has been used since antiquity (Mead and Chem, 1977).

Raw sugar, centrifugal sugar, refined sugar, and molasses are described in the entry on **Sugarcane**. *Turbinado sugar* is raw sugar that has been refined to remove impurities and most of the molasses. It is edible when produced under sanitary conditions and has a molasses flavor. *Brown sugar* consists of sucrose crystals covered with a film of molasses syrup that give the characteristic color and flavor. The sucrose content varies from 91 to 96%. *Confectioner's* or *powdered sugar* is another form of sucrose made by grinding the sugar crystals. It is usually mixed with about 3% starch to prevent clumping. It is used for household baking, canning, and table use, or industrially where rapid solution in cold liquids is desirable. See also **Sugar**.

Sugar Alcohols. These are polyols, chemically reduced carbohydrates. Important in this group are *sorbitol, mannitol, maltitol*, and *xylitol*. Xylitol is described later.

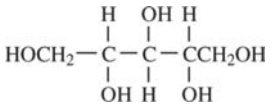
Polyols are frequently used sugar substitutes and are particularly suited to situations where their different sensory and functional properties are attractive. In addition to sweetness, some of the polyols have other useful properties. For example, although it contains the same number of calories/gram as other sweeteners, sorbitol is absorbed more slowly from the digestive tract than is sucrose. It is, therefore, useful in making foods intended for special diets. When consumed in large quantities (1–2 oz; 25059 g)/day, sorbitol can have a laxative effect, apparently because of its comparatively slow intestinal absorption.

When sugar alcohols are ingested, the body converts them first to fructose, which does not require insulin to facilitate its entry into the cells. For this reason, ingesting these sweeteners (including fructose itself) does not cause the immediate increase in blood sugar level which occurs upon eating glucose or sucrose. Within the body, however, the fructose is rapidly converted to other compounds, which *do* require insulin in their metabolism. One effect of this stepwise metabolism is to "damp out" the peaks in blood sugar levels which occur immediately after ingesting sucrose, but which are absent after ingesting fructose, even if the eventual insulin requirements are the same. Thus, individuals with metabolic

problems should not make the assumption that fruit sugars are perfectly all right to consume, but first should consult their physicians. In fact, some health scientists are dubious about pursuing the apparent claims for substituting fructose and sugar alcohols for sucrose as a major sweetener, particularly for diabetics, until more research is done on their long-range nutritional and biophysiological consequences. Research interest has also focused on these sweeteners because of their relatively low potential for causing dental caries. Studies have shown about a 30% reduction in dental caries in laboratory animals on sorbitol and mannitol diets, and virtually complete elimination of caries in the animals when on xylitol diets. See also **Sugar Alcohols**.

Xylitol. [CAS: 87-99-0]. This is a 5-carbon sugar alcohol that occurs widely in nature — raspberries, strawberries, yellow plums, cauliflower, spinach, and many other plants. Although widely distributed in nature, it is present in low concentrations and this makes it uneconomic to extract the substance directly from plants. Thus, commercial xylitol must be produced from xylan or xylose-rich precursors through the use of chemical, enzymatic, and other bioprocessing conversions. A frequently used source has been birch tree chips. Other appropriate starting materials include beech and other hardwood chips, almond and pecan shells, cottonseed hulls, straw, cornstalks (maize), and corn cobs. The base source in the aforementioned agricultural waste materials is hemicellulose xylan. The hemicellulose is acid hydrolyzed to yield xylose which, followed by hydrogenation and chromatographic separation, yields xylitol.

Xylitol is equally as sweet as sucrose. This property is of advantage to food processors because in reformulating a product from sucrose to xylitol, approximately the same amounts of xylitol can be used. Because xylitol has a negative heat of solution, the substance cools the saliva, producing a perceived sensation of coolness, quite desirable in some food products, notably beverages. Recently, this property has been used in an iced-tea-flavored candy distributed in the European market. As of the late 1980s, 28 countries have ruled positively in terms of xylitol for use in commercial products. Xylitol has been found particularly attractive for use in chewing gum, mint and hard candies, and as a coating for pharmaceutical products. Xylitol has the structural formula shown below, with a molecular weight of 152.1. It is a crystalline, white, sweet, odorless powder, soluble in water and slightly soluble in ethanol and methanol. It has no optical activity.



Isomalt. [CAS: 64519-82-0]. Developed in Germany, isomalt is described as an energy-reduced bulk sweetener and marketed in Europe under the tradename *Palatinit*™ *mark*. The compound is produced from sucrose in a two-step process, as shown in Fig. 1.

In the first step, the easily hydrolyzable 1-2 glucoside linkage between the glucose and fructose moieties of sucrose are catalyzed by immobilized enzymes to produce isomaltulose, *Palatinos*.™ *mark* After crystallization, the isomaltulose is hydrogenated in a neutral aqueous solution using a nickel catalyst.

It is claimed that isomalt is odorless, white, crystalline, and sweet tasting without the accompanying taste or aftertaste. Sweetening power is from 0.45 to 0.6 that of sucrose. A synergistic effect is achieved when isomalt is combined with other artificial sweeteners and sugar substitutes. Principal applications are in confections, pan-coated goods, and chewing gum. The substance was approved for use in most European countries in 1985. Classification of isomalt as a GRAS substance was petitioned in the United States. (GRAS = generally regarded as safe.)

Crystalline Maltitol. [CAS: 585-88-6]. Classified as a bulk sweetener with taste and mouthfeel similar to sucrose, crystalline maltitol contains maltitol as the major component (88+%), with small amounts of sorbitol, maltotriitrol, and hydrogenated oligosaccharides. Its use is in tabletop sweeteners, chocolate, candy, and baked goods. Maltitol has been a major component of hydrogenated glucose syrup in the United States since 1977 and has been used in Japan since 1963. The product was introduced in Europe in 1984. Classification of crystalline maltitol as a GRAS substance was petitioned in the United States in 1986.

Nonnutritive Sweeteners

The worldwide total manufacturers's sales of high potency sweeteners is dominated by six sweeteners. In descending order, these are aspartame, sucralose, acesulfame-K, cyclamate, saccharin, and stevioside. Sucralose has experienced significant growth since its approval by the U.S. Food and Drug Administration (FDA) in 1998. Neotame was approved by the FDA in 2002. Alitame appears to be dormant as there was no

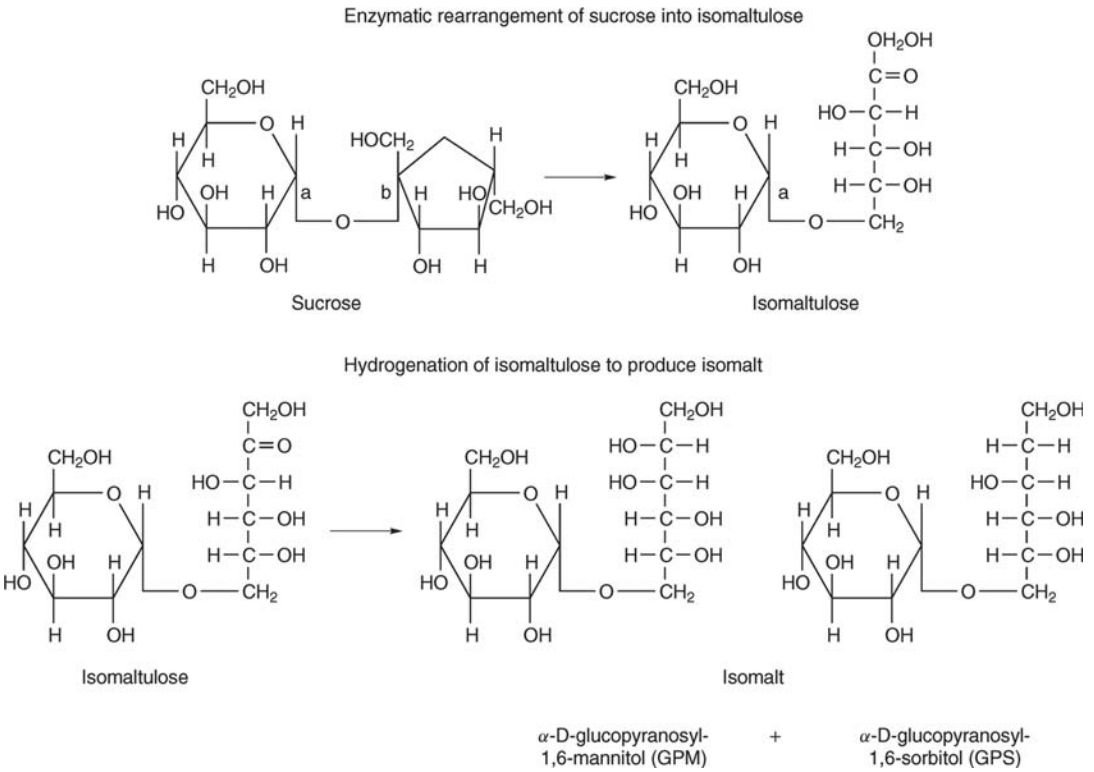


Fig. 1. Isomalt

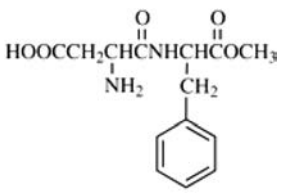
commercial development activity since ~1996. Thaumatin, neohesperidin dihydrochalcone, and glycyrrhizin are flavor modifiers, but not approved as sweeteners in the United States. They can be used as flavors with GRAS (generally recognized as safe) status affirmed by Flavor and Extract Manufacturers Association (FEMA) of the United States.

Aspartame. [CAS: 22839-47-0]; [CAS: 53906-69-1] (APM, L-α-aspartyl-L-phenylalanine methyl ester) [1], is the most widely used nonnutritive sweetener worldwide. This dipeptide ester was synthesized as an intermediate for an antiulcer peptide at G. D. Searle in 1965. Although this compound was known in the literature, its sweet taste was serendipitously discovered when a chemist licked his finger, which was contaminated with it. Many analogues, especially the more stable esters, were made and their taste qualities and potencies determined. It was the first compound to be chosen for commercial development. Following the purchase of G. D. Searle by Monsanto, the aspartame business was split off to become a separate Monsanto subsidiary called NutraSweet. The J.W. Childs Associates purchased NutraSweet in 2000. NutraSweet is a tradename of aspartame produced by NutraSweet. Tradenames for tabletop products produced by Merisant include NutraSweet, Equal, Canderal, and Sucaryl. The other principal producers of aspartame include Ajinomoto (trade name: Pal Sweet), Holland Sweetener Company (trade name: SANECTA), a joint venture of Dutch (DSM) and Japanese (Toyo Soda) companies, and Dae Sang (formerly Miwon), which established a business relationship with NutraSweet in 2003.



(1)

Aspartame was approved by the FDA in 1981 for use in dry goods. Two years later it was approved for use in carbonated beverages. Additional approvals came in 1993 for baked goods, candies, and still beverages. Aspartame can be used legally in just about all food categories. Economically, the most important use of nonnutritive sweeteners is in carbonated beverages. Aspartame has enjoyed great success in this category. The top five diet beverages in the United States in 2004 use aspartame as a stand alone sweetener. The U.S. patent for aspartame expired in December, 1992. Subsequently, the price has declined. See also **Carbonated Beverages**.

Aspartame is caloric. As a dipeptide, it yields ~4 kcal/g (16.7 kJ/g). However, because of its high sweetness potency (200X), only a minute quantity is consumed, resulting in negligible caloric contribution. Aspartame is soluble in water at room temperature (~1 g/100 mL at pH 3) [Butchko, 2001). The solubility is a function of pH and temperature. Higher temperature and lower pH increase the solubility. These conditions also have impact on the rate of decomposition. Aspartame, in its common fine powder form, does not have a high dissolution rate in water. This can be a problem for manufacturing diet beverages. Methods for improving the dissolution rate of aspartame by cogrinding it with food acids or polysaccharides, cospray drying with edible bulking agents, agglomeration, and complexation with metal ions have been described in patents.

The methyl ester group of aspartame is very susceptible to deesterification. When this reaction takes place, the resulting deesterified dipeptide is not sweet, but is otherwise tasteless. Avoidance of excessive heat exposure to aspartame is therefore desirable. The impact of heat degradation can be reduced by the encapsulation of aspartame in maltodextrin; fatty acids, eg, hydrogenated cottonseed oil; or other coatings for baking purposes. In tropical climates, addition of excess aspartame (a costly option) and rapid supermarket shelf turnover have been employed to maintain product quality. For the same reason, most diet drinks dispensed from a beverage dispenser, ie, soda fountain, contain a blend of aspartame and saccharin or aspartame, acesulfame-K and saccharin, instead of 100% aspartame.

In aqueous solution, the relationship between pH and stability of aspartame is a bell curve having maximum stability at pH 4.3 (Fig. 2). At higher or lower pH, the half-life of aspartame in water diminishes quickly. Most soda and fruit-flavored ready-to-drink beverages are formulated at a pH centered ~3.0. To convert these beverages to aspartame-containing diet products, it would be advantageous to adjust the pH as close to 4.3 as possible without changing the original flavor and taste. Otherwise, overage of aspartame may be required to compensate anticipated decomposition during beverage shelf-life.

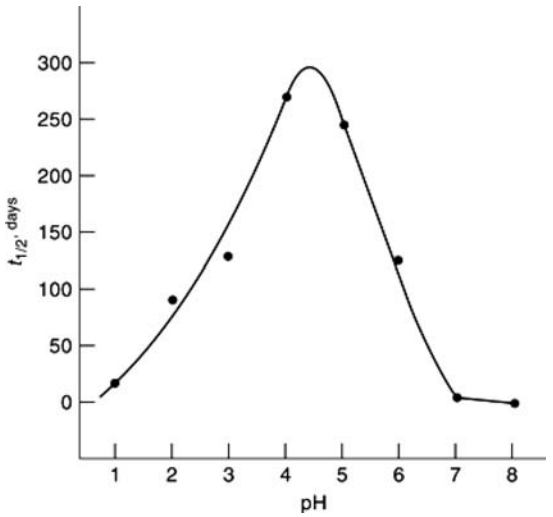


Fig. 2. Stability of aspartame in water at 25 °C, where $t_{1/2}$ is the half-life in days

The principal pathway for the decomposition of aspartame begins with the cleavage of the ester bond, which may or may not be accompanied by cyclization (Fig. 3). The resultant diketopiperazine and/or deesterified dipeptide can be further hydrolyzed into individual amino acids. See also **Amino Acids**.

The rate of aspartame degradation in dry mixes is more dependent on the water activity than on the temperature. In dry mixes, aspartame may also engage in Maillard reactions with the aldehyde moieties of flavoring agents, resulting in the loss of sweetness and flavor. Use of the corresponding acetals of the flavor compounds to avoid this reaction has been reported.

In principle, aspartame is produced through the coupling of two amino acid moieties. One moiety consists of L-phenylalanine methyl ester hydrochloride (2) made by treating the amino acid in methanol and hydrochloric acid; the other is aspartic acid anhydride hydrochloride or formic acid salt. The coupling reaction generates two positional isomers, α and β.

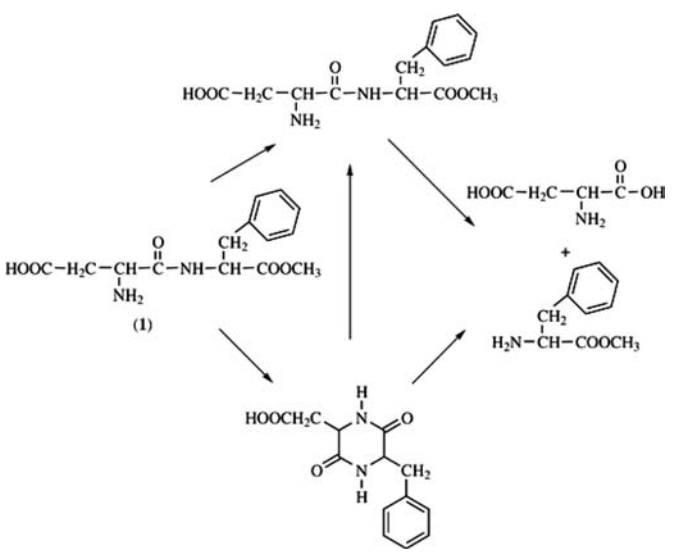

Fig. 3. Decomposition of aspartame to diketopiperazine and/or aspartyl-phenylalanine, and then to the amino acids, aspartic acid and phenylalanine

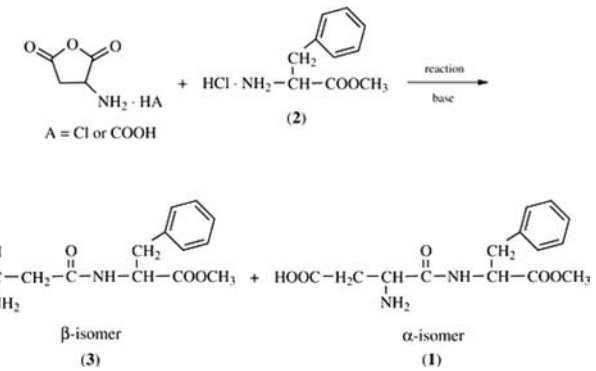
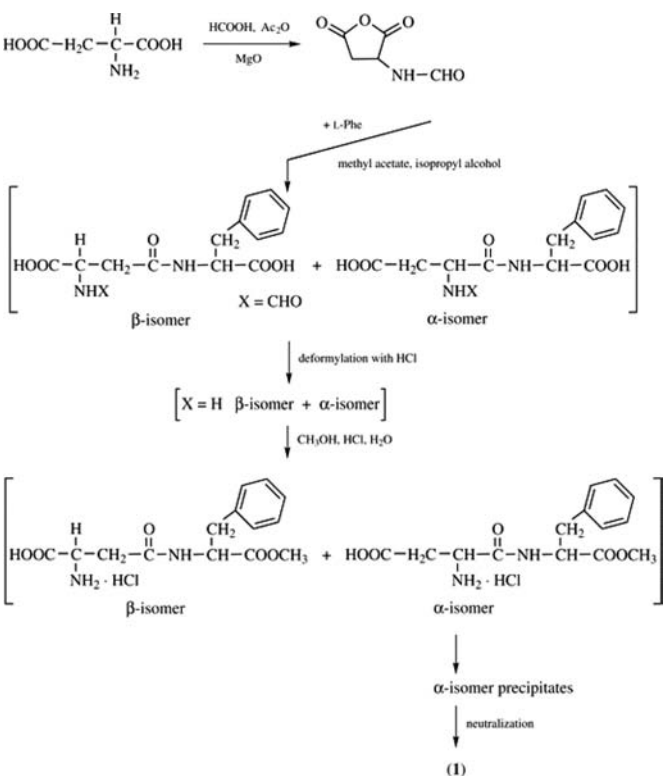
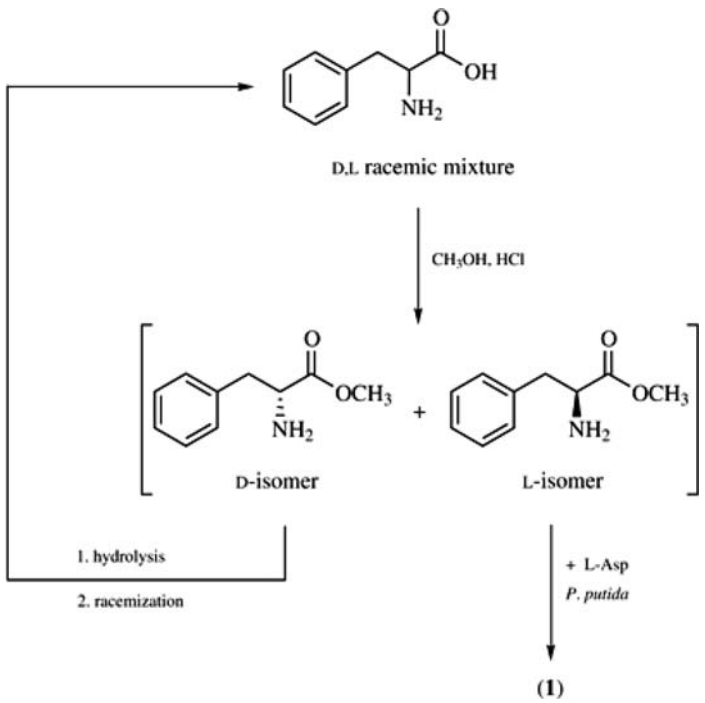
Methods to increase the ratio of the desired α-isomer (1) versus the unsweet β-isomer [22839-61-8] (3) exist and are proprietary. The isomers can be separated by subjecting the solution of the final step to hydrochloric acid. The desired α-isomer hydrochloride salt crystallizes out of the solution; the β-isomer remains. There are many patented synthetic processes.



NutraSweet has streamlined the synthesis of aspartame into a more cost-effective one pot process. Their process begins by mixing L-aspartic acid with a minimal amount of formic acid and acetic anhydride in the presence of magnesium oxide, resulting in the formation of *N*-formyl-L-aspartic anhydride. L-phenylalanine is coupled with *N*-formyl-L-aspartic anhydride in equimolar amounts in the presence of methyl acetate and/or isopropyl alcohol. These two solvents increase the α/β ratio. The propensity for the reaction mixture to solidify can be reduced by adding acetic acid, raising the temperature to 35 °C (95 °F), and having slow, periodic agitation. The α and β isomers of *N*-formyl-L-aspartyl-L-phenylalanine are then deformylated with hydrochloric acid. After distilling off methanol, methyl acetate, and methyl formate by-products, the resulting mixture of α- and β- L-aspartyl-L-phenylalanine and their various methyl ester is then esterified by adjusting the concentration of hydrochloric acid, methyl alcohol, and water to produce a high yield of α-aspartame hydrochloride. The esterification reaction, at ambient temperature with gentle agitation, completes in ~6 days. The desirable α-aspartame hydrochloride salt is easily separated from the β-isomer since α-aspartame hydrochloride dihydrate has a lower solubility in water. The precipitated α-isomer is filtered off and is then neutralized with a base to form aspartame.



Toyo Soda Manufacturing Co. holds a number of patents related to the synthesis of aspartame with microorganisms (U.S. Pat. 4,506,011 (Mar. 19, 1985), T. Harada, H. Takemoto, and T. Igarashi (to Toyo Soda Mfg. Co.), and U.S. Pat. 4,587,214 (May 6, 1986), T. Harada, T. Takemoto, and T. Igarashi (to Toyo Soda).). Their technology is the backbone of manufacturing process employed by Holland Sweetener Company — a joint venture between DSM and Toyo Soda. The process starts with methylation of a synthetic racemic mixture of phenylalanine, instead of a more expensive L-phenylalanine. The D- and L-phenylalanine methyl esters and L-aspartic acid are contacted with a culture or treated cultured product of a microorganism belonging to the genus Pseudomonas (eg, *Pseudomonas putida* FERM BP 159) to produce aspartame. The microbial coupling does not form the β-isomer of aspartame. The unreacted D-phenylalanine methyl ester is recovered, deesterified, isomerized back to racemic mixture, and recycled into the process.



To reduce the manufacturing cost, aspartame companies tend to produce L-phenylalanine via fermentation themselves. Effort to improve the yield of microorganism via genetic engineering technology has been reported (U.S. Pat. 5,304,475 (Apr. 19, 1994), H. Y. Kim and co-workers (to Miwon).

The safety of aspartame for human consumption has been studied extensively. The results of these studies have satisfied the FDA. However, because phenylalanine is a metabolite of aspartame, people who lack the ability to metabolize this amino acid should refrain from using aspartame. Any aspartame-containing diet food must indicate that the product contains phenylalanine.

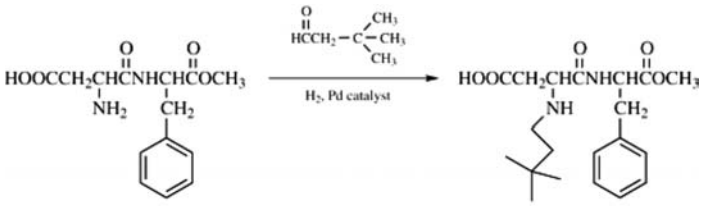
In addition to aspartame, two dipeptide sweeteners, neotame and alitame, have been commercialized.

Neotame. [CAS: 165450-17-9] (4), *N*-[*N*-(3,3-dimethylbutyl)-L-α-aspartyl]-L-phenylalanine 1-methyl ester, is the most potent commercial sweetener to date (~2005). It is ~8000 times sweeter than sucrose or ~40 times sweeter than its analogue, aspartame (U.S. Pat. 5,480,668 (Jan. 2, 1996), C. Nofrr and J-M. Tinti). The very high potency means that a much lower dose of neotame is required to achieve equivalent sweetness by other sweeteners. Low dosage translates into significant cost savings and reduced logistic resources. Because the molecule is not metabolized into free amino acids in the body, an information statement for phenylketoureic consumers is not required for neotame-containing products.

Neotame follows similar degradation kinetics as that of aspartame. The main difference is that neotame does not generate diketopiperazine (DKP). As in the case of aspartame, once the methyl ester of neotame is hydrolyzed, the sweetness is lost.

Neotame was approved by the FDA as a sweetener for general purposes in 2002. Unlike aspartame, neotame is more commonly used as a partial substitution of sugar or high fructose corn syrup, and in blends with other high potency sweeteners, instead of a stand alone sweetener.

Neotame is manufactured via a reductive alkylation of aspartame with 3,3-dimethylbutyaldehyde [2987-16-8] (U.S. Pat. 5,728,862 (Mar. 17, 1998), I. Prakash (to NutraSweet).



(4)

Alitame. [CAS: 80863-62-3], L-α-aspartyl-D-alanine *N*-(2,2,4,4-tetra methylthietan-3-yl)amide (**5**), was developed by Pfizer, but is owned by Danisco now. In 1986, Pfizer filed a food additive petition with the FDA. As of 2006, it was still pending. Alitame was approved for use as a sweetener by Australia in 1993, by China, Mexico, and New Zealand in 1994, by Indonesia in 1995, and by Colombia in 1996.

Alitame (trade name: Aclame) is a water-soluble, crystalline powder of high sweetness potency 2000 times sweeter than sugar. The sweet taste is clean, and the time–intensity profile is similar to that of aspartame. Because it is a sterically hindered amide rather than an ester, alitame is expected to be more stable than aspartame. At pH 2–4, the half-life of alitame in solution is reported to be twice that of aspartame. The main decomposition pathways (Fig. 4) include conversion to the unsweet β-aspartic isomer (**6**) and hydrolysis to aspartic acid and alanine amide. No cyclization to diketopiperazine or hydrolysis of the alanine amide bond has been reported.

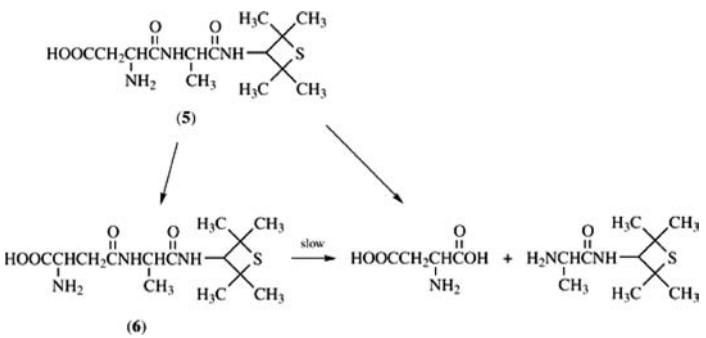


Fig. 4. Main degradation pathways of alitame.(Courtesy of Marcel Dekker, Inc.)

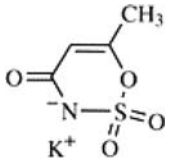
Alitame has the potential to be used in almost all areas where sweeteners are presently used — e.g., baked goods and baking mixes, hot and cold beverages, dry beverage mixes, milk products, frozen desserts and mixes, fruit preparations, chewing gums and candies, tabletop sweeteners, toiletries and pharmaceuticals.

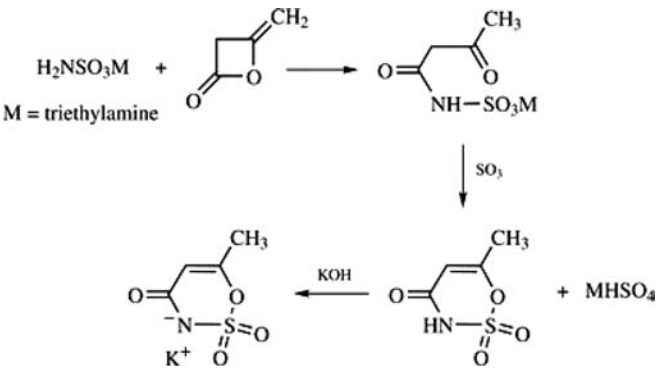
Acesulfame-K. [CAS: 55589-62-3] (7), the potassium salt of acesulfame [CAS: 33665-90-6] (6-methyl-1,2,3-oxathiazin-4(3*H*)-one 2,2-dioxide), is a sweetener that resembles saccharin in structure and taste profile. 5,6-Dimethyl-1,2,3-oxathiazine-4(3*H*)-one 2,2-dioxide, the first of many sweet compounds belonging to the dihydrooxathiazinone dioxide class, was discovered accidentally in 1967. From these many sweet compounds, acesulfame was chosen for commercialization. To improve water solubility, the potassium salt was made. Acesulfame-K (Sunett™) was approved for dry product use in the United States in 1988 and in Canada in October, 1994. In 2003, acesulfame-K was approved as a general purposes sweetener by the FDA.



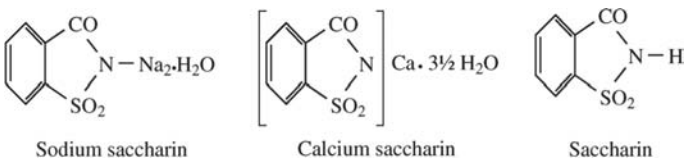
(7)

Acesulfame-K is a white crystalline powder having a long (6 years or more) shelf-life. It readily dissolves in water (270 g/L at 20 °C). Like saccharin, acesulfame-K is stable to heat over a wide range of pH. At higher concentrations, there is a detectable bitter and metallic off-taste similar to saccharin. Use of the sodium salt of ferulic acid [CAS: 437-98-4] (FEMA no. 3812) to reduce the bitter aftertaste of acesulfame-K has been described (U.S. Pat. 5,336,513 (Aug. 9, 1994), J. A. Riemer (to Kraft General Foods). The sweetness potency of acesulfame-K (100–200 times, depending on the matching sucrose concentration) is considered to be about one-half that of saccharin, but is about the same as that of aspartame.

The principal commercial process for acesulfame-K is depicted below:



Saccharin. [CAS: 81-07-2]. A noncaloric sweetener that is about 300 times sweeter than sugar. The compound is manufactured on a large scale in several countries. It is made as saccharin, sodium saccharin, and calcium saccharin, as shown by formulas below.



Sodium saccharin Calcium saccharin Saccharin

Saccharin (3-oxo-2,3-dihydro-1,2-benzisothiazole 1,1-dioxide (*o*-sulfo benzimide or *o*-benzosulfimide) (8) was accidentally discovered in 1879 by I. Remsen and C. Fahlberg when they were researching the oxidation products of toluene sulfone amide. A pilot plant was set up in New York to manufacture saccharin, which was displayed in a London exposition in 1885. Since that time, saccharin has been used in many parts of the world.

In 1969, a chronic toxicity study on a cyclamate/saccharin (10:1) blend indicated bladder cancer problems in rats. Cyclamate was soon banned by the FDA, but saccharin remained an approved sweetener. In 1977, the FDA proposed a ban on saccharin because of the discovery of bladder tumors in some male rats fed with high doses of saccharin. Because no other nonnutritive sweetener was available at that time, the proposed ban faced strong opposition. Legislation to stay the ban has been passed in the U.S. Congress periodically. In December, 1991, the FDA withdrew its proposed ban. All saccharin-containing packaged products were required to carry a warning label indicating that saccharin has been determined to cause cancer in laboratory animals. In 2001, the warning label requirement was lifted by the Congress. In 2003, saccharin was delisted from California Proposition 65 (the so-called carcinogen list).

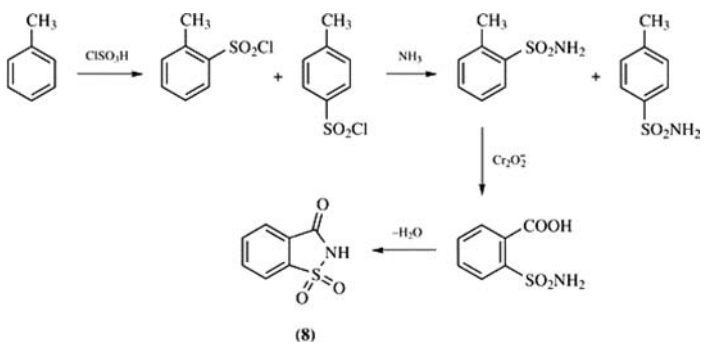
The main utility of saccharin had been in beverages and as a tabletop sweeteners, baked goods, soft drinks, jams, chewing gum, canned fruit, candy, dessert toppings and salad dressing. Upon the approval of aspartame for carbonated beverages in 1983, aspartame displaced saccharin in most

canned and bottled soft drinks. However, saccharin is still used, usually blended with aspartame, in carbonated soft drinks dispensed from soda fountains.

Saccharin is acidic and not very soluble in water. For improved solubility, the food industry prefers the sodium [CAS: 128-44-9] or calcium [CAS: 6485-34-3] salt. Sodium saccharin is so widely used that it is often referred to simply as saccharin. The aqueous solubilities of both salts are about the same, ie, 0.67 g/mL. Saccharin, stable to heat over a wide pH range, can withstand most food processing conditions. See also **Food Processing**. Interactions between saccharin and other food ingredients have not been reported.

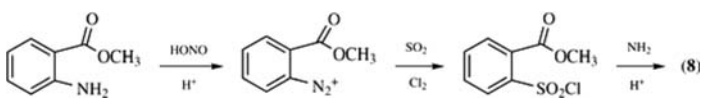
Saccharin imparts a sweetness that is pleasant at the onset, but is followed by a lingering, bitter aftertaste. Sensitivity to this bitterness varies from person to person. At high concentration, however, most people can detect the rather unpleasant aftertaste. Saccharin is synergistic with other sweeteners of different chemical classes. For example, saccharin–cyclamate, saccharin–aspartame, saccharin–sucralose, and saccharin–alitame combinations all exert synergy to various degrees. The blends, as a rule, exhibit less aftertaste than each of the component sweeteners by themselves.

The original Remsen–Fahlberg process for saccharin synthesis requires the separation of ortho- and para-isomeric intermediates.



(8)

In early 1950, a newer process for saccharin production was developed and the Maumee Chemical Company was subsequently formed. The Maumee process uses anthranilic acid [CAS: 118-92-3] as the starting material. After the merger of the PMC Specialties Group and the Maumee Chemical Company, the process was improved to a one-pot continuous process using methyl anthranilate [CAS: 134-20-3] as the starting material. As of this writing, PMC is the sole producer of saccharin in the United States. Saccharin is also produced in Japan, China, Korea, and Taiwan. In 2003, PMC scored a victory in antidumping cases against multiple Chinese manufacturers.



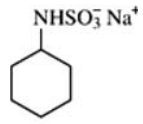
(8)

Many analogues of saccharin have been synthesized since its discovery. With the exception of one compound, thieno[3,4-*d*]isothiazolone dioxide [CAS: 59337-79-0], 1000 times, this effort has not generated more potent compounds. Acesulfame-K could be considered a ring-modification derivative of saccharin, however.

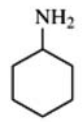
Consumers and health professionals can find accurate and reliable information about saccharin on the Web via www.saccharin.org. The new and improved saccharin Web site has anupdated look and feel with expanded information on the benefits and safety of this low-calorie sweetener.

Saccharin is approved in more than 100 countries and has been reviewed and determined safe by the U.S. Food and Drug Administration (FDA), Joint Expert Committee on Food Additives (JECFA) of the World Health Organization and the Scientific Committee for Food of the European Union. In addition, leading health authorities such as the American Cancer Society, American Diabetes Association, American Dietetic Association and the American Heart Association have acknowledged saccharin's safety.

Cyclamate. Sodium cyclamate [CAS: 139-05-9] (**9**), the sodium salt of cyclamic acid [CAS: 100-88-9], was so widely used that it was often just called cyclamate. The other common salt, calcium cyclamate [CAS: 139-06-0], is useful in low sodium diets.



(9)



(10)

Cyclamate was first synthesized in 1937. Like the other sweeteners, its sweet taste was accidentally discovered (U.S. Pat. 2,275,125 (Mar. 3, 1942), L. F. Andrieth and M. Sveda (to E. I. du Pont de Nemours & Co., Inc.). The FDA in 1958 classified sodium cyclamate as a GRAS sweetener. In 1969, a 2-year chronic toxicity study with a sodium cyclamate–sodium saccharin (10:1) mixture found bladder tumors in rats. The FDA took cyclamate off the GRAS list, banning it from foods and beverages, but permitting its sale in pharmacies. In 1970, after a congressional investigation, the FDA banned the use of cyclamate entirely. Abbott Laboratories, which has conducted additional toxicity and carcinogenicity studies with cyclamate, a 10:1 mixture of cyclamate–saccharin, and cyclohexylamine [CAS: 108-91-8], claimed to be unable to confirm the 1969 findings. Abbott then filed a food additive petition for cyclamate in 1973, which was denied by the FDA in 1980. In 1982, the Calorie Control Council and Abbott Laboratories filed a second food additive petition containing the results of additional safety studies (The Calorie Control Council and Abbott Laboratories, Food Additive Petition for cyclamate 2A3672 (Sept. 22, 1982). That petition remains active. Cyclamate is, however, allowed for use in any or all three categories, ie, food, beverage, and tabletop, in ∼50 countries. In 2004, the maximum beverage use level of cyclamate in the European Union was lowered to 250 ppm (as cyclamic acid). Sweet 'n Low, known in the United States as a saccharin-based tabletop sweetener, contains exclusively cyclamate in Canada.

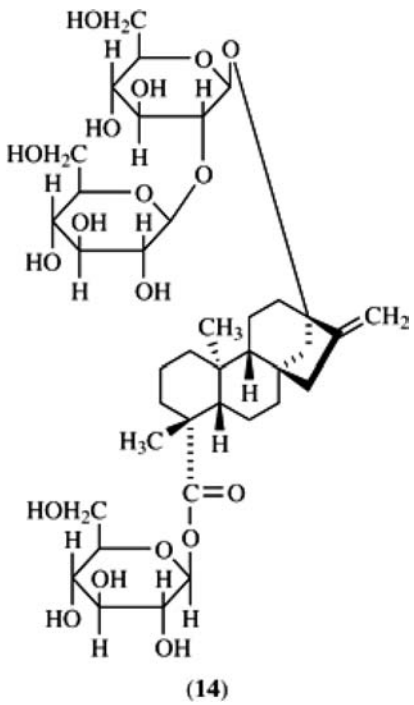
Cyclamate is ∼30 times more potent than sugar. Its aftertaste is minor compared to saccharin and acesulfame-K. The mixture of cyclamate and saccharin, especially in a 10:1 ratio, imparts both a more rounded taste and a 10–20% synergy. Cyclamate (9) is manufactured by sulfonation of cyclohexylamine (10). Many reagents can be used, including sulfamic acid, salts of sulfamic acid, and sulfur trioxide. See also http://www.cyclamate.com/.

Sucralose. [CAS: 56038-13-2], 1,6-dichloro-1,6-dideoxy-β-D-fructofuranosyl-4-chloro-4-deoxy-α-D-galactopyranoside, is a trichloro-*galacto*-sucrose sweetener developed by the British sugar company Tate & Lyle during the 1970s (U.S. Pat. 4,343,934 (Aug. 10, 1982), M. R. Jenner and D. Waite (to Talres Development), (U.S. Pat. 4,362,869 (Dec. 7, 1982), M. R. Jenner and co-workers (to Talres Development), and (U.S. Pat. 4,435,440 (Mar. 6, 1984), L. Hough, S. P. Phadnis, and R. A. Khan (to Tate & Lyle). It was licensed to McNeil-PPC, Inc., a Johnson & Johnson subsidiary, in the United States until a new agreement took place in February, 2004. McNeil Nutritionals retained ownership of SPLENDA Brand and the right for its worldwide retail and food service business. Tate & Lyle became the sole manufacturer of SPLENDA Brand sucralose and owned the right for its worldwide ingredient sales. See also **Sucralose**.

Monellin. The sweetness of this compound is claimed to be 1500 to 3000 times that of sucrose, but a different flavor profile prevails. The detection of a sweet taste is slow, commencing after a few seconds in contact with the taste buds, then gradually increasing to its peak intensity. The sweet taste can persist for up to an hour. The source is the relatively rare serendipity berry, the fruit of a noncultivated West African vine. Extraction of the sweet component is effected by treating the berry with a series of enzymes (pectinase and bromelain), followed by dialysis and

chromatographic separation. The compound resulting contains the protein *monoellin* with a molecular weight of about 10,700 and composed of two nonidentical polypeptide chains of 50 and 43 amino acids. Neither of the individual chains imparts sweetness. Regulatory measures have not been instituted because of the compound's apparent instability and limited raw resources for processing. However, to date, tests with mice have shown no evidence of toxicity.

Stevioside. [CAS: 57817-89-7] (14) is a naturally occurring sweetener (~200 times sweeter than sucrose) extracted from a South American plant, *Stevia rebaudiana* Bertoni. The dried leaves, the water extract of leaves, and the refined chemical ingredients, eg, (14) and Rebaudioside A [CAS: 58543-16-1] (~300 times sweeter than sucrose) (15), can all be used as sweetening agents. These are collectively referred to as stevia. Discovered in Paraguay and Brazil, the plant was identified in the early 1970s as a plant of high economical value and transported to Japan for cultivation, where the commercialization of stevia leaves extract as a natural sweetener became a success. Today Stevia plant is cultivated primarily in China.

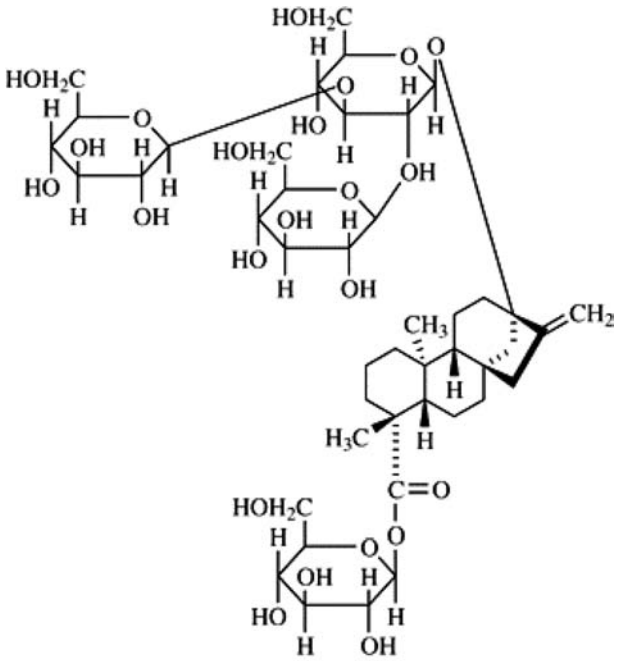


(14)

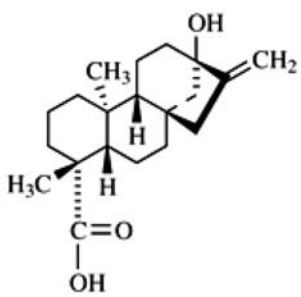
Stevioside and rebaudioside A are diterpene glycosides. The sweetness is tainted with a bitter and undesirable aftertaste. The time–intensity profile is characteristic of naturally occurring sweeteners: slow onset, but lingering. The aglycone moiety, steviol [CAS: 471-80-7] (16), which is the principal metabolite, has been reported to be mutagenic. Wide use of stevia in Japan for >30 years did not produce any known deleterious side effects. In Japan, enzymatically glycosylated blend of stevioside and rebaudioside A, which appears to impart a cleaner taste profile, is also available commercially.

Because no food additive petition has been presented to the FDA, stevioside and related materials cannot be used in the United States as food ingredients. An import alert against stevia was issued by the FDA in 1991. In 1995, however, the FDA revised this import alert to allow the importation and use of stevia as a dietary supplement, but not as a sweetener or an ingredient for foods. In 2004, JECFA (Joint Expert Committee of Food Additives) issued a preliminary ADI (Allowed Daily Intake) of 2-mg/kg body weight (based on steviol) for stevia extract. This action may impact favorably on worldwide regulatory approval. As consumer's demand on naturally sweetened products increases, interest in Stevia, and naturally occurring potent sweeteners in general, is expected to grow. A comprehensive review of stevia is available [Kinghorn, 2002].

Glycyrrhizin. (17), also known as glycyrrhizic acid [CAS: 1405-86-3], is a glycoside isolated from the roots of licorice, *Glycyrrhiza glabra* L. For improved water solubility, an ammoniated salt is commonly used. This can be in the form of either ammonium glycyrrhizinate or monoammonium glycyrrhizinate.

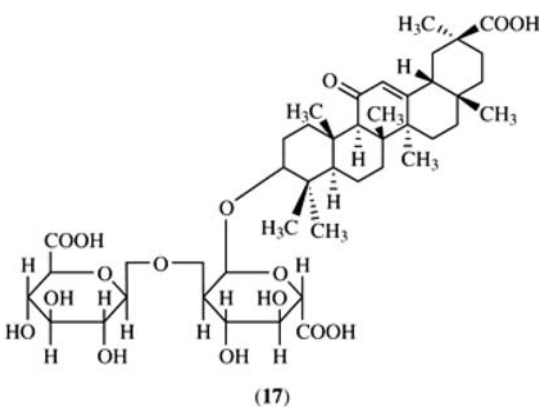


(15)



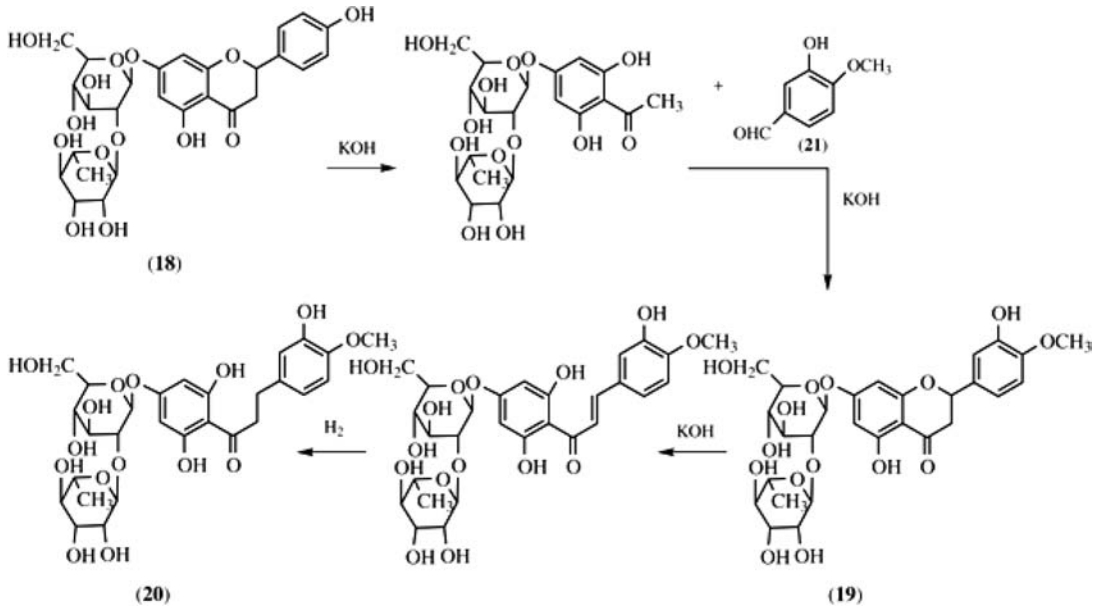
(16)

The sweetness potency of glycyrrhizin is ~33 times sweeter than sucrose. Its taste, however, is accompanied by a characteristic licorice flavor, making it incompatible with many other food ingredients. The time–intensity profile is similar to that of other naturally occurring high potency sweeteners: slow onset followed by lingering aftertaste. It is claimed to be heat stable. Ammonium glycyrrhizinate, which tends to precipitate < pH 4.5, is affirmed in the United States as a GRAS flavoring agent (FEMA no. 2528). It is not approved for use as a sweetener.



(17)

They are available in powder or liquid form and with color, or as odorless, colorless products. These compounds are stable at high



temperatures (132 °C; 270 °F) for a short time and thus can be used in bakery products. In some chocolate-based products, the sweetener has been used to replace up to 20% of the cocoa. The sweetener also has excellent foaming and emulsifying action in aqueous solutions. Typical products in which these sweeteners may have application include cake mixes, ice creams, candies, cookies, desserts, beverages, meat products, sauces, and seasonings, as well as some fruit and vegetable products. Generally available as malted and ammoniated glycyrrhizin.

The basic compound is a triterpene glycoside. It is extracted from the licorice root, of which the principal sources are China, Russia, Spain, Italy, France, Iran, Iraq, and Turkey. The roots, containing 10% moisture, are dried and shredded, after which they are extracted with aqueous ammonia, concentrated in vacuum evaporators, precipitated with sulfuric acid, and crystallized with 95% ethyl alcohol.

Neohesperidin Dihydrochalcone. In the 1960s, there was a strong effort by the U.S. Department of Agriculture (USDA) to study the structure–activity relationship of citrus-derived chemicals. The goal was to reduce the bitter taste of citrus juices derived from bitter principles, such as naringin [CAS: 10236-47-2] (18), neohesperidin [CAS: 13241-33-3] (19), and limonin [CAS: 1180-71-8]. Neohesperidin is a glycoside composed of a flavanone and a disaccharide (glucose and L-rhamnose [CAS: 3615-41-6]). Upon treatment with potassium hydroxide, the flavanone ring opens up to yield a chalcone. Catalytic hydrogenation of this chalcone produces neohesperidin dihydrochalcone [CAS: 20702-77-6] (NHDC) (20), which tastes sweet.

Many other dihydrochalcones have been made, but most of the toxicological studies have been conducted using NHDC and thus **20** has been petitioned and allowed for use. Neohesperidin (19) is best isolated from the bitter orange (Seville orange), but it can also be synthesized from **18** and isovanillin [CAS: 621-59-0] (21).

NHDC imparts a sweetness that has a much slower onset and much greater lingering than sucrose. There is a slight aftertaste. The sweet potency at the 10% sucrose solution sweetness equivalence is ∼300 times. The most significant advantage of **20** is its ability to reduce the bitterness of the citrus bitter principles: naringin (18) and limonin. For example, at 5% sucrose equivalence, NHDC increased the threshold for **18** from 20 to 49 mg/kg.

NHDC is an off-white powder having low solubility in water (0.5 g/L at room temperature). It is quite stable over a broad range of pH and temperature. Under extreme conditions, hydrolysis of the ether linkage between the saccharides and the aglycone can take place. However, the aglycone itself is reported to be sweet. NHDC is allowed for use as a sweetener according to the European Union Sweeteners Directive in 1994. It has not been approved as a sweetener in the United States. However, in 1993, NHDC was affirmed by FEMA as a GRAS flavor modifier (FEMA no. 3811) for many food categories.

Thaumatin. [CAS: 53850-34-3] is a mixture of proteins extracted and purified from the fruit of a West African plant, *Thaumatococcus danielli*. The leaves of the plant have been used for many years in Africa for wrapping food during cooking. Thaumatin (trade name: Talin) is a very potent sweetener (∼2000 times sweeter than sucrose). However, its potency is overshadowed by inferior taste qualities. The onset of sweetness is very slow, and after reaching maximum sweetness, a very long-lingering sweetness combined with an unpleasant aftertaste follows. Primarily owing to this poor taste quality, thaumatin is not considered a practically useful sweetener. It is, however, used as a flavor enhancer, especially in products such as chewing gum. Thaumatin and thaumatin B-recombinant were affirmed GRAS flavors (FEMA no. 3732 and 3814, respectively). They are not approved as sweeteners in the United States.

As a protein, thaumatin is remarkably water-soluble (up to 60%) and is stable to heat at low pH. It has been reported that a thaumatin solution at pH < 5.5 can be heated at 100 °C (212 °F) for several hours without loss of sweetness.

Table 1 compiles examples of other compounds reported to be sweet.

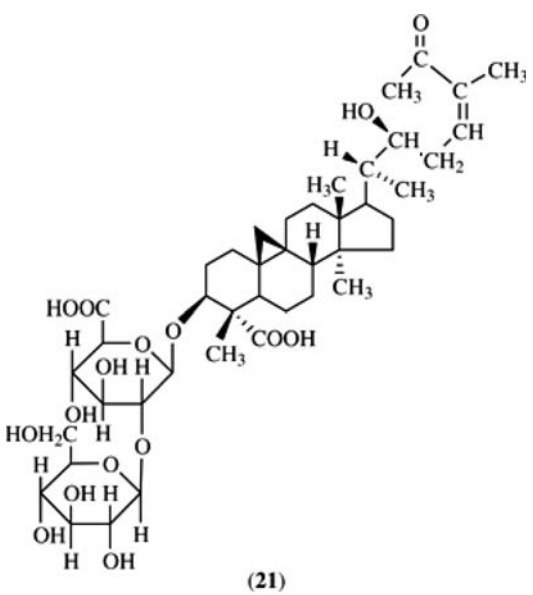


TABLE 2. OTHER COMPOUNDS REPORTED TO BE SWEET

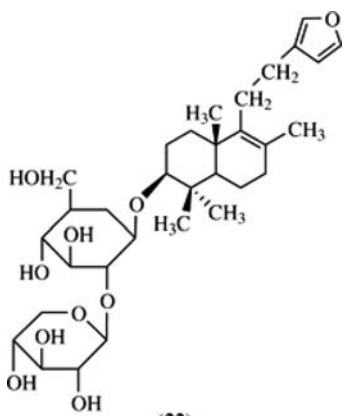
Compounds	CAS Registry Number	Structure number	Potency (times sweeter than sucrose)
Abrososide D	[125003-001]	21	75X
Baiyunoside	[86450-75-1]	22	500X
Brazzeina[a]	[160047-05-2]		200X
Chloroform	[67-66-3]		40X
6-Chloro-D-tryptophan	[17808-35-4]	23	1300X
Dulcin	[150-69-6]	24	250X
Glycergic acid	[84215-86-1]	25	500X
Hernandulcin	[108944-70-3]	26	1000X
Hydrofluorene sweeteners	[34069-54-0]	27	1400X
Mogroside V	[88901-36-4]	28	256X
Monatin	[146142-94-1]	29	2000X
Monellin[a], [b]	[9062-83-3]		2500X
Osladin	[33650-66-7]	30	3000X
P-4000	[553-79-7]	31	4000X
Pentadin	[61391-05-7]		500X
Perillartine	[30950-27-7]	32	2000X
Phyllodulcin	[55555-33-4]	33	400X
SRI oxime V	[59691-20-2]	34	450X
Suosan	[140-46-5]	35	700X

[a]Materials is a protein.
[b]The mabinlins, another group of proteins, are also sweet.



(22)

Bulking Agents. Although food technologists can use nonnutritive sweetener(s) to match the sweetness of regular caloric products, invariably they face the texture or mouthfeel issues in developing sugarless or sugar reduced products. Ideal bulking agents that impart no calories and cause no gastrointestinal side effects remain elusive. Principal examples of bulking agents are the sugar alcohols, eg, sorbitol [CAS: 50-70-4]; mannitol [CAS: 69-65-8]; xylitol [CAS: 87-99-0]; maltitol [CAS: 585-88-6]; lactitol [CAS: 585-86-4]; erythritol [CAS: 149-32-6]; hydrogenated starch hydrolysate; and isomalt, a mixture of glucosyl sorbitol [CAS: 534-73-6] and glucosylmannitol [CAS: 20942-99-8]. These alcohols are reduced saccharides resulting primarily from catalytic hydrogenation and, for the most part, are less sweet and less caloric than sugar [∼2.4 pkcal/g (10.0 kJ/g)] (88) and mostly noncariogenic. The other examples include polydextrose [68424-04-4] [∼1 kcal/g (4.18 kJ/g)] and D-tagatose [CAS: 87-81-0].

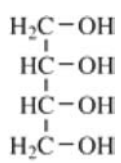
Erythritol. Erythritol (**36**), a four-carbon sugar alcohol of 0.6 times sweetness potency, is produced commercially via glucose fermentation by yeasts, such as *Moniliella pollinis*. Unlike other sugar alcohols, erythritol is largely absorbed into our body, but excreted out in urine intact. The unique metabolic profile renders it a very low calorie (0.2 kcal/g) sweetener. In 2001, erythritol was accorded GRAS status (GRN 000076) under FDAs GRAS notification policy. Maximum beverage use is 3.5%.



(36)

D-Tagatose. D-Tagatose (37) is a ketohexose that only differs from D-fructose [CAS: 57-48-7] at the C-4 position. At this chiral carbon, it is a mirror image between the two ketohexoses. Commercial production of D-tagatose starts with lactose recovered from whey: A waste product from cheese making. Lactose is hydrolyzed into galactose and glucose via lactase enzyme isolated from microorganisms, eg, *Aspergillus oryzae*. After separation from glucose, D-galactose is isomerized into D-tagatose via calcium hydroxide complexation followed by neutralization with acid. D-Tagatose imparts a sweetness of same intensity as sucrose, but with only a fraction of calories [1.5 kcal/g (6.27 kJ/g)]. D-Tagatose was accorded GRAS status in 2001 (GRN 000078). The maximum usage in beverage is 1%. See also **Tagatose**.

D-Fructose

Sweetness Enhancers, Inducers, and Inhibitors

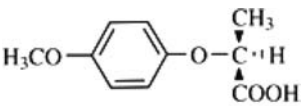
Enhancers and Inducers. A sweetness enhancer is defined as a compound that imparts no sweet taste by itself, but when combined with a sweetener in small quantities, it increases sweetness intensity. A true sweetness enhancer has yet to be found. However, in 2005, Senomyx, a biotechnology firm in California, claimed to have identified up to three chemicals capable to cause x % sugar solution to taste like an $x + n$ % solution.

A good sweetness inducer, miraculin [CAS; 143403-94-5] or [CAS: 125267-18-7], is known. Miraculin is a glycoprotein found in the fruit (called Miracle Fruit) of a West African shrub, *Richardella dulcifica*. By itself, miraculin imparts no sweetness. When activated in the mouth by acidic substances, however, a sucrose-like sweetness is perceived. Thus, sour lemon, lime, grapefruit, rhubarb, and strawberry taste sweet when combined with miraculin. The taste conversion effect can last an hour or longer.

In 1974, a petition for affirmation of the GRAS status of miracle fruit was submitted by the Miralin Company, mainly based on the fact that miracle fruits have been consumed by humans since before 1958. In 1977, the petition was denied by the FDA. However, miraculin remains a research curiosity. Its structure was elucidated in 1989. Another protein, curculin [CAS: 151404-13-6], has also been reported to exert a sweet-inducing activity similar to miraculin.

Inhibitors. Sugar is used in large quantities in fruit jams as a preservative. The strong sweetness, however, prevents fruity flavors from being noticed. For these and other foods that must use a large amount of sugar for purposes other than sweet taste, there is need for a sweet-taste inhibitor.

Lactisole [CAS: 13794-15-5], the sodium salt of racemic 2(4 methoxyphenoxy)propionic acid, is a sweet-taste inhibitor marketed by Domino Sugar. It was affirmed as a GRAS flavor (FEMA no. 3773). At a concentration of 100–150 ppm, lactisole eliminates the sweet taste of a 10% sugar solution. This inhibition appears to be receptor related because lactisole also inhibits the sweet taste of aspartame. The (*S*−) enantiomer [CAS: 4276-74-8] (38), isolated from roasted coffee beans, is the active isomer; the (*R*+) enantiomer is inert.



(38)

Several natural products, eg, gymnemic acid [CAS: 122168-40-5] and ziziphin [CAS: 73667-51-3], have also shown sweet-inhibiting activities. These are not allowed for foods in the United States, however.

Sweeteners in Formulating and Processing

In using low-calorie sweeteners in various food products, the problems are not limited to flavor, but often much more importantly involve texture, acidity, storage stability, and preservability, among others. Acceptable

nonnutritively sweetened products cannot be developed by the simple substitution of artificial sweeteners for sugars. Rather, the new product must be completely reformulated from the beginning. Three examples follow.

Jams, Jellies, and Preserves. Traditional products in this category contain 65% or more soluble solids. In low-calorie analogs, soluble solids range from 15% to 20%. Under these circumstances, commonly used pectins (high methoxyl content) do not suffice. Thus, special LM (low methoxyl) pectins must be used, along with additional gelling agents, such as locust bean gum, guar gum, and other gums and mucilagenous substances, some of which may require some masking. In the absence of sugar, a preservative, such as ascorbic acid, sorbic acid, sorbate salts, propionate salts, and benzoates, usually is required to the extent of about 0.1% (weight).

Soft Drinks. In addition to providing sweetness, sugar also functions to provide mouthfeel and to stabilize the carbon dioxide of soft drinks. To contribute to mouthfeel, the use of hydrocolloids and sorbitol has been attempted with limited success. Hydrocolloids also help to some degree with the problem of carbonation retention, but the principal solutions to this problem involve avoiding all factors which contribute to carbonation loss. Thus, the requirement for very well filtered water to eliminate particulates as possible nucleation points; any substances that promote foaming must be avoided; any emulsifying agents used in connection with flavoring agents must be handled carefully to avoid foaming; carbonation should be carried out at low temperature (34 °F; 1.1 °C); and trace quantities of metals must be absent from the water.

Bakery Products. These foods are among the most difficult as regards the use of artificial sweeteners. A listing of the functions of sugar in baked goods beyond that of providing sweetness is indicative of these problems. Sugar contributes to texture in forming structures, in providing moist and tender crumbs by counteracting the toughening characteristics of flour, milk, and egg solids. In the emulsification process required to retain gas during leavening, sugar is an effective accessory agent. Ingredients frequently used in bakery products to compensate for the absence of sugar include carboxymethylcellulose, mannitol, sorbitol, and dextrins, but, generally, these have not been very satisfactory — either to processor or consumer. This remains a large area of challenge for the food processors and ingredient manufacturers.

Sweet-Taste Transduction Mechanisms

Scientific curiosity and commercial interests in developing new potent sweeteners have driven efforts to learn how sweet taste is initiated at the taste bud level on our tongues, to the biochemical events in the taste receptor cell that transduce the receptor–stimulus binding recognition process into a cellular depolarization. This cellular excitation releases neurotransmitter onto the innervating sensory nerve, changing its firing rate, sending the taste signal to the brain. For decades, scientists debated the existence of sweet receptors. On the one hand, the existence of potent sweeteners as well as a sweet inhibitor means there must be specific sweet receptors. On the other hand, low potency of carbohydrate sweeteners seems to indicate a sweet taste initiation without binding with a receptor. The recent discovery of a sweet taste receptor, namely, T1 R2/T1 R3, appears to give the receptor proponents an upper hand[1].

Starting in the 1960s and 1970s, the binding space of a putative sweet taste receptor was under empirical study. Schallenberger and Acree proposed the "A-HB" theory to explain the structural features of sweet carbohydrates [Shallenberger, 1993]. The "A" denotes a hydrogen acceptor and "HB" represents a hydrogen donor. Kier added a third site "Y", a hydrophobic site or hydrophobic cluster, to show enantiomeric specificity of more complex sweeteners. Since then, numerous modifications and additions have been made by other scientists. Tinti and Nofre's multipoint attachment theory would appear to have reached an entropic high point by suggesting an eight-point model shown in Figure 5 [Rohse, and Belitz, 1991]. Purportedly, sucrononic acid [CAS: 116869-55-7] (39), the most potent sweetener (200,000 times) known to mankind and neotame were the fruits of this model. While these and other models were refined and tested, such activity did not bring us closer to discovering the actual receptor itself.

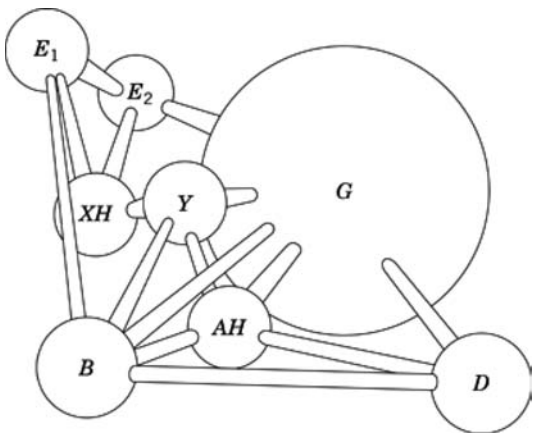

Fig. 5. Sweetener receptor binding sites postulated by Tinti and Nofre, where *B* is an anionic group,eg,CO_2^-, SO_2^-, or CN_4^-; *AH*,a hydrogen-bond donor group, eg, NH or OH; *G*, a hydrophobic, hydrocarbon group; *D*, a hydrogen-bond acceptor group, eg, CN, NO_2, or Cl; *Y*, E_1, and E_2 are hydrogen-bond acceptors, eg, CO or halogen atoms; and *XH* is a hydrogen-bond donor group, eg, NH or OH. (Courtesy of American Chemical Society.)

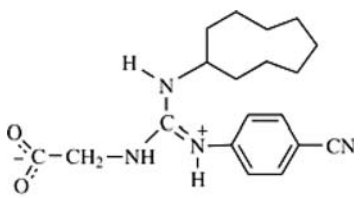

(39)

The advancements of molecular biology have led to the identification of the sweet taste receptor. In 1999, Hoon and coauthors from Zucker and Ryba's laboratories reported the cloning and characterization of two class C, family three proteins from rat. Their expression in taste buds and their topographical restriction to specific areas of the tongue led them to claim these as taste receptors, designated as TR1 and TR2. As class C, family 3 receptors, both are members of the large superfamily of G (guanosine triphosphate)-protein coupled receptors (abbreviated as GPCR), characterized by the presence of seven transmembrane segments, a number of conserved cysteine residues in the extracellular domain and several short sequence motifs dispersed throughout the molecule. The fact that the gene for TR1 was expressed almost exclusively in cells of fungiform papillae on the anterior tongue surface and that it was at least near to a region of a chromosomal locus known to affect taste preference for sweet (called the Sac locus) led the authors to claim that TR1 was the sweet receptor. In addition, since they reported that TR2 was expressed exclusively in the posterior taste buds, it was assumed to be a bitter receptor. These specificity judgments were made on the false assumption that the posterior tongue was almost exclusively sensitive to bitter while the anterior was sensitive to sweet. The claims for modality specificity were soon found to be false. In fact, it would be found that TR1 (later renamed as T1 R1) is part of an amino acid taste receptor while TR2 (later renamed as T1 R2) is part of the sweet taste receptor.

As discovery of more taste receptors was reported by many other groups, nomenclatures changed to avoid confusion and to give a common abbreviation designation to receptors of related structural classes. The taste receptors first identified by Hoon and co-workers, having long extracellular domains, were hereafter to be referred as the T1 R family of taste receptors, falling into family 3 of Class C proteins. The bitter receptors reported by Chandrashekar and co-workers all have short extracellular domains, are known as the T2 R family. They are Class C receptors of family 1.

The third member of the T1 R family, T1 R3, was identified and characterized by seven laboratories soon after the Sac locus of the human genome

[1] The author is in debt to J. G. Brand at Monell Chemical Senses Center, Philadelphia, for his valuable advice and assistance in preparation of this section.

was sequenced [Bachmanov; Kitagawa; Max; Montmayeur; Nelson; Sainz; and Li Refs.]. T1 R3 was found to be the pivotal receptor, as it was soon realized that both the sweet receptor and the amino acid "umami" receptor were, presumably, heterodimers of members of the T1 R family. The sweet receptor is T1 R2/T1 R3, and the umami receptor is T1 R1/T1 R3. The discovery of receptors for sweet, umami, and bitter tastes will undoubtedly propel more research toward better understanding of how human taste transduction is initiated.

There is evidence to suggest that the binding of sugars to the sweet GPCR activates several secondary messenger cascades including those generating the rapid production of cyclic-GMP and the inositolpolyphosphate/diacetylglycerol family of compounds, and the slower accumulation of cyclic-AMP [Krizhanovsky, 2000]. This generation of second messengers presumably activates protein kinases that, in turn, alter the activity of potassium channels and allow the influx of calcium ions from extracellular space. These events lead to the depolarization of the cell and the release of neurotransmitter [Brand, 1994]. It was reported that some sweeteners were able to block their own sweet taste signal termination mechanism, which might explain their sweet aftertaste lingering effect [Zubare-Samuelov, 2005].

The nerve fibers that innervate taste bud cells respond to sweet stimuli also respond to sour or bitter or salty. The arguments between those scientists who favor a direct, or "labeled line" theory, and those favoring a mixed, or "across fiber pattern" theory continue to enliven the field. It is hoped that molecular biology can help resolve this division as well as many unknowns in the complicated sweet, and indeed all tastes, system.

THOMAS D.LEE, PepsiCo

SWEETGUM TREE. A relatively large American tree (*Liquidambar styraciflua*). The tree achieves its largest stature in the south Atlantic states. The mature tree rises straight up on a tall trunk that is usually free of branches for up to 70 feet (21.3 meters) above ground. In the immature tree, the head is narrow and pyramidal. As the tree matures, the head becomes irregular when not pruned. The leaves are star-shaped (5 lobes), glossy, dark, and rather thick. They turn into many brilliant colors in autumn. The flowers are quite inconspicuous. Brown and twisted seed capsules tend to hang by long stalks through most of winter. The wood has a tendency to warp and is difficult to season; otherwise it would rival black walnut for working. Sweetgum trees are known in Asia (*L. orientale*).

The record sweetgum tree growing in the United States is located in North Carolina. As compiled by the American Forests, this specimen has a circumference (at 4.5 feet; 1.4 meters above ground level) of 178 inches (452 cm), a height of 136 feet (41.5 meters), and a spread of 66 feet (20.1 meters).

SWEETNESS ENHANCERS AND INDUCERS. See **Sweeteners**.

SWEETNESS INHIBITORS. See **Sweeteners**.

SWEET POTATO *(Ipomoea Batatas; Convolvulaceae).* The plant is a trailing perennial, the stems of which twine in counter-clockwise direction around supporting objects. These stems arise from much-thickened roots, which are rich in starch. In cultivation many varieties have been developed, with many different leaf shapes. Dark green, heart-shaped leaves with shining surface occur in several varieties, while in others the leaves are variously lobed and dissected. The flowers, seldom produced in plants grown in northern latitudes, are about 2 inches (5 centimeters) across,

purple, and borne either singly or in small axillary cymes. The fruit is a capsule.

Various methods of propagation are employed. Small roots may be planted whole, adventitious buds soon forming and giving rise to shoots which appear above the ground in about four weeks. Root cuttings from growing plants may also be used, especially in regions where the growing season is long. On occasion stem cuttings may be used, but necessarily demand a long growing season and reach maturity very late in the season. Seed may be grown, but germination is slow and uneven, and the product not uniform.

The sweet potato is an American plant, a native of the West Indies and Central America. In cultivation it has gradually spread out of tropical lands, new varieties being developed to suit new localities. At present the crop is grown as far north as Cape Cod.

The principal use of the sweet potato is for human consumption, although some are fed to swine. The vines are frequently used as stock food. From the roots, starch, flour, glucose, and alcohol are extracted, to a limited extent.

Sweet potatoes are frequently called yams. This application of the name yam to the sweet potato is confusing, since the true yam is an entirely different plant, *Dioscorea alata* (*Dioscoreaceae*), widely grown in tropical lands for its edible tubers, which are rich in sugar, watery, and soft when cooked. The flowers are white. Propagation is mainly by cuttings of tubers, each containing one or more eyes, or small buds, such as are found in the white potato tuber. Yams are widely used as food.

Another species of *Ipomoea, I. purpurea*, is the Morning Glory, frequently cultivated for its showy flowers.

SWIFT GAMMA-RAY BURST MISSION. See **Explorers Program**; and **Space Science Missions: Universe**.

SWIFT (Lizard). (*Reptilia, Squamata*). A lizard. The name is applied without scientific accuracy to some of the iguanas, including small species of two different genera. Most of these lizards occur in the southwestern United States and Mexico but one species, the pine or fence lizard, *Sceloporus undulatus*, is found as far north as Michigan, New Jersey, and Oregon.

SWIFTS AND HUMMINGBIRDS *(Aves, Apodiformes).* The swift is a small bird with a short wide beak and long slender wings. The swift is superficially like the swallows, but is more closely related to the hummingbirds. The numerous species of swifts are widely distributed in both hemispheres, five species occurring in North America. The common chimney swift, *Chaetura pelagica*, which has abandoned its original habit of nesting in hollow trees to occupy chimneys, is both widely distributed and abundant. The remaining species are found only in the far West and Southwest. The swift makes its nest of various materials cemented together and fastened to their support with saliva. One species of the Oriental region uses the secretion alone, without foreign materials. The nests of this species are attached to the walls of caves and are the famous edible bird nests of Chinese epicures.

The hummingbird is a small bird of the New World whose wings are moved so rapidly in flight that they produce a low-pitched sound. The hummingbird is capable of hovering in one spot in the air, and habitually poises before flowers which are visited for nectar and insects. The wings may beat up to 90 times per second. There are about 320 species of hummingbirds, many of these occurring in the northern Andes of South America. However, hummingbirds range from Alaska southward into much of the South American continent. They are found up to the snow line, 16,000 feet (4,800 meters), in Ecuador. The hummingbird has short legs, small feet, narrow wings, and long feathers. The bill may be from $\frac{1}{3}$ to 5 inches (0.8–13 centimeters) in length, depending upon the species. It usually is straight. The tongue is specialized and tube-like. The voice is comprised of a weak chippering sound. The nest is very small, cup-like, built of plant fibers and spiderwebs, and lined with down. The nest opening is only about 1 inch (2.5 centimeters) in diameter. There are usually two white eggs.

The hummingbird exhibits rather brave behavior around homes and people, wherever food is put out for them, or where flowers are in bloom. The bird can appear and disappear from the scene with great rapidity. The male hummingbird shows no concern for family affairs, leaving the nest building care and feeding of the young to the female. The female is often quite pugnacious when watching over her eggs and young, and can be quite dominating in terms of other hummingbirds when they encroach on a favorite feeding cup or flower bed. A few species of hummingbirds hibernate in winter. The ruby-throated hummingbird is one of the few species that inhabits the eastern United States. See Fig. 1. The coquette is one of a group of species found from southern Mexico to southern Brazil. These birds are distinguished by the crested head and conspicuous frills at the sides of the neck. See also **Apodiformes**.

Fig. 1. Ruby-throated hummingbird. (*Harrison.*)

SWINE *(Mammalia, Artiodactyla).* Pigs, boars, hogs, and peccaries comprise one of the more primitive groups of the order *Artiodactyla* (even-toed hoofed animals). The group is not large in terms of identifiable species in the wild, as contrasted, for example, with the antelopines and even the bovines, but because they are so highly valued in terms of the domestic breeds, they do comprise an extremely large population group of mammals.

Pigs are native to the warmer parts of Europe and Asia, the Oriental region, and Africa. None are attributed to originating in North or South America, although the closely related Peccaries have inhabited these continents for many, many centuries. Pigs are not ruminants, i.e., they do not chew their cuds. They all dig with their muzzles and have a preference in nature for vegetable matter. They are characterized by having large litters. There are certain misconceptions concerning pigs that should be clarified. In general, these animals are not at all stupid as sometimes portrayed, but are very intelligent and rate only second to the Great Apes among the mammals, except humans, for their mental abilities. By nature, they are not dirty. When in the wild and left to their own habits, these animals are exceptionally orderly and clean. Thus, likening a person to a pig really should not be considered uncomplimentary. It is true that most species of *Swine* enjoy mud wallows where they go to cool off, to remove external parasites from their bodies, and to cleanse themselves. Mud, as some beauticians acclaim, is an excellent cleaner, containing helpful antibiotics. The pig in captivity that wallows in mud that is littered with excrement, rotting garbage, etc., does not do this out of choice. In the wild, these animals never excrete in their mud wallows.

In connection with the domesticated pigs, certain terminology often requires clarification. The terms *pig* and *swine* are generally considered synonymous in most parts of the world, but in the United States, swine usually refers to pigs that are under three months of age. In England, Canada, and Australia, pigs are swine of any age or weight. Informally, untamed, wild pigs are sometimes referred to as *wild swine*. Adult animals are often referred to as hogs, particularly the marketable and commercial animals. Hog also refers to a castrated boar. A *gilt* is a young female pig, often referring to an animal with its first litter. A *sow* is an adult female pig. A *boar* is a well-developed male used for breeding service. A *boar pig* is a male animal under breeding age (usually less than six months old). A *stag* is a male animal that has been castrated in maturity — after

the tusks, shields, enlarged sheath, crest, and other characteristics have developed. A *barrow* is a male animal that has been castrated before sexual characteristics have developed. A *shote* is an immature animal of either sex.

There are over 400 breeds of domestic pigs. Some of the more important are listed here. *Berkshire* (Fig. 1), originated in England and Japan. It is of medium size, black, with white on face, legs, and tail tip. *Chester White* (Fig. 2) originated in Chester County, Pennsylvania. The animal has a pink skin and is highly regarded for its lard. *Duroc* originated in New York State, is of red coloration and considered an excellent pig for large-scale production. *Essex* is black with white saddle on shoulder, legs, nose, and tail. *Gloucestershire* originated in England, is lop-eared, white with black spots, and is highly considered for bacon and cross breeding. *Hampshire* is derived from the Saddleback and appears much like it; it is highly regarded for bacon. *Hereford* is red with white head, a good producer. *Iberian* is a red-colored animal with short ears; it resembles pigs of medieval times. It is of no commercial importance outside Spain and Portugal. *Landrace* is a white animal with lop ears, popular in Denmark, Germany, Norway, and Sweden. This breed was exported from Sweden to England in 1953. It is a highly regarded breed. The bacon from these animals is often called Wiltshire bacon. *Cornwall* is an all-black animal with lop ears; it originated in England and is mainly raised for bacon and cross-breeding. *Mangalitza* is a white pig, is much like the Chester White, but smaller and dishfaced. *Pietrain* originated in Belgium, is lop-eared and off-white color. This breed has attracted much attention since 1960 and essentially has been confined to Belgium, France, England, Denmark, and the Netherlands. *Poland China* (Fig. 3) originated in Ohio (Warren and Butler counties). It is a very large animal, black with white face, feet, and tail tip, and drooping ears. *Spotted Poland China* originated in Indiana. It is much like the Poland China except with white spots over body. It is an excellent lard producer. *Tanworth* originated in England and is found in Canada, Australia, and New Zealand. It is golden red with long snout and erect ears. Its major use is for bacon and cross breeding. *Welch* is white with lop ears; excellent for bacon; found in Africa, France, Poland, and the former U.S.S.R. *Wessex Saddleback* is black with white saddle. It originated in England; is extensively produced in Australia. Major uses are for bacon and crossing with white boars. It was introduced into the United States several years ago as a special breed. *West French White* is lop-eared, white; a major pork producer. *Yorkshire* is one of the most widely distributed of all breeds and a good producer. It is a white animal with erect ears. Other important breeds include the *Cheshire*, *Duroc-Jersey*, *Large Black*, and *Razorback*. Breeders look for: (1) prolific sows that farrow and raise large litters; (2) animals that grow rapidly and that show economical gain during feeding periods; and (3) animals that are resistant to infection and parasites and that have carcasses that withstand handling, transporting, and processing well. In particular, boars are sought that are prolific, and have a high degree of masculinity, good disposition, and an ability to sire strong, healthy pigs. In selecting sows, the length of the body and femininity are important, particularly a well developed udder and two rows of teats with a minimum of six teats in a row.

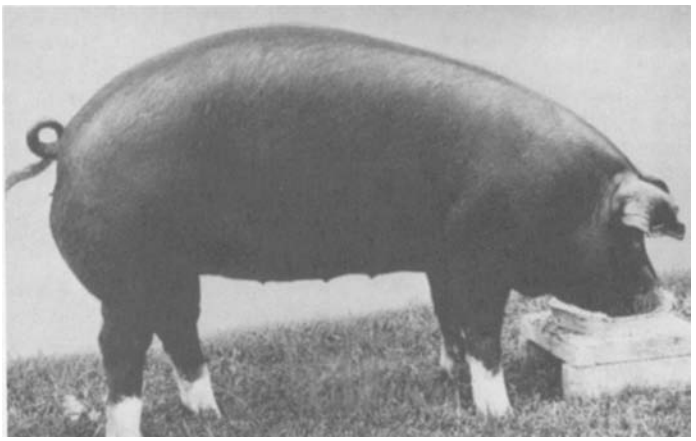

Fig. 3. Poland china gilt. (*USDA*.)

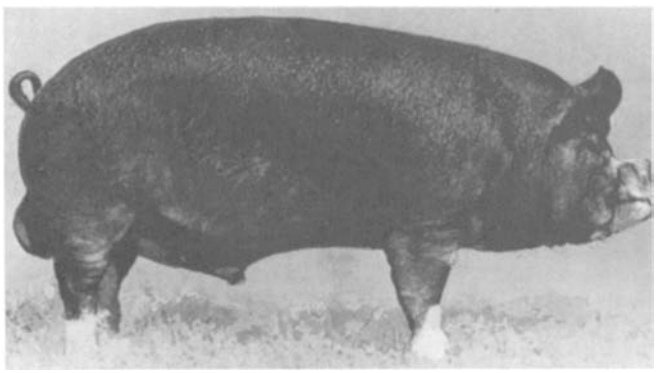

Fig. 1. Berkshire boar. (*USDA*.)

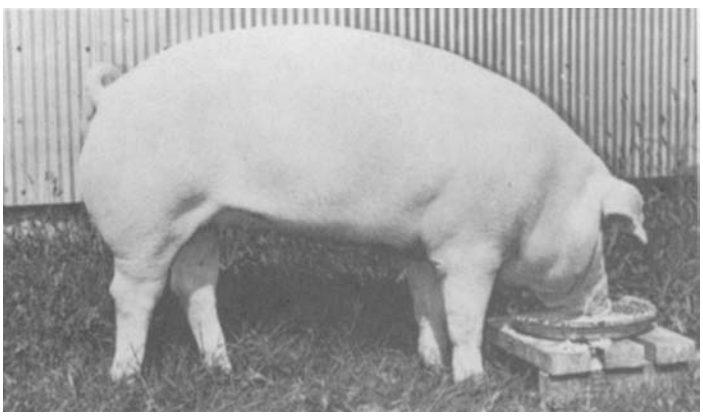

Fig. 2. Chester White gilt. (*USDA*.)

Young boars may breed at about 8 months of age. They usually will be mated to 20 to 30 sows during their first breeding season. Mature boars will be mated with from 40 to 60 sows per season. The sow's period of estrus (heat) is about 3 days, occurring every 3 weeks. Mating usually occurs on the second or third day. Gestation period is 114 days. A gilt will have her first litter at about one year of age.

Pigs also can be classified by the main type of product for which they are best suited. Lard producers are large of frame. Animals with longer frames are more suitable for bacon. Because of increased demands for lean meat, an animal with a lean carcass is desired. Usually white pigs require more intensive care than the colored varieties. Most of the white breeds originated in Canada and the United States. They usually are excellent lard producers.

Of the Eurasian Pigs found in the wild state, most species are found in the Oriental Region. However, the Wild Boar, of which there are many races, occurs in Western Europe, North Africa, across India and to southeast and central Asia. However, the animal is not found north of the Caspian Sea, in the U.S.S.R., or the great Asian mountain chains. They are characterized by long, pointed muzzles. Coloration is red-brown-chocolate-black. The hair is stiff and bristly. The amount of hair varies with climate. Some authorities consider the bite of the wild boar the worst of any mammal with the exception of the Killer Whale. The bite is more of a ripping than a slicing nature and is considerably worse than that inflicted by the Great Cats. The smaller Pigmy Pig is found in the Himalayas. The mature boars stand only about 1 foot (0.3 meter) high at the shoulders. On the other hand, the Giant Bornean Pig will attain a length of some 6 feet (1.8 meters), with very large heads. They are characterized by an upturned moustache.

The African Bush-Pigs and Forest-Hogs are found widely throughout that continent. The Bush-Pigs are known for their rooting abilities. These animals like to turn over fallen logs for the snakes, rats, snails, and fungi found thereunder. It is interesting to note that the Giant Forest-Hog was not discovered by naturalists until the present century. It is a giant, low-slung animal with big head and widespread ears. Warts are located below

the eyes. The body is covered sparsely with long, stiff bristles which, as the animal matures, could almost be described as spines.

The Wart-Hog is well known for its ugly appearance, characterized by a large flattened head out of which grow most unattractive warts. They are known for their erratic behavior. The Babirusa of the East Indies is a nocturnal, forest-loving beast. The males have pronounced teeth. They are known for their excellent flesh.

It is believed that the peccaries migrated to North America when there was a land bridge with Asia. The collared peccary or muskhog ranges from the southwestern United States to southern South America, and the white-lipped peccary is found only from Belize to Paraguay. The latter species is gregarious, living in large bands. Its vicious nature makes it dangerous to encounter, although a single animal is too small to trouble a human being. The collared peccary lives singly or in small groups and is inoffensive. The collared peccary attains a length of about 3 feet (1 meter) and a height of close to 16 inches (40 centimeters).

The early Chinese in America are credited with bringing the breed of domesticated true pig to the New World. This animal readily takes to the wilds and breeds with wild species. This gave rise to the feral or so-called razorback hogs of the American south.

SWORD-BEARER *(Insecta, Orthoptera)*. A long-horned grasshopper of the group known as cone-headed grasshoppers, from the conical prolongation of the head. The sword-bearer is named from the long ovipositor of the female. This organ is a slender slightly curved blade longer than the entire body. The species is found in the northern states of the United States, east of the Rockies. See also **Grasshopper**.

SYCAMORE AND PLANE TREES. Of the family *Platanaceae* (plane family), these trees are known as plane trees in Europe, but in America are more commonly referred to as sycamores or buttonwoods. To add to the confusion of nomenclature, the maples of Europe (family *Aceraceae*) of particular species, such as *A. pseudoplatanus*, are known as sycamore-maples. Plane trees are very common in Europe. At one time, it was estimated that over 60% of the trees in London were plane trees. The London plane is considered to be an early cross between the eastern plane (*Platanus orientalis*), which is native to Turkey, and the western plane (*P. occidentalis*), known as the sycamore or button wood in America. This tree is found extensively in the eastern United States, as well as in Turkey, Greece, southeastern Europe, and Asia Minor. The tree ranges from 75 to 100 feet (22.5 to 30 meters) in height, with a large trunk and broad spread. See Table 1. The bark is dark gray, peels easily, with a lighter gray color underneath. The leaf is large, smooth, coarse, and permanently lobed. The flower is unisexual, about 1 inch across. The wood of the sycamore is light yellow, with a red-brown heartwood. It is tough, close-grained, and firm. Commercial sycamore wood, when cut and quartered, appears much like oak. The surface is lustrous and takes readily to a fine polish. The wood is used for tool handles, rollers, flooring, cooperage, furniture, and veneers. Other species include *P. silver*, native to the eastern United States; *P. racemosa*, found mainly in California; and *P. wrightii*, found in the southwest United States, notably Arizona.

SYENITE. A coarse-grained, granular, therefore intrusive, igneous rock of the general composition of granite except that quartz is either absent or present in a relatively small amount. The feldspars are alkaline in character and the dark mineral is usually hornblende. Soda-lime feldspars may be present in small quantities. The term syenite was originally applied to hornblende granite like that of Syene in Egypt from whence the name is derived. Syenite is not a common rock, some of the more important occurrences being, in the United States, in New England, Arkansas, Montana, and New York State (syenite gneisses), and elsewhere, in Switzerland, Germany, and Norway.

SYLVANITE. A mineral, a telluride of gold and silver approximating the formula $AgAuTe_4$. Sylvanite is monoclinic, occurring in bladed, columnar, and granular forms as well as arborescent and branching. It is a brittle mineral; hardness, 1.5–2; specific gravity, 8.16; luster, metallic; color and streak, steel gray to yellowish-gray. This mineral is found associated with gold and tellurides of gold and silver or with sulfides such as pyrite. It is found in Rumania, Australia, Colorado and California. It was named for Rumanian Transylvania where it was first found.

Krennerite is another telluride of gold and silver with a similar composition to sylvanite, but crystallizing in the orthorhombic system. Calaverite is a gold telluride with only a small silver content.

SYLVANSHINE. An optical phenomenon in which some species of dew-covered plants become strongly retroreflective. On a warm summer evening when a beam of light, such as car headlights, illuminates dew-covered trees, the scene is reminiscent of snow-covered trees in the moonlight. Four things must be present for the sylvanshine to be seen: the proper species of tree, the proper season of the year, dew-covered leaves, and a view looking directly down the beam of light illuminating

TABLE 1. RECORD SYCAMORE TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Western sycamore (1999) (*Platanus occidentalis*)	334	848	95	29	105	32	Virginia
Arizona sycamore (1981) (*Platanus wrightii*)	283	719	114	34.7	116	35.4	New Mexico
Arizona sycamore (1999) (*Platanus wrightii*)	335	851	69	21	88	26.8	Arizona
California sycamore (1998) (*Platanus racemosa*)	344	874	94	28.7	104	31.7	California

the tree in an otherwise dark scene. The sylvanshine is closely related to the heiligenschein. See also **Heiligenschein**.

SYLVITE. A mineral, potassium chloride, KCl, occurring in cubes, or as cubes modified by octahedra. Sylvite is therefore isometric. It has a perfect cubic cleavage; uneven fracture; is brittle; hardness, 2; specific gravity, 1.9; luster, vitreous; colorless when pure but may be white, bluish, yellowish or reddish due to impurities. It is soluble in water. It is much rarer than halite and has been found as sublimates at Mt. Vesuvius and as bedded deposits at Stassfurt, Germany. Extensive deposits occur in sedimentary deposits in the Permian basin of southwestern New Mexico, near Carlsbad, in the United States.

It is used as a source of potash salts. Potassium chloride was called by the early chemists *sal digestivus Sylvii*, whence the name of the mineral.

SYMBIOSIS (Ecology). A close association between two organisms of different species in which at least one of the two benefits. The two organisms may be both plants, one may be a plant and the other an animal, or both may be animals. Three different kinds of symbiosis are recognized by ecologists:

1. *Mutualism*, the condition where both of the symbionts benefit from the association. A lichen, for instance, is a composite plant formed in actuality from two different plants. One, a fungus, gains nutrients from the alga, and the other, an alga, gains protection and an increased supply of water from the fungus. The result is a highly efficient plant structure, which can grow in places where either type of plant alone could not exist. The nitrogen-fixing bacterium, *Rhizobus leguminosum*, lives in the roots of the legumes. The bacteria are protected in the nodules which form on the roots and the legumes benefit by an increased supply of nitrates fixed by the bacteria. The pollination of flowers by insects is an example of a more loosely knit mutualistic association, involving plants and animals. The rhinoceros and the tick bird provide a good example of mutualism among two higher animals. See Fig. 1. The tick bird picks the ticks off the rhinoceros and gets food, and the rhinoceros gets rid of its ticks. Also, the tick bird has much keener eyesight than the nearsighted rhinoceros and gives warnings in times of danger by jumping up and down and uttering shrill cries.

Fig. 1. An example of mutualism: a tick bird on the back of a rhinoceros. (*A.M. Winchester*.)

In some cases, the mutualism is *facultative* — either organism can exist without the other; but in other cases, the association is *obligatory* — neither organism can live without the other. An example of the latter is the association of termites and certain protozoa that live in their intestines. The termites eat wood, but have no enzymes for digesting wood. The protozoa have such enzymes, but cannot live on wood unless it is first chewed to a pulp by the termites. Termites die if the protozoa are killed by antibiotics and the protozoa die when they leave the body of the termites. The Smyrna fig and a tiny wasp are also entirely dependent upon one another. The fig can produce neither fruit nor seeds unless this species of wasp enters the young flower and accomplishes cross-fertilization. The wasps die without the fig because the eggs are laid within some of the figs.

2. *Commensalism*. When one symbiont benefits from the association and the other is neither harmed nor benefited. The shark sucker, *Remora*, which attaches itself to sharks and gets a free ride as well as some share of the food killed by the shark, benefits from the association, but the shark is not affected one way or another. Many of the bacteria living in the human mouth and intestine are also classed as commensals. The green hydra, *Chlorohydra viridisima*, is green in color because there are small one-celled algae in its gastrodermal cells. The hydra neither benefits nor is harmed by the presence of these plants; it gets along just as well without them. Hence, this is a case of commensalism.

3. *Parasitism*. When one symbiont benefits and the other is harmed. A tapeworm living within the intestine of a vertebrate animal is a good example of a parasite, since the host animal is definitely harmed. The tapeworm is an endoparasite, since it lives within the body of another animal; ectoparasites, such as fleas, leeches, and ticks, live outside the body and have a more temporary association.

SYMMETRIC. Arranged in accordance with a certain similarity with reference to a certain geometrical entity or position, which may be a point (center or point of symmetry), a line (axis of symmetry), or a plane (plane of symmetry), etc.

SYMMETRIC FUNCTION. A function whose value remains unchanged under any permutation of its independent variables. That is, any function $f(x_1, x_2, \ldots, x_n)$ not affected by an interchange of any x_i and x_j. If these are roots of an algebraic equation

$$x^n - c_1x^{n-1} + c_2x^{n-2} - \cdot \pm c_n = 0$$

then

$$c_1 = \sum x_i, \quad c_2 = \sum x_i x_j, \quad c_3 = \sum x_i x_j x_k \ldots$$

are the elementary symmetric functions, where the summations are extended over all distinct products of distinct factors, the x_i being themselves considered independently varying. Any rational symmetric function of the x_i is a rational function of the c_i.

See also **Permutation**.

SYMMETRY. Arrangement of the constituents of molecule in a definite and continuously repeated space pattern or coordinate system. It is described in terms of three parameters called elements of symmetry. (1) The center of symmetry, around which the constituent atoms are located in an ordered arrangement; there is only one such center in a molecule, which may or may not be an atom. (2) Planes of symmetry, which represent division of a molecule into mirror-image segments. (3) Axes of symmetry, represented by lines passing through the center of symmetry; if the molecule is rotated it will have the same position in space more than once in a complete 360-degree turn, e.g., the benzene molecule with 6 axes of symmetry requires 60-degree rotation to return to its identical position.

See also **Stereochemisty**.

SYMMETRY (Axis of). A line drawn within a body or within a set of points in such a location and direction that a rotation of the body through an angle $(2\pi/n)$ radians about the line as an axis, n being an integer, greater than unity, results in a configuration indistinguishable from the original configuration. A body or set having such an axis is said to have n-fold symmetry, and the line is said to be an n-fold axis. Thus a line through the center of a cube and parallel to a face is a fourfold axis of symmetry, while a body diagonal of the cube is a twofold axis.

SYMMETRY (Center of). A symmetry element such that any line through it will intersect the crystal at equal distances on either side. Schoenflies symbol, subscript i.

SYMMETRY (Plane of). A plane passed through a body or through a set of points in such a location and direction that the reflection of all points in the plane results in a configuration indistinguishable from the original configuration. Thus, a cube has many planes of symmetry through its center, including those parallel to the faces and those passing through face diagonals.

SYMMETRY (Zoology). The arrangements of the parts of animal bodies in relation to centralized axes. The bodies of some one-celled animals are asymmetrical and of others, notably the Heliozoa, spherically symmetrical with the hard parts of the skeleton radiating in various directions from a common center. By far the most common forms of symmetry, however, are those known as radial and bilateral.

Radial symmetry is especially common among the sessile animals such as sea anemones and the related jellyfishes whose movements are weak. These animals have a principal axis passing through the mouth from which similar structures extend on several radii. The same form of symmetry appears in the echinoderms although these animals begin life as bilaterally symmetrical larvae. The radial symmetry of the adult accompanies sluggish movement and in some forms food-securing habits like those of sessile animals.

Bilaterally symmetrical animals have similar halves flanking a median plane in the principal axis of the body. Sense organs are concentrated near the end that goes first in locomotion, forming a head in which the mouth opens as a rule. This end of the body is the cephalic end, in contrast with the opposite caudal end where the tail is attached in the vertebrates. The originally upper and lower or dorsal and ventral surfaces are also differentiated, since the animal rests on the latter while the former is exposed to surrounding influences, and the sides of the body are known as right and left. This type of symmetry prevails in all actively moving animals.

The value of each type of symmetry is clearly correlated with the mode of life in which it is found. Sessile animals receive food and are subjected to dangers only when the responsible factors approach under their own powers of locomotion or on currents in the water. It is an advantage to the animal to be able to perceive such factors as easily in one direction as another. Bilaterally symmetrical animals move about in search of food. Hence, the end of the body that normally goes first has the chief need of powers of perception, while the upper and lower surfaces are exposed to different environmental conditions and the sides are similar in their contacts.

SYMPHYLA. Small and rare animals living in moist debris at the surface of the ground. They are related to primitive insects and centipedes and are usually regarded as a class of the phylum *Arthropoda*. They have a pair of antennae but no eyes. The segments of the body are well marked, bearing 11 or 12 pairs of legs. The animals breathe by means of tracheae.

SYNAPSE. The association between nerve cells of animals above the level of coelenterates. In the latter, the nerve network is composed of cells whose processes are structurally connected, but in higher nervous systems, the fine terminal branches of nerve processes merely come into close contact with those of adjacent cells.

Synapses can be defined as regions of structural specialization between two or more neurons. Since, as a rule, synapses conduct impulses only unidirectionally, some type of asymmetry might be expected in their structure — and there being regions of apposition between adjacent neurons, they may involve almost any parts of the two neuronal surfaces. The most common type of synaptic junction is that between an axon and a dendrite or a soma, the efferent fiber being expanded at its end to form a small bulb. When a nervous impulse reaches the terminal bulb of the axon, acetylcholine is liberated and depolarizes the secondary neuron, thus creating a nervous impulse throughout its length. Cholinesterase at the synapse, however, quickly inactivates the acetylcholine and prevents it from stimulating the dendrites of the secondary neuron more than once.

In the intact nervous system, the impulses normally travel only from the dendrites to cell body or soma, to the axon and finally to the end bulb.

How neurons form synapses in the development nervous system and distinguish appropriate from inappropriate synapses remains one of the central, unsolved problems in neurobiology. However, it has recently been found that cyclic AMP (adenosine $3'$: 5-cyclic phosphate) effects synaptogenesis by regulating the expression of voltage sensitive Ca^{2+} channels suggesting that cyclic AMF affects post-translational modification of some glycoproteins and the cellular levels of certain proteins.

The nervous system mediates adaptive response of an organism to environmental changes or to changes in the organism itself. To this end, the nervous system is uniquely modifiable or plastic. Neuronal plasticity is largely the capability of synapses to modify their function, to be replaced, and to increase or decrease their number when required. Neuronal plasticity is maximal during development and is expressed after maturity in response to external or internal perturbations, such as changes in hormonal levels, environmental modification, or injury.

SYNCHRONOUS. A synchronous operation takes place in a fixed time relationship to another operation or event, such as a clock pulse. See also **Asynchronous**. When a set of contacts is sampled at a fixed time interval, the operation is termed synchronous. This situation is to be contrasted with that where the contacts may be sampled randomly under the control of an external signal. Generally, the read operation of a main storage unit is synchronous. The turning on of the X and Y selection drivers and the sampling of the storage output on the sense line are controlled by a fixed-frequency clock.

SYNCHRONOUS COMPUTER. A computer in which the starting time of every ordinary operational cycle is controlled by signals which occur at regular intervals.

SYNCLASTIC SURFACE. A surface, or portion of a surface, on which the two principal radii of curvature at each point have the same sign. Also called *surface of positive total curvature*.

SYNCLINE. The syncline is a structure in which the strata are bent downward in an inverted arch, the sides of which are designated the limbs. The syncline may be a broad open fold or tightly compressed with steep dips, and pitch either upward or downward.

SYNCOM COMMUNICATION SATELLITES. Syncom 2 (Synchronous Communications Satellite) was the first geosynchronous satellite. Although the period was 24 hours and the spacecraft remained at a nearly constant longitude, the orbit was inclined at 33 degrees so it was not truly geostationary but moved in an elongated figure eight pattern 33 degrees north and south of the equator. Syncom 2 was an experimental communications satellite placed over the Atlantic Ocean and Brazil at 55 degrees longitude. It began regular service on August 16th. It demonstrated the feasibility of geosynchronous satellite communications. Voice, teletype, facsimile,

and data transmission tests were successfully conducted between the Lakehurst, New Jersey ground station and the USNS Kingsport while the ship was at sea off the coast of Africa and television transmissions were relayed from Lakehurst to the telstar ground station at Andover, Maine. The Syncoms were the forerunners of the Intelsat series of satellites. See also **Intelsat (International Telecommunications Satellite Organization (ITSO)**.

Syncom 2 was launched into a high altitude orbit from Cape Canaveral on 26 July 1963. Six hours after launch the apogee motor was fired to place the spacecraft in an orbit ranging from 34,100 to 36,440 km (21,189 to 22,643 miles) with a drift rate of 7.5 degrees per day eastward. The apogee was then raised and the drift rate changed to 4.5 degrees per day westward toward the desired position over 55 degrees longitude. After two weeks of drifting the nitrogen jets were pulsed in a series of four firings to slow the spacecraft to near-zero drift on August 16, followed by an alignment maneuver. The final orbit was geosynchronous with an inclination of 33 degrees. Operations were turned over to the Department of Defense on 1 January 1965.

The Syncom satellites were 71 cm (28 in) diameter, 39 cm (15 in) high cylinders. The fully fueled mass of the spacecraft was 68 kg (150 lbs). See Fig. 1. The nozzle of the solid propellant apogee motor (1000-lb-thrust designed to impart a velocity increase of 1431 meters/sec) extended from the bottom of the cylinder and a co-axial slotted array communications antenna from the top. The total height including the nozzle was 64 cm (25 inches). The radial exterior was covered with 3840 P-on-n silicon solar cells which provided direct power of 29 watts the 99 percent of the time the spacecraft was in sunlight. Nickle-cadmium rechargeable batteries provided power when the spacecraft was in the Earth's shadow. No active thermal control was required. Most of the central interior of the spacecraft consisted of the tanks and combustion chamber for the apogee motor, around this were arranged two hydrogen peroxide and two nitrogen tanks and the electronics. Attitude and velocity control was provided by nitrogen jets to align the spin axis and hydrogen peroxide jets to position the satellite. Each system had two jets, one parallel and one perpendicular to the spin axis.

Syncom employed a redundant, frequency-translation, active repeater communication system designed to handle one two-way telephone or 16 one-way teletype channels. The dual transponders utilized 2-watt traveling wave tubes. Selection of receiver and transmitter was made by ground command. One receiver had a 13 megacycle bandwidth for TV transmission, the other a 5 megacycle bandwidth. The receiving gain was 2 dB through the slotted dipole antenna. Signals were received on two frequencies near 7360 megacycles and retransmitted on 1815 megacycles. The slotted dipole transmitting antenna radiated a pancake-shaped beam 25 degrees wide with its plane perpendicular to the spacecraft spin axis. There were also four whip antennas oriented normal to the spin axis for telemetry and command.

Syncom 3. Syncom 3 was the first geostationary satellite. (The earlier geosynchronous Syncom 2 had an orbit inclined to the equator.) It was an experimental geosynchronous communications satellite placed over the equator at 180 degrees longitude in the Pacific Ocean. The satellite provided live television coverage of the 1964 Olympic games in Tokyo, Japan and conducted various communications tests. Operations were turned over to the Department of Defense on 1 January 1965, Syncom 3 was to prove useful in the DoD's Vietnam communications.

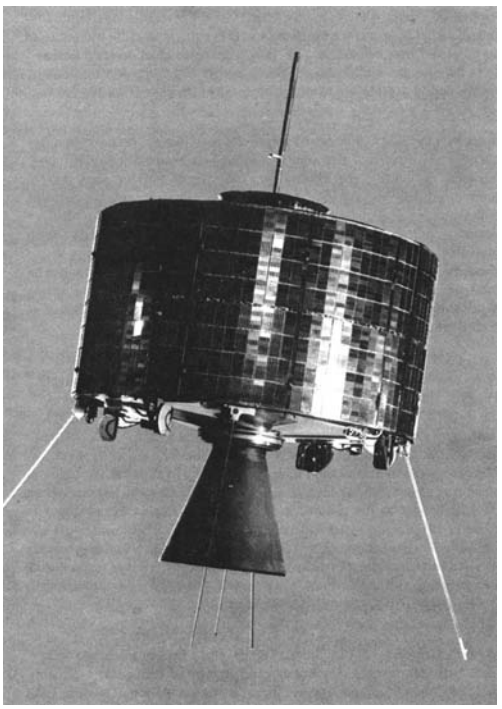

Fig. 1. Syncom Satellite. (courtesy of NSSDC).

Syncom 3 was launched from Cape Kennedy on 16 August 1964 and injected into an elliptical orbit inclined 16 degrees to the equator following a third stage yaw maneuver. The apogee motor was fired to remove most of the remaining inclination and to provide a circular near-synchronous orbit of 35,670 km × 35,908 km (22,164 mi × 22,312 mi). The spacecraft next carried out a series of attitude and velocity maneuvers to align itself with the equator at an inclination of 0.1 degrees and to slow its speed so it drifted west to the planned location at 180 degrees longitude where its speed at altitude was synchronized with the Earth. These maneuvers were completed by 23 September, and Syncom 3 was used in a variety of communications tests, including the transmission of the Olympics, transmissions between the Philippines, USNS Kingsport, and Camp Roberts, California, and teletype transmissions to an aircraft on the San Francisco-Honolulu route.

Syncom-4-1, 2, 3, 4, 5 (Leasat 1, 2, 3, 4, 5). In September 1978, the United States Navy announced a contract award to Hughes Communication Services, Inc., a Hughes Aircraft Company subsidiary, to provide worldwide communications satellite service to the Department of Defense for at least five years at each of four orbital locations. The Navy would act as executive agent on behalf of the Department of Defense. The new satellite, known as Leasat, began service in 1984. See Table 1. The system's primary user is the US Navy, with some support also provided to the Air Force

TABLE 1. LEASAT LAUNCH FACTS

Name Notes	Int'l Desig.	Date	Site	Vehicle	Orbit	Mass(kg)
Leasat 1 (Syncom 4-2)	1984-093 C	8/30/84	ESMC	STS 41D	GEO	1315
Released from STS 41D 8/31/84; 105 deg W; leased to U.S. government						
Leasat 2 (Syncom 4-1)	1984-113 C	11/8/84	ESMC	STS 51A	GEO	1315
Released from STS 51A 11/10/84; 105 deg W; leased to U.S. government						
Leasat 3 (Syncom 4-3)	1985-028 C	4/12/85	ESMC	STS 51D	LEO	1315
Released by STS 51D 4/13/85; failed to orbit and subsequently repaired by STS 51-I on 8/31/85; 178 deg E; leased by U.S. government						
Leasat 4 (Syncom 4-4)	1985-076D	8/27/85	ESMC	STS 51I	GEO	1388
Released by STS 51I 8/29/85; 178 deg E; leased by U.S. government						
Leasat 5 (Syncom 4-5)	1990-002B	1/9/90	ESMC	STS 32	GEO	7711
Deployed from STS 32 1/10/89; 177 deg W; leased to U.S. government						

and ground mobile forces (using FLTSATCOM terminals). Hughes Space and Communications Group, later known as Hughes Space and Communications Company, built the satellites. Hughes was paid $84 M per year for each operational satellite. At the end of each satellites' designed 7 year life, the Navy has the option of purchasing the satellite for $15 M. The Leasats, along with the Navy's FLTSATCOM spacecraft, are being replaced by the UFO (UHF Follow-on) spacecraft.

Leasat is 4.26 meters (14 ft) in diameter and 6.17 meters (20 ft) high with its UHF and omnidirectional antennas deployed. With its antennas stowed in the launch configuration, Leasat is 4.29 meters (14 ft) high. See Fig. 2. Total payload weight (including launch cradle) in the shuttle is 7,711 kg (17,000 lbs). Weight after separation from the shuttle is 6,895 kg (15,201 lbs), and the satellite's weight on station at the beginning of life is 1,388 kg (3,060 lbs).

Fig. 2. Leasat 1. (*courtesy of Boeing BSS*).

The satellites are spin-stabilized, with the spun portion containing the solar array and sun and Earth sensors for attitude determination and Earth pointing reference, batteries for eclipse operation, and all propulsion and attitude control hardware. The despun platform contains Earth-pointing reference, batteries for eclipse operation, and all propulsion and attitude control hardware. The despun platform contains Earth-pointing communication antennas, communication repeaters, and the majority of the telemetry, tracking, and command (TT&C) equipment.

Mechanical interface with the shuttle is achieved through a reusable cradle, with five contact points between the spacecraft and the cradle, and five contact points between the cradle and the shuttle.

Solar panel output is 1238 watts after seven years in orbit. Three 25 A-hr nickel-cadmium batteries for eclipse operation are designed for a nominal maximum 45 percent discharge. Redundancy resulting from the three-battery system permits full load support with loss of one of the batteries.

Two large helical UHF antennas provide receive and transmit capability in the UHF band (240 to 400 MHz). Telemetry, command, and the Fleet Broadcast uplink and beacon are in the "exclusive" portions of the SHF band (7250 to 7500 MHz, and 7975 to 8025 MHz). Twelve UHF repeaters provide the main communications capability.

The principal Navy Fleet Broadcast function includes an SHF uplink, and both SHF and UHF downlinks. The additional antennas for this channel are the SHF uplink and downlink earth coverage horns, which support the uplink and acquisition/timing function, respectively. The UHF downlink for Fleet broadcast is multiplexed onto the UHF transmit helix.

Mounting the antennas on deployable structures allows them to be stowed for launch, resulting in considerable savings in the cost of launching the satellite from the space shuttle. (Shuttle launch costs are based on a formula which takes into account the ratio of either weight or length of satellite cargo, whichever is greater, to the shuttle's total capacity.)

The space shuttle places Leasat in a circular parking orbit at approximately 180 miles (296 km) altitude with 28.6 degrees inclination. Ejection of the spacecraft from the shuttle is initiated when locking pins at the contact points are retracted. An explosive device then releases a spring that ejects the spacecraft in a "Frisbee" motion. This gives the satellite its separation velocity and gyroscopic stability.

Two further sets of maneuvers are required to place the satellite in its circular orbit 22,300 miles (35,744 km) over the equator within a 5 degree inclination. The first set boosts the satellite into an elliptical transfer orbit where apogee and perigee are equatorial, with apogee at synchronous altitude. The second maneuvers circularize the orbit and remove all but 5 degrees of inclination, yielding the final synchronous orbit. Because of high satellite velocity in the parking orbit, a solid fuel perigee motor is used to accomplish rapid firing. Two liquid fuel motors are used to augment the velocity on successive perigee transits, to circularize the orbit, and to remove inclination.

The Leasat spacecraft were designed exclusively for launch on NASA's space shuttle. Leasat F1 was scheduled for launch in June 1984, but the shuttle mission was aborted only seconds before liftoff. Leasat F2 became the first in the series to be launched, on 30 August 1984. Leasat F1 followed on an 8 November 1984 launch. Leasat F3 was launched on the shuttle on 12 April 1985, but did not achieve orbit when the satellite failed to start. Four months later, NASA and Hughes mounted a salvage attempt during the 27 August 1985 shuttle mission on which Leasat F4 was launched. After attaching special electronics assemblies to Leasat 3 during two days of space walks, astronauts manually launched the satellite again. The electronics allowed ground controllers to turn on the satellite and, at the end of October, fire its perigee rocket and send Leasat 3 into orbit. Leasat 4 successfully obtained orbit and was undergoing tests about a week after launch when its UHF downlink failed. The satellite was declared a loss. The fifth and last Leasat, which was built as a spare, was successfully launched in January 1990 (Table 1).

See also **Satellites (Communications and Navigation)**.

SYNCOPE. A fainting spell, in which the unconsciousness is due to a temporary cerebral anemia, i.e., insufficient circulation of blood in the brain. Differing only in degree from *true syncope* is dizziness (lightheadedness). Syncope also may occur from noncardiovascular causes, such as head injury, hypoglycemia, seizures, and hysteria.

SYNDETS. See **Detergents**.

SYNDROME. A group of symptoms characterizing or occurring in any abnormal state or disease.

SYNERESIS. The contraction of a gel with accompanying pressing out of the interstitial solution or serum. Observed in the clotting of blood, with silicic acid gels, etc. See also **Colloid System**.

SYNERGIC CURVE. A curve plotted for the ascent of a rocket vehicle calculated to give the vehicle an optimum economy in fuel with an optimum velocity. This curve, plotted to minimize air resistance, starts off vertically, but bends toward the horizontal between 20 and 60 miles (32 and 96 kilometers) altitude to minimize the thrust required for vertical ascent.

SYNGE, RICHARD LAURENCE MILLINGTON (1914–1994). Richard Synge was a British biochemist who, with A.J.P. Martin, developed the techniques of partition chromatography.

Synge was born in Liverpool on 28 October 1914. Educated at Winchester College, Hampshire, he won an Exhibition at Trinity College, Cambridge in 1933, graduated BA (1936) and PhD (1941). Under N. W. Pirie he worked on the separation of acetylamino acids. About the same time A.J.P. Martin was working on the purification of vitamin E and their common interest in separations led to the invention of liquid–liquid chromatography. Synge also suggested using a gas or vapor as the mobile phase; gas chromatography was later developed by Martin. In 1941 Synge joined Martin at the Wool Research Association laboratory in Leeds. From 1943 to 1948 he worked on the chemistry of antibiotic peptides at the Lister Institution of Preventive Medicine in London. With Martin he developed the technique of two-dimensional partition chromatography using two different mobile phases moving at right angles. He determined the structure of gramicidin-S, a simple antibiotic peptide. In 1946–1947 Synge worked with A. Tiselius in Uppsala, Sweden; from 1948 to 1967 he was administrator at the Rowett Research Institute in Aberdeen, Scotland. In 1958–1959 he worked on the isolation of the toxic fungal component sporidesmin at the Ruakura Animal Research Station, Hamilton, New Zealand. His last post, from 1967 to 1984, was at the Food Research Institute, Norwich, where he served as Honorary Professor in the School of Biological Sciences at the University of East Anglia. Synge was elected FRS in 1950; he was a Fellow of the Royal Society of Chemistry and an honorary member of the American Society of Biological Chemists. In 1951, Richard Synge shared the Nobel Prize for Chemistry, jointly with A.J.P. Martin. See also **Martin, Archer John Porter (1910–2002)**.

SYNODIC PERIOD. The synodic period of any member of the solar system is the time required for the object to go from some particular position relative to the sun as seen from the earth back to the same position. In the case of the moon, the synodic period is the time required to go from conjunction, or new moon, back to conjunction. This period of approximately 29.5 days is the original month as used by ancient astronomers in the construction of the calendar.

Since a planet is best observed at opposition, the synodic period of the planet gives the interval of time between successive positions of favorable observation. The synodic period is related to the sidereal period, i.e., the actual period of revolution of an object about the sun, by a simple relationship:

let P be the sidereal period of the object;
S the synodic period of the same object;
E the sidereal period of the earth (approximately 365.25 days);

then, for planets with orbits inside that of the earth, $1/S = 1/P - 1/E$; and for planets with orbits outside that of the earth, $1/S = 1/E - 1/P$.

SYNOPTIC. 1. In general, pertaining to or affording an overall view. In meteorology, this term has become somewhat specialized in referring to the use of meteorological data obtained simultaneously over a wide area for the purpose of presenting a comprehensive and nearly instantaneous picture of the state of the atmosphere. Thus, to a meteorologist, "synoptic" takes on the additional connotation of simultaneity.

2. A specific scale of atmospheric motion with a typical range of many hundreds of kilometers, including such phenomena as cyclones and tropical cyclones.

SYNOPTIC CHART. See **Meteorology**.

SYNOPTIC CLIMATOLOGY. The study of climate from the perspective of atmospheric circulation, with emphasis on the connections between circulation patterns and climatic differences. The common approach is to determine distinct categories of synoptic weather patterns and then to assess statistically the weather conditions associated with these patterns. The term, which refers to synchronous weather systems such as cyclones and anticyclones, originated during the 1940s when military services became concerned with the climatology of weather types and its implications for transportation. While dynamic climatology is often global in scope, synoptic climatology generally deals with hemispheric or local climates.

SYNOPTIC STATION. See **Meteorology**.

SYNOPTIC WEATHER OBSERVATION. See **Meteorology**.

SYNTHESIS (Chemical). The process of building chemical compounds through a planned series of steps (reactions, separations, etc.). Synthesis usually is the method of choice: (1) when the desired compound is not present in natural materials from which it can be isolated: (2) when the compound cannot be easily obtained from reacting readily available materials in a few simple steps; and (3) although a compound may be available within a natural complex, the economic separation and purification are prohibitive, or often in the case of biochemicals, too little natural raw material is available to meet the demand.

Even more important, synthesis plays a key role in developing new, untried chemical structures which, on paper, appear to have properties that may be of great value, e.g., a new synthetic material, a new drug, or a new fuel. Chemicals by design from prior knowledge of related materials generally are created via the route of synthesis. Further, synthesis is fundamental to broadening the base of chemical knowledge. Sometimes unexpected results occur, i.e., compounds with unusual, unexpected, and often desirable practical chemical and/or physical properties.

Because of the hundreds of thousands of organic substances already established, but many yet remaining to be "built," organic synthesis predominates. Most of the synthetics (elastomers, fibers, and other polymers, coatings, films, adhesives, and numerous other products) that have appeared during the last 30 to 40 years resulted from research involving organic synthesis. Some of the early work in organic synthesis dealt with the creation of certain fatty acids and ketones. A few examples are given to provide an insight into the workings of synthesis.

In the following examples, only the main starting ingredients and products are shown. No attempt is made to indicate byproducts or the conditions of the reactions involved:

(a) Target compound: Ethylpropylacetic acid, $(C_2H_5)(C_3H_7)CH{:}COOH$
  (1) Acetic anhydride → ethyl acetate
    (+ alcohol)
  (2) Ethyl acetate → ethyl acetoacetate
    (sodium + dilute acids)
  (3) Ethyl acetoacetate → sodium derivative of ethyl acetoacetate
    (+ sodium ethoxide)
  (4) Sodium derivative of ethyl acetoacetate → ethyl ethylpropyl acetoacetate
    (+ propyl iodide)
  (5) Ethyl ethylpropyl acetoacetate → ethylpropylacetic acid
    (concentrated alcohol and potash)

(b) Target compound: Butyl acetone, $CH_3 \cdot CO \cdot CH_2 \cdot C_2H_4$
  (1) through (3), same as given in example (a)
  (4) Sodium derivative of ethyl acetoacetate → ethylbutylpropyl acetoacetate
    (+ butyl iodide)
  (5) Ethylbutylpropyl acetoacetate → butyl acetone
    (+ dilute alcohol and potash)

(c) Target compound: *n*-valeric acid, $CH3{\cdot}CH_2{\cdot}CH_2CH_2COOH$
  (1) Potassium chloroacetate → potassium cyanoacetate
    (+ potassium cyanide)
  (2) Potassium cyanoacetate → ethyl malonate
    (+ alcohol and hydrogen chloride)
  (3) Ethyl malonate → sodium derivative of ethyl malonate
    (+ sodium ethoxide)

(4) Sodium derivative of ethyl malonate → ethylpropyl malonate (+ propyl iodide)

The compounds on the right-hand side of intermediate reactions are often called *intermediates*. See also **Intermediate (Chemical)**.

Some of the notable syntheses from the early history of the technique include:

Inorganic Syntheses

1746 Sulfuric acid (chamber process)
1800 Soda ash (Le Blanc process)
1861 Soda ash (Solvay process)
1890 Sulfuric acid (contact process)
1912 Ammonia (Haber-Bosch process)

Organic Syntheses

1828 Urea (Wohler)
1857 Mauveine (Perkin)
1869 Celluloid (Hyatt)
1877 Ethylbenzene (Friedel-Crafts)
1884 Rayon (Chardonnet)
1910 Phenolic resins (Baekeland)
1910 Neoarsphenamine (Ehrlich)
1920 Aldehydes, alcohols (Oxo synthesis)
1925 Insulin (Banting)
1927 Methanol
1930 Neoprene (Nieuwland)
1935 Nylon (Carothers)
1940 Styrene-butadiene rubber
1950 Polyisoprene

SYNTHESIS GAS. For a number of industrial organic syntheses that proceed in the gaseous phase, it is advantageous to prepare a chargestock to specification. When a mixture of gases is so prepared, the term *synthesis gas* is often used. Thus, there are several mixtures which qualify under this definition: (1) a mixture of H_2 and N_2 used for NH_3 synthesis; (2) a mixture of CO and H_2 for methyl alcohol synthesis; and (3) a mixture of CO, H_2, and olefins for the synthesis of oxo-alcohols. Ammonia synthesis gas is described briefly here.

The hydrogen required for NH_3 synthesis gas may be obtained in commercial quantities from coke oven water gas; from steam reforming of hydrocarbons; from the partial oxidation of hydrocarbon chargestocks; or from the electrolysis of H_2O. The nitrogen required may come from the introduction of air to the process, or where specifically required, pure nitrogen may be obtained from an air separation plant. Since NH_3 synthesis occurs under high pressure, it is advantageous to generate the synthesis gas at high pressure and thus avoid additional high compression costs. For this and other economic situations, coke oven gas and hydrogen from electrolysis are eliminated. This leaves hydrocarbons as the logical choice.

In the steam-hydrocarbon reforming process, steam at temperatures up to 850 °C and pressures up to 30 atmospheres reacts with the desulfurized hydrocarbon feed, in the presence of a nickel catalyst, to produce H_2, CO, CO_2, CH_4, and some undecomposed steam. In a second process stage, these product gases are further reformed. Air also is added at this stage to introduce nitrogen into the gas mixture. The exit gases from this stage are further purified to provide the desired 3 parts H_3 to 1 part N_2 which is the correct empirical ratio for NH_3 synthesis. See also **Ammonia**.

SYNTHETIC APERTURE RADAR (SAR). Some solar system objects are covered by clouds or haze, making optical imaging difficult or impossible. However, these atmospheres are transparent to radio frequency waves and can be imaged using synthetic aperture radar (SAR) instruments.

An aperture is the part of the sensor's collecting area, such as the telescope or antenna diameter. A filled aperture consists of just one aperture while a synthetic aperture consists of several units placed in formation. This formation behaves as one large aperture, "synthesized" from smaller elements. And, radar is a type of energy, similar to light. But unlike light, we can't see radar energy. It acts like sound, bouncing off surfaces and making "echoes." These echoes are "heard" by the radar antenna.

SAR instruments bounce a radar signal off the ground, then measure the strength of the signal that comes back and how long it takes. From this information, scientists can determine if the terrain high or low, wet or dry, rough or smooth. They can also tell if the surfaces are straight up and down (like walls) or slanted (like hills) and what covers the surfaces.

SYNTHETIC DIVISION. An abbreviated process, using detached coefficients, for finding the quotient of a polynomial in one variable x by a divisor of the form $x - r$, where r is a constant. The procedure may be illustrated by the polynomial $a_0x^4 + a_1x^3 + a_3x + a_4$. The results can be obtained in the following form, which should be self-explanatory:

$$\begin{array}{cccc} a_0 & a_1 & a_2 & \\ & a_0r & A_1r & \\ a_0 & A_1 = a_0r + a_1, & A_2 = A_1r + a_2 & \end{array}$$

$$\begin{array}{cccc} a_3 & a_4 & r & \\ A_2r & A_3r & & \\ A_3 = A_2r + a_3 & R = A_3r + a_4 & & \end{array}$$

The quotient is $a_0x^3 + A_1x^2 + A_2x + A_3$ and the remainder is R. A similar process applies to a polynomial of any other degree. In the general case, if the coefficient of any power of x is missing, a zero should be supplied in the appropriate place in the first line of the scheme. If the remainder in the synthetic division is zero, then the divisor is a factor of the given polynomial.

See also **Polynomial**.

SYPHILIS. Syphilis is a complex sexually transmitted disease (STD), congenital or acquired, caused by the bacterium, *Treponema pallidum*. It has often been called "the great imitator" because so many of the signs and symptoms are indistinguishable from those of other diseases. Syphilis is characterized by primary and secondary stages, during which it is highly contagious, and a noncontagious, late, or tertiary stage, marked by involvement of many organs and tissues. In the congenital form, there is no primary lesion, and late manifestations predominate.

Epidemiology. The number of cases of syphilis reported and the reporting requirements range widely from one country to the next. In most industrialized nations, the disease is reasonably well documented, but even then most health officials believe that the disease is underreported, mainly in the underdeveloped countries, as exemplified by parts of Africa. There were alarming trends of case numbers in the United States since the mid-1950s. As observed by E.W. Hook (University of Alabama, Birmingham) and C.M. Marra (American Social Health Association) in April 1992, "In the early 20th century, syphilis was a major public health problem. In the 1920s more than 20 percent of the patients in U.S. mental institutions had tertiary syphilis (general paresis). Even before the therapeutic efficacy of penicillin was described, public health measures such as serologic-screening programs and treatment through government-funded rapid-treatment centers had begun to reduce the rate of syphilis in the United States. By 1941, only 10 percent of patients in mental institutions had tertiary syphilis. These changes accelerated after World War II as penicillin became widely available. In 1979 only 162 syphilis-related admissions to mental institutions were reported, 98 percent fewer than 60 years earlier. Similarly, the number of syphilis-related deaths declined more than 50-fold between the early 1940s and the 1980s."

By the mid-1950s only about 6500 cases of primary and secondary syphilis were reported per year in the United States. In the late 1950s and early 1960s, the number of cases increased, fluctuating between 19,000 and 26,000 cases per year until 1978. The rates increased slightly in the late 1970s and early 1980s, and a disproportionate number of cases occurred in homosexual men. In the mid-1980s, primarily because of behavioral changes adopted in response to the AIDS epidemic, syphilis declined among homosexual men, as did the male-to-female ratio of cases.

In 1985, the incidence of syphilis among heterosexual men and women began to increase rapidly, a trend that also led to dramatic increases in congenital syphilis. Between 1983 and 1990, when 50,225 cases of primary and secondary syphilis were reported, there was a 75% increase in the incidence of the disease. Although widespread, the changes were not geographically or racially uniform. The rates among black men increased 126% (from 69 to 156 per 100,000) and among black women 231% (from 35 to 116 per 100,000), whereas the rates for other subgroups of the population remained stable or even declined. Rates for non-Hispanic

white men declined 50%, from 6 to 3 per 100,000 during the same period. Although rates of syphilis remain highest in urban areas of the southeastern United States and Texas, changes have been reported nationwide in both rural and urban areas. From 1989 to 1990 some of the greatest increases occurred in Midwestern cities where syphilis had previously been uncommon. For example, in three Ohio cities the rates increased between 235% and 293%, and similar increases occurred in St. Louis (172%) and Milwaukee (153%).

Several factors have contributed to the changing epidemiology of syphilis: (1) limited access to health care has delayed the diagnosis of syphilis; (2) a linkage with concomitant epidemics of illegal drug use, particularly of "crack" cocaine because cocaine is associated with prolific engagement in sexual practices as well as the "exchange" of sex in payment of drugs; and (3) the difficulty in tracing sexual partners among drug users. To address these problems, public health officials in some areas have modified traditional intervention activities, performing screening at crack houses and considering mass treatment of well-defined, identifiable risk groups.

By 1999 over 35,600 cases of syphilis in the United States, were reported by health officials in, including 6,650 cases of primary and secondary syphilis (a decline of 5.4% from 1998) and 556 cases of congenital syphilis in newborns. More cases occur each year than come to the attention of health officials. Of the nine states with the highest 1999 syphilis rates (2–5 times higher than the national rate of 2.5 cases per 100,000), eight were in the South. Although syphilis rates remain higher in the South than in other regions, the South had a 32% decline in the primary and secondary syphilis rate from 1997 to 1999, illustrating that the greatest improvements in disease control have taken place where syphilis incidence has been the greatest. In 1999, 25 counties accounted for 50% of all primary and secondary syphilis cases. Two hundred sixty-five counties had syphilis rates above the U.S. Public Health Service's Healthy People 2000 objective of 4 cases per 100,000. These 265 counties (9% of the total number of counties in the U.S.) accounted for approximately 74% of the total primary and secondary syphilis cases reported in 1999.

In 1999, syphilis occurred primarily in persons aged 20 to 39, and the reported rate in men was 1.5 times greater than the rate in women. The incidence of syphilis was highest in women aged 20 to 29 years and in men 30 to 39. Some fundamental societal problems, such as poverty, inadequate access to health care, and lack of education are associated with disproportionately high levels of syphilis in certain populations. Cases of primary and secondary syphilis in 1999 had the following race or ethnicity distribution: African Americans 75%, whites 16%, Hispanics 8%, and others 1%. Syphilis reflects one of the most glaring examples of racial disparity in health status, with the rate for African Americans nearly 30 times the rate for whites.

Social Vectors of the Disease. A.M. Brandt (Harvard Medical School) has reviewed how past experience in connection with the sociological aspects of syphilis may be helpful in relation to the current crisis concerning AIDS (acquired immunodeficiency syndrome). Brandt observes that AIDS, like syphilis in the past, engenders powerful social conflicts about the meaning, nature, and risks of sexuality; the nature and role of the state in protecting and promoting public health; the significance of individual rights in regard to communal good; and the nature of the doctor-patient relationship and social responsibility. The analogs that AIDS poses to syphilis are striking: the pervasive fear of contagion, concerns about casual transmission, the stigmatization of victims, and the conflicts between public health and civil liberties. The importance of the history of syphilis (reviewed by Brandt in *Science*, **239**, 375–369, January 22, 1988) is that it reminds the public of that range of forces that influence disease, health, and social policy.

Chronology of Syphilis. The early history of syphilis is not entirely clear. It is thought by some historians that the disease was first introduced into Europe by Columbus' returning sailors, and subsequently spread through Italy where it became a great scourge, by the soldiers of Charles V. Another view is that the disease has existed in civilized man since antiquity. Early Egyptian and Assyrian inscriptions as well as bony changes found in mummies are interpreted as supporting this theory. In the Middle Ages, syphilis occurred in severe, widespread epidemics with enormous mortality rates. Later it became a milder disease, and its venereal nature was recognized. It was not until 1905, when Schaudinn discovered the *Treponema pallidum* to be the causative organism, that syphilis and gonorrhea were recognized as two distinct diseases. Development of the dark field microscope made it possible for the first time to detect the causative spirochete.

Acquired Syphilis

The disease is almost always transmitted during sexual intercourse. The causative agent gains entry through an abraded surface, usually on the genital organs. In the male, the primary sore is commonly on the penis, where it is easily seen. In the female, it is found either on the mucous surface of the vulva or within the vagina, where it may remain unnoticed.

The primary stage is marked by the appearance of the chancre, which develops at the site of invasion, usually 2–4 weeks after exposure. Before the chancre develops, the organisms often have invaded the body tissues by way of the lymph channels and blood stream. A fully developed chancre appears as a clean, slightly raised, hard circumscribed ulcer, which exudes a thin, highly infectious secretion. By darkfield microscopic examination, this secretion can be seen to teem with spirochetes. The lesion is painless, but tender lymph nodes may develop in the groin.

The secondary stage begins 6 weeks to 6 months after the primary. By the time of onset of this period, the organisms have invaded the tissues, and the body's defense reactions are active. Antibodies are being produced, and the Wassermann reaction is positive. The second stage may be so mild as to pass unnoticed, but it is usually ushered in with a rash over the skin and mucous membranes. The eruption is extremely variable and may imitate any skin disease. The commonest type is the macular, in which the lesions consist of flat, or slightly raised, rose-colored spots, most prominent over the abdomen and chest. Characteristic features of the secondary eruption are its symmetrical distribution, painless, non-itching nature, and its tendency to appear on the palms and soles. Its duration is variable from weeks to months, and it may fade and leave a faint pigmentation for a time. With treatment the rash disappears promptly. Spirochetes are present in skin and mucous membrane lesions, and are particularly easy to demonstrate in the soft moist sores on the genitalia, the condylomata.

Constitutional symptoms in the secondary stage are usually mild. They consist of sore throat, slight fever, headache, and some enlargement of the superficial lymph nodes.

The latent period is the interval between the secondary and tertiary phases of the disease. During this time, the patient may enjoy excellent health, and be unaware that he has syphilis. The duration is variable — from a few weeks to many years — even 25 to 30. During this time, the various organs and tissues are harboring spirochetes, but these are inactive, hibernating, as it were.

The tertiary stage is the late picture, which is usually seen only in untreated syphilis. It is marked by the development of gumma, tumor-like masses in the skin and visceral organs, and inflammatory changes in the cardiovascular and central nervous systems. Since any organ or tissue may be attacked in tertiary syphilis, the signs and symptoms are extremely varied.

The most common types of tertiary syphilis are those involving the cardiovascular and central nervous systems. Cardiovascular involvement usually appears earlier — 10 to 15 years after infection. It occurs as aortitis, aortic aneurysm and sometimes coronary occlusion. In syphilitic heart disease, aortitis is commonly followed by insufficiency of the aortic valve. This mechanical defect puts a tremendous strain on the heart, which compensates by hypertrophy of the muscle. Eventually the strain is too great for the reserve, and heart failure and finally death are the result.

Central nervous system syphilis may not develop for 30 years after the primary infection. It occurs as a meningitis, as an arteritis or inflammation of the small cerebral vessels with secondary changes in the brain tissue, and as involvement of the cells of the brain and cord in tabes dorsalis and paresis.

Congenital Syphilis

It is important that no pregnant woman have syphilis, for the causative organism of this disease is one of the few that can pass through the placental barrier to the unborn child. Once the disease establishes itself in the baby, abortion or stillbirth may follow. If syphilis is diagnosed early

in pregnancy, treatment can be started which may curb the disease and allow the baby to develop normally. In the most severe forms of infection, the child may show at birth an extensive skin eruption, fissures about the angles of the mouth and nose, a characteristic nasal discharge, bone lesions, and enlargement of the liver and spleen. Underdevelopment and poor nutrition are conspicuous. Such a child rarely lives longer than a few days. In other instances, the infected infant may appear normal at birth, yet after a few months develop the typical signs and symptoms of the disease.

Children who survive the active congenital disease, or those in whom the infection remains latent, often show certain permanent stigmata which make the diagnosis apparent at a glance. "Saddle nose" and deformed (Hutchinson's) teeth — peg-shaped notched incisors which are widely spaced — are characteristic. Bony lesions, inflammation of the cornea of the eye (interstitial keratitis), deafness, and central nervous system syphilis, such as occur in the acquired form, are also seen in children with congenital syphilis.

A test for syphilis should be performed on all pregnant women at the initial visit to the obstetrician, and repeated during the third trimester in all cases where there may be a risk of acquiring syphilis. Where diagnosis is positive, the patient should be treated. Early syphilis in pregnancy is treated with the same dosage of antibiotics as for any other person in whom the disease has been diagnosed. Tetracycline is not recommended for syphilitic infections in pregnancy because of potential toxicity for mother and fetus. Monthly tests for syphilis should be made during the full period of pregnancy. Where effective treatment is given, the risk of congenital syphilis in the newborn is minimized.

Diagnosis of Syphilis

The first blood test for the disease was developed by August von Wassermann, a German bacteriologist, in 1907. The Wassermann test was used for many years, but during the interim a number of other serologic tests have been developed. These tests fall into two main categories: (1) treponemal tests which are designed to detect the treponemal antibody produced in response to syphilitic infection; and (2) nontreponemal or reagin tests, which detect an antibody-like substance (reagin), the latter found in the serum of an infected patient. Reagin is assumed to result from the interaction of *T. pallidum* with body tissue. Compared with the nontreponemal tests, the treponemal tests are relatively time-consuming and costly.

To guide therapeutic decisions and disease-intervention activities, syphilis is divided into a series of clinical stages. Despite its usefulness, clinical staging is imprecise. Patients with late stages of disease may have no recollection of signs of earlier stages, possibly because most syphilitic lesions are painless or because some patients may not have clinically apparent primary or secondary lesions. Also, there is considerable overlap between stages. For greater detail pertaining to diagnostic procedures, refer to the Hook-Marra paper.

Therapy for Syphilis. The primary goals of therapy are to prevent transmission and avoid the late complications in affected patients. *Treponema pallidum* cannot readily be propagated in vitro. Consequently, much research has been conducted using rabbit models.

Penicillin remains the best-studied and the preferred therapy for syphilis. A single dose of 2.4 million units of penicillin G benzathine results in a serum penicillin concentration of more than 0.018 micrograms per milliliter, which remains effective for about 3 weeks. Studies have shown that this dose for early syphilis is not complete and that retreatment is required in up to 10% of patients. There have been reports that penicillin G benzathine does not relieve neurological and ocular syphilis. However, prior to the era of the HIV epidemic, penicillin G benzathine therapy for early syphilis had a success rate of 95% or higher. This high rate was attributed to the fact that the therapeutic regimen and an intact immune system act together to clear peripheral organisms as well as those sequestered in the central nervous system and the eye. When symptoms of neurosyphilis are evidenced, the preferred treatment may be the use of high-dose intravenous penicillin (sterile) or a combination of intramuscular penicillin G procaine with oral probenecid.

Treatment of persons who are allergic to penicillin, repeated dosage of tetracyclines (although not for pregnant women), and possibly erythromycin may be considered. Information is still being collected on the efficacy of other antibiotics. Persons with the HIV infection present a considerably more complex situation. Both syphilis and HIV are protean diseases, and they interact on a number of levels. Syphilitic genital ulcers may enhance the acquisition and transmission of HIV. The natural history of syphilis may be modified in patients co-infected with HIV (human immunodeficiency virus). The results of laboratory tests for syphilis may be different in HIV-infected persons, thus misleading the proper therapy to be used. Numerous studies have shown that syphilis, as well as other genital-ulcer diseases, are disproportionately common in HIV-infected patients and vice versa, suggesting that syphilis increases the risk of the acquisition and transmission of HIV. Much more detail on this subject is given in the Hook-Marra reference listed.

Untreated Syphilis

As a cause of death, untreated syphilis has received extensive attention of medical statisticians and long and complex studies of this topic continue. Questions for which specific answers have not been fully provided include: To what degree does syphilis masquerade as another disease? If left untreated, what is the ultimate pathway of destruction caused by syphilis? To what degree is syphilis indirectly associated with death from other causes?

In an extensive study (Gjestland) of Figures gathered by Boeck and Brusgaard pertaining to 2,000 syphilitic patients who lived in Oslo, Norway during the period 1891–1910 and who had received no specific therapy for the disease, the following findings were revealed: (1) untreated syphilitic patients exceeded their expected mortality rates by 53% (male) and 63% (female); (2) the male patients developed cardiovascular syphilis in 13.0% of the cases — 7.6% (female); (3) neurosyphilis developed in 9.4% (male) and 5.0% (female); (4) the mortality rate from syphilis among males was double that of females; (5) clinical or autopsy evidence of syphilitic pathology of a serious nature was noted in 23% of all patients.

A similar study was made of males 25 years or older in the United States. Known as the Tuskegee Study, these findings have been summarized as follows: (1) Only one-fourth of the untreated syphilitics were normal after an infection of 15 years' duration. Most of the abnormal findings were associated with the cardiovascular system; (2) During the first 12 years of observation, 25% of the syphilitics and 14% of the control group (no syphilis) of comparable ages had died. At age 25, untreated male syphilitics would have a reduction of life expectancy of about 20%; (3) After 25 years of follow-up to this study, the life expectancy of individuals with syphilis (ages 25 to 50) was found to be 17% of the control group. A male with untreated syphilis of more than 10 years' duration and a sustained reactive serology would have approximately a 1:1 chance of having demonstrable cardiovascular involvement (autopsy findings).

Another interesting study concerned with the outcome of untreated syphilitic infection was done by Rosahn (Yale) by analyzing autopsy records from 1917 to 1941, consisting of 3,907 cases over age 20. Major observations included the following. (1) About 9.7% of the population studied had clinical laboratory or anatomic evidence of syphilis. Earlier, in 1938, Vonderlehr and Usilton estimated that one person in ten in the United States would have syphilis before dying. (2) Males with lesions at autopsy comprised 4.7% of the male population; 2.7% of the females, indicating a sexual bearing upon the resistance to tissue changes of late syphilis. (3) Syphilis significantly reduced longevity, whether or not there were tissue lesions. (4) No greater frequency of anatomic lesions was apparent among blacks than whites, but whites with such lesions died at a greater rate than blacks, indicating that as previously believed, syphilis does not run a more fatal course among blacks than among whites. (5) About 39% of untreated syphilitics indicated anatomic evidence of syphilis at autopsy. (6) About 23% of the untreated syphilitics died primarily as the result of the disease. There were several parallels between the Yale study and the Brusgaard study previously described.

SYSTEMATICS: HISTORICAL OVERVIEW. Prior to Linnaeus, the father of modern taxonomy, the origin of systematics dates back to the Greeks, but it was the development of the Greek model by Linnaeus in the middle of the eighteenth century that is recognized as the starting point of systematics. The changes in method that have come about since that time are largely due to different appreciations as to what constitutes homology, hierarchy and the relationship between systematics and evolution. See also **Linnaeus, Carl (Linné) (1707–1778)**.

Systematic relationships among organisms are usually represented by branching diagrams (dendrograms, phylograms, cladograms, etc.) that represent hierarchies — groups within groups. The original concept of a group within a group was not a branching diagram at all, but could be formulated in a ranked name scheme. Linnaeus (1758), in the 10th edition of the *Systema Naturae*, proposed that the names of the ranks should be given as follows: Regnum (Kingdom), Classis, Ordo, Genus, Species, to which the categories Phylum and Family were added later. Branching diagrams in classifications are now used today, but over time the principles for making them and the meanings ascribed to them have changed as views have been affected by changes in systematic philosophy, the discovery of the meaning of the "scalae naturae" in relation to classification and the distinction between homology, analogy and homoplasy.

The Scala Naturae and its Eventual Replacement

Perhaps the most important concept in the Western civilization is the Scala Naturae or "Great Chain of Being." It contains two ideas, the principle of plenitude based on Plato's philosophical idealism in which all material phenomena are imperfect representations of an unchanging world of ideas. The second is the notion of a linear series attributed to Aristotle and the neo-platonists, particularly Plotinus. This refers to the idea that there are no gaps in the history of life and every organism fits somewhere into a linear scheme, however imperfect this might be. At the bottom of the scale organisms are degenerating into inanimate objects, while organisms at the top achieve perfection above the primates and man through to the angels and the archangels.

In trying to piece together the comparative biology of the last two centuries one could ask how has the scalae naturae affected systematics? Interestingly, Lamarck (1815–1822) distinguished two distinct operations in animal classification: first the 'distribution générale', referring to the correct place each organism is placed in the scalae naturae, the second, classification, or the making of divisions of the length of the scalae to yield convenient clusters of taxa to name in an hierarchy. The latter was considered to be merely a scheme of convenience — the anatomical gaps between the different classes were purely artificial denoting our ignorance of orders, genera and species.

Early in the nineteenth century several biologists rejected the Great Chain of Being. They considered that organisms and especially animals could not be arranged into a linear series. This was particularly true for the work of Lamarck and his successor, Cuvier. According to Cuvier (1830) there was no such thing as a scalae as the animals were adaptive and so they formed a hierarchy of ranks. He particularly arranged the animals in relation to vertebrate heart characters and details of the nervous system as the overarching characters. The classification was denoted in four branches: vertebrates, articulates, mollusks and radiates. Within each branch were four subclasses diagnosed to represent the adaptive creations of the Kingdom Animalia. It was also independently discovered by von Baer. Later Louis Agassiz emphasized the three-fold parallelism that had been the centerpiece of Cuvier's classification–classification, embryology and fossil succession. However, he rejected evolution. The fossil record was a succession of creations within each geological period and every species and every taxonomic category became a real entity: Branches or types are characterized by the plan of their structure; Classes, by the manner in which that plan is executed, as far as ways and means are concerned; Orders, by degrees of complication of that structure; Families, by their form, as determined by that structure; Genera, by the details of the execution in special parts; and Species, by the relation of the individuals to one another and to the world in which they live as well as by the proportions of their parts and their ornamentation. An exceptional example of this 'natural' arrangement represented by a series of parallel scalae naturae can be seen in Thomas Henry Huxley's classification of mammals. Huxley suggested that the divergence of clades of mammals represented by the natural orders had taken place some time in the distant past, and all the orders had taken place and at the same time unrecorded, to their definitive grade. Thus, the natural classification of mammals was represented by a series of parallel scale naturae, for each order.

Critically for modern classification, the system of Linnaeus was essentially the same concept and persists in our present-day schemes. In his earlier efforts Linnaeus accepted the scalae naturae as a natural order for animals. Although, the relationships in Linnaeus's classification could be represented by a branching diagram, it was clear that it contained critical elements of Lamarck's scheme, with a natural order representing a scalae naturae and an artifical classification.

Linnaeus's system of classification followed an ancient Greek model of logical division. From the time of Plato onwards the system of classification was known as the 'tree-of-Porphyry'. In the example shown in Figure 1 it is important to note that at each node only one branch was successively divided into a lower class. In other words, this was a way of classifying an individual so that its place in the world could always be detected and its position in each level of the higher scheme of things.

In the early nineteenth century, the tree-of-Porphyry obtained a more general use when it became associated with the concepts of higher and lower organisms in animal classification, thus reinforcing the conceptual connection between the tree and the scalae naturae. Since that time in many different guises and renditions, the tree has taken over as the method of representation of relationships of organisms, reinforcing the idea of progress in evolution, an idea which persisted well into the late twentieth century and today.

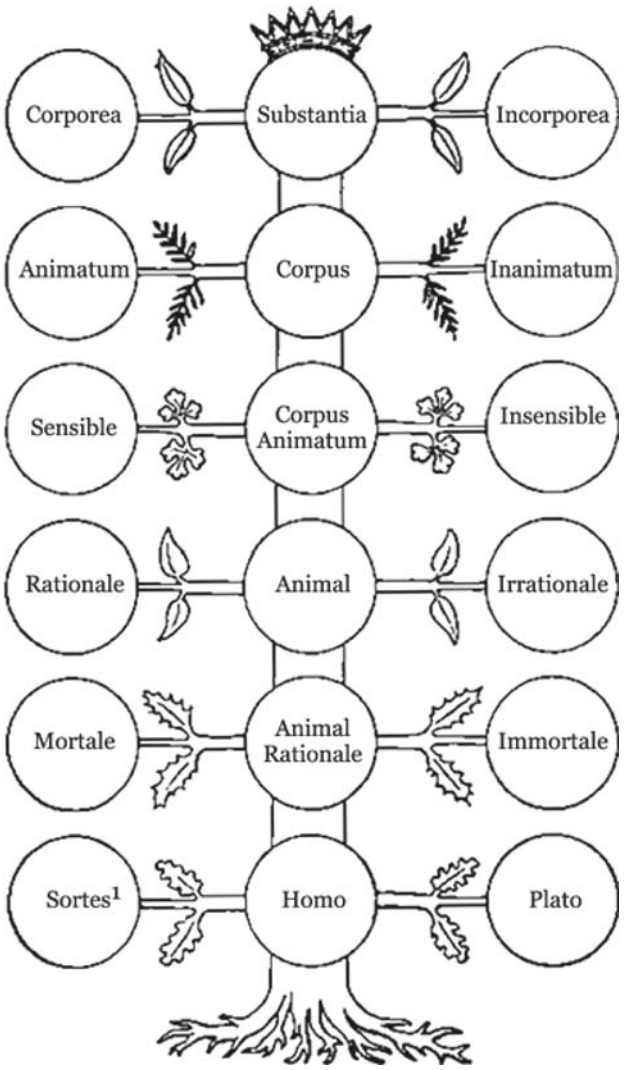

Fig. 1. The tree-of-Porphyry.

Karl Ernst von Baer set out to refute the connection between ontogeny and the scalae naturae. In his classic work, *Entwickelungsgesichte der Thiere*, von Baer (1828) established the principle of divergence. His system was similar to that of Cuvier, with its four branches, and he was clearly aware of the adaptation of characters. Nevertheless, he differed greatly by considering characters as body plans within each embranchment. His fundamental belief was that there were four laws of branch: recognition, the general features of a large group of organisms appear earlier in the developing embryo than the more specialized features; less general characters are developed from the most general and succeed gradually until the specialized features appear; each embryo of a given species (*Thierform*), instead of passing through the stages of other animals depart more and more from them; consequently, the embryo of a higher animal is never like the adult of a lower animal, but only like its embryo at certain stages. Thus, according to von Baer, the classification should be depicted as a series of subdivisions, with shared early ontogenetic features followed higher in the tree by divergent later ones.

Macleay, Strickland, Bronn, Owen and Darwin

Macleay's (1819, 1821) major work of two volumes was a monograph on scarab beetles in the first volume, and a major discussion of homology and analogy in the second. He considered both concepts as critical in natural classification in which affinity (recognized by homology) was expressed as a linear series. Running parallel to these morphoclines was an equal number of taxa arranged as *rungs* based on analogous features. He had a third principle, wherein affinities of taxa of any related taxa would form circles (e.g. A-B-C-D-E, with A also adjacent to E in circle).

Similarly, its parallel series would form a similar ring (e.g. A′-B′-C′-D′-E′ with A′ also adjacent to E′ in a circle). Furthermore, all groups of taxa forming a group of the next higher rank also had five members and hence the term 'quinarian' was applied to his method. Macleay's classification, therefore, could be seen as a brave attempt to combine, homology, homoplasy, the principle of plenitude (in the sense of Cuvier) and the adaptive nature of characters. The animal kingdom thus became divided into five groups: Radiata, Acrita (dividing Cuvier's Radiata into echinoderms and polyps, respectively), Mollusca, Vertebrata and Annulosa, and these were arranged diagrammatically in a circle. Each subgroup was thus supposed to be characterized by homology and each was arranged in an analogous position next to each other.

The system was rejected. The question was asked: given any species A which of two others, B or C, was its nearest relative. He did not use a linear sequence but a rooted tree similar to the techniques of Sokal and Sneath in the twentieth century (see below). As seen earlier the tree-of-Porphyry was also a tree, both dichotomous and asymmetrical.

The fact that the dendogram could represent a cladogram as well as a phenogram meant that it could be used as an evolutionary tree as Darwin showed in the Origin of Species in (1859). In fact, the notion of phylogenetic trees was understood well before the work of Darwin. It was possible at this time to recognize the relationships between species as real, von Baer's embryological principles, an improved grasp of the importance of fossils, and to be able to reconcile the work functional anatomy of Cuvier with the idealistic morphology of the 'Naturphilosophen'. The key players were von Baer, Milne-Edwards and Agassiz, who adopted the three-fold parallelism of embryology, progression in palaeontology and classification — the three notions that cemented together the idea of evolution. See also **Agassiz, Jean Louis Rodolphe (1807–1873)**.

The work of Bronn (1858) was crucial in bringing about a consensus of the essential concepts that created acceptance of the theory of evolution just before Darwin published the Origin (1859). Bronn accepted a progressive advance of fossils in palaeontology with time, the external factors producing adaptation in anatomy and in pattern, in turn causing divergence in groups both in geological time and level of organization, so that the side branches in a tree were taken to continue through time but not necessarily reaching a higher grade (Fig. 2). The central axis of his tree was shown as strong trunk suggested gradual adaptation to higher organisms — some, but not all, investigators considering the highest organisms to be humans.

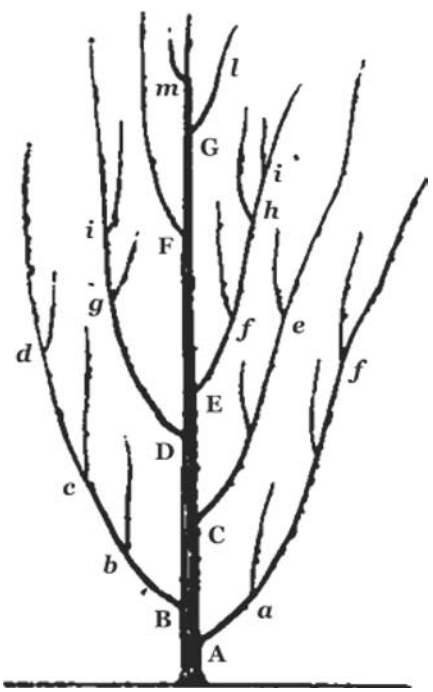

Fig. 2. Bronn's tree of animal relationships, with geological time and level of organization conflated along the axis. After Bronn (1858).

Richard Owen must also be considered as a key player from around the middle of the nineteenth century. He has to be credited with the reconciliation of idealistic morphology, of the Naturphilosophen with the functional anatomy of Cuvier to create a new version of 'functional morphology'. In Owen's work, every taxonomic group had a Platonic archetype (Bauplan), wherein members of the taxon represented variants of the archetype brought about by adaptive necessity. Those furthest from the archetype constituted the highest taxa. Owen is often remembered because at the same time he created the distinction between analogy and homology, and as a result showed that the archetype was a conservative force and not directional, as compared with the scalae naturae that was directional, and the differences perceived in it were due to adaptation. Thus while Owen's scheme incorporates the notions of higher and lower, the factor forming 'height' (adaptation) is also the factor that creates diversity. It was from Owen that Darwin embarked on his greatest works on the classification of living and fossil barnacles. It was here that the tree metaphor came to mean classification and phylogeny, and that the tree-of-Porphyry and dendograms based on distance data were first shown to be irrelevant.

Haeckel and the Phylogenetic Tree

The publication of the *Origin* established the idea that the classification of higher ranks was far more useful for representing phylogenetic relationships than relatively distant taxa. The fashion for representing trees as successive ranks terminating with humans at the apex of the tree and the lower organisms at the base of the tree was perhaps best popularized by Haeckel 1866. In fact, he produced a most vivid rendition of a phylogenetic tree as a European oak, *Quercus robur*, with the central axis, the trunk representing the scalae naturae, a morphocline of grades as they were to become known, and the branches of the tree became the individual taxa.

Origins, Grades and Ancestors: Evolutionary Systematics

The fallout from using phylogenetic trees as described by Haeckel was that even by the mid-twentieth century, after almost 150 years since systematics became a coherent discipline, the methods were still in some kind of conflict and lacked a general code. There were effectively three schools of thought that became known as evolutionary systematics (gradistics), phenetics and cladistics. Grades were the concern of evolutionary systematists with the view that ancestors and basal groups were important; phenetics quantified systematics into a distance method, but sadly failed to make any distinction between clades or grades and cladistics is the grouping of monophyletic groups by homologies or synapomorphies.

Perhaps the most famous examples of evolutionary systematics were published by Mayr (1969). In these examples, both cases can utilize the same topology (Fig. 3). In each case, they involve the separation as a taxon of high rank of an advanced group from the more inclusive group in which it should be contained, leaving behind the more primitive member as a separate group based on absence of characters shared by the members of the advanced group — a grade or paraphyletic group according to cladists. In the first example, the Homidae are separated from the rest of the great apes (the paraphyletic group). In the second example, birds of the class Aves are separated from the more primitive Reptilia, leaving the crocodiles with reptiles as a paraphyletic group.

Mayr's view is that taxonomic clustering should represent genes in common, and the latter is represented by proximity along a horizontal axis. In Figure 3, the first example would be characterized as follows B would represent the orang-utan; C, chimpanzees and gorillas; D, man; and A the common ancestor of the group, BCD. In the second case, B would represent diapsid reptiles; C crocodiles; and D birds. As before A would represent the common ancestor of the group BCD. According to Mayr, in each case, taxon D, because it is so distinctive and so different from its relatives, should be separated off as a different group. Importantly one has to note that the classification in both cases is seen by Mayr to represent grades rather than clades. Patterson showed that such claims of Mayr were completely false. Biochemical and genetic tests have shown clearly that man is more closely related to African apes than either is to orangutan, and birds are more closely related to crocodiles than either is to other reptiles.

Phenetics

The goal of the computer-assisted analyses of data that became popular in the late 1950s and 1960s was to produce objective classifications of maximum utility based on the analysis of as many characters as possible. This goal had been promoted from the 1930s onwards. However, it was the work of James Michener, a bee taxonomist in Kansas, Robert Sokal, a statistician from the State University of New York and Peter Sneath, a bacteriologist in Leicester, UK, who developed the principles and described the methods. See also **Taxonomy**.

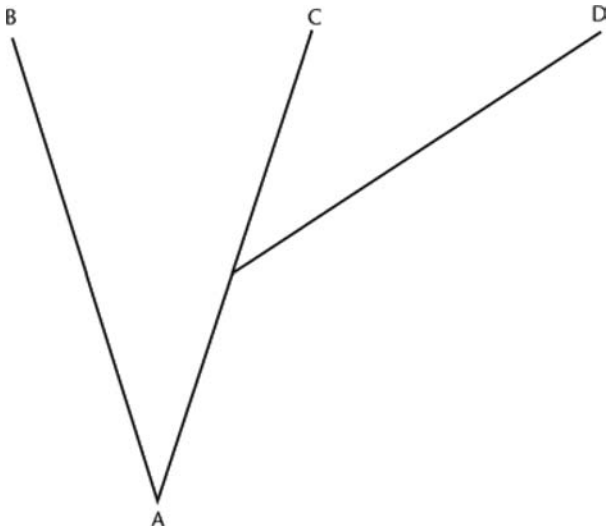

Fig. 3. A presumed phylogeny used to depict a 'grade' classification of Mayr and others. In example 1, B = orang-utan, C = gorilla and chimpanzee, D = Homo sapiens (Mayr, 1969). In example 2, B = other diapsid reptiles, C = crocodilians and D = birds. A = the common ancestor in both examples.

Overall similarity or phenetics came instinctively into vogue to explain how taxonomic conclusions were drawn. Neo-Adansonian, phenetic or numerical taxonomy developed in the late 1950s in part to correct the often unarticulated and apparently circular methodology of evolutionary systematics; in short, it claimed to make systematics a science. The quantification and attempts to make systematics scientific came straight out of the methods of operations research and especially the use of matrices. Phenetics is grouping by 'overall similarity' (Sneath and Sokal, 1973) and both the internal and terminal nodes of the dendrogram represent all of the characters shared by the dependent branches and ultimately the operational taxonomic units (OTUs — the pheneticist's quantitative name for taxa). Dendrograms (Phenograms) were produced by comparing degrees of similarity and difference in taxa by one to one comparisons of consistently scored character matrices.

The main diagnostic feature of phenograms is that the ranks of OTUs are all arranged at the same level. The horizontal distances between them have virtually no meaning except for the branches that connect OTUs. However, the vertical axis is the crucial aspect. A pair of OTUs will have the shortest distance between themselves and the nearest internal branch of the phenogram. They are closely related if the distance is short, but less if the distance is larger. The axis of the upright phenogram is a measure of relative distance between OTUs and clusters of OTUs. The importance of distance along the branches is that it gave some level of confidence to the dendrogram, but the fact that the internal nodes could appear anywhere, depending on the position of clustering, as a result of the amount of similarity and difference meant that there was no comparable ranks available for creating name hierarchies. Sneath and Sokal got around the problem by using 'phenons', parts of the phenogram which are analogous to taxa. These were created by drawing horizontal lines across the phenogram, and everything above a particular line along a particular branch became a named taxon. The lack of any underlying theory of how one might undergo this procedure, however, meant that the technique fell into disrepute and was replaced by cladistics.

Cladistics

Willi Hennig compiled the principles of cladistics and first summarized his ideas in which a few people applied his argumentation method for fleshing out phylogenetic trees and discovering relationships as genealogies. He

became widely known with the publication of an English revision of his earlier German work, *Phylogenetic Systematics* (Hennig, 1996), and it was pioneering efforts of Brundin and others that influenced other comparative vertebrate biologists. Within a year of the translation and revision of Hennig [1996] by Rainer and Zangerl, the techniques were so compelling that a revolution in systematics was afoot. See also **Cladistics**.

Cladograms are produced by searching for the pattern of cladogenesis or speciation but not anagenesis or the phyletic evolution of clades. Neither the horizontal nor the vertical axes represents any measurable quantity in the phenetic sense; morphology is not represented on the horizontal axis, and the vertical axis accounts only for special similarity or homology. A cladogram is a tree-of-Porphyry — a phylogeny with a relative time axis. Cladistic analyses produce sets and can thus be represented just as equally by Venn diagrams as they can be by dendrograms.

Led largely by a cohort of comparative biologists at the American and Field Museums (New York and Chicago, respectively), Nelson, Platnick, Gaffney, Rosen and Cracraft, and others, showed that special similarity was equivalent to homology. While homologous characters co-varied on cladograms, nonhomologous characters did not. James S. Farris, when developing numerical cladistics beyond numerical phenetics, did so by showing that the basic principles of cladistics had one property. Characters that co-varied on cladograms were considered to be special. He also worked tirelessly to show that parsimony was the scientific criterion of choice among competing monophyletic group propositions (cladograms), because it could be justified on the theoretical principle that the most parsimonious cladogram was the easiest to defend and the shortest cladogram was the most robust. Parsimony was applied on the basis of looking for the cladogram supporting the greatest amount of evidence (special similarity or homology) that had the best fit, i.e. the largest number of synapomorphies explainable as homologues.

The pattern cladists showed that Hennig's hypotheses of characters and of groups both appealed to ancestors, a problem solved by saying that hypotheses of characters gave rise to hypotheses of groups. The notion of ancestor-descendent sequences and the concepts of hypotheses of characters and of groups appealing to ancestors had gone forever. Characters thought to be homologues could be tested by congruence with other characters rather than relying on ancestors for their justification.

Phylogenetic relationships among species, or groups of species, are interpreted strictly genealogically, as sister-lineages, or clade relations. Shared, evolved, modified, derived characters (synapomorphies) provided the only evidence for identifying relative recency of common ancestry. Consequently, it was realized that Hennig's overriding contribution to systematic technique was that similarity was asymmetrical: genealogy implied similarity amongst characters but the converse was not true, because some characters were homoplasious or nonhomologous. Hennig viewed historical inference as a strictly logical and scientific endeavor. A cladogram was a phylogenetic hypothesis that tried to determine monophyly among groups and resolve para- and polyphyly. Homologies supported monophyletic groups, homoplasies and absence characters left para- and polyphylies. Polyphyletic characters are those that occur two or more times on the tree, whereas paraphyletic characters are the absence characters that define the rump — the reptiles or the orang-utan and chimps together after birds or humans are separated off (Fig. 3). Furthermore, whenever possible, Hennig said that taxonomy (the name hierarchy) must be logically consistent with the inferred pattern of historical relationships. The naming of groups followed the rule of monophyly such that each clade can have its unique place in the hierarchy of taxonomic names. Thus, Figure 3 has only one component of information and the classification for both examples is AB(CD).

While Hennig was not the first to articulate any one of these principles, he must be given credit for how he integrated the empirical and methodological aspects and his view that knowledge of processes often benefited from, but did not always contribute to, our understanding of historical patterns. He was able to convince the systematics community that population genetics, natural selection and adaptation have little to do with the discovery of genealogical relationships, because it was in the 1950s and 1960s that evolutionary systematics was generally accepted, and which held that such population thinking was a necessary part of phylogenetic inference. Hennig intended his principles to be methodological, although initially many of his critics misunderstood his intentions as being empirical.

Most subsequent techniques and computer algorithms written to calculate trees are based on Hennig's phylogenetic systematics, albeit the methods are invariably described under the rubric of cladistics. The success of the methods is remarkable with many thousands of papers emerging each year. Over the last 15 years or so many of the analyses are undertaken on molecular characters, particularly plastid sequence data, and cladistics has undoubtedly become the choice in efforts to try and assess the entire tree of life.

Conclusions

It is clear that the scalae naturae was dominant throughout the history of systematics and especially since the turn of the nineteenth century. However, there was a conflict between the scalae, seen as the natural order of organisms from the ecology of primeval ooze to primate taxa, and the results of classification, seen as the logical division into groups, an incongruency which had to be resolved before systematics became coherent. Lamarck's original theory was simply to explain progression along the scalae naturae. The Quinarians, despite derision being heaped on their curious groups of five because their classifications could not deal with irregularity of classification, were actually correct to suggest that a theory, evolution, was required to justify the underlying aspiration of determining the relationships of organisms as a hierarchy. The method of logical division naturally yields a divergent inclusive hierarchy of groups within groups. The idea that the pattern could be a natural classification required the rejection of the scalae naturae in comparative anatomy as undertaken by Cuvier and Agassiz and in embryology by von Baer. The divergence of the hierarchy was supported by the division into homology and anatomy as highlighted and described by Owen's classifications. Darwin, therefore, could consider the rather irregular classification as being caused by evolution. Paleontologists created a problem of not understanding progression until they stopped trying to explain history and accepted ancestor-descendent sequences well into the twentieth century. Haeckel produced the rooted spanning tree that implied a distinction of clades and grades, the latter of which made a return to the scalae naturae. Grades were important to the evolutionary biologists, such as Mayr, a problem that exacerbated progress in systematics. Phenograms and cladograms are trees, but the horizontal axes were not indicators of morphological/anatomical divergence of grades. Rather, nodes were critical in defining monophyletic groups and in cladistics the application of special characters (homologies) to discover monophyletic groups provided a general method of systematics, which is preferred in contemporary analyses.

SYSTEMIC LUPUS ERYTHEMATOSUS. Generally grouped with the rheumatic diseases, *systemic lupus erythematosus* (frequently shortened to *lupus* and abbreviated, SLE) was, until a few years ago, considered to be a rather rare condition. With an improved understanding of the disease and the use of more definitive diagnosis and precise nomenclature, the disease has become better identified. It is now variously estimated to affect 5 cases per 100,000 population — to as high as 50,000 new cases per year in the United States alone. Records to date indicate that SLE occurs in women at a rate nearly ten times that of men and that it usually appears during the second and third decade of life. Thus, the generalization can be made that SLE is predominantly a disease of young women.

Systemic lupus erythematosus is a chronic multisystem inflammatory disease with currently unknown origin. Clinical features are quite variable.

SLE ranges from a moderate, benign condition to one with serious consequences that can lead to death. As with rheumatoid arthritis, SLE is an autoimmune disease, in which the body's natural defense mechanisms behave erratically. See **Immune System and Immunology**.

The diagnosis of SLE is frequently complex, but the physician will suspect the condition when a young female is seen with a combination of fever, skin rash, and arthritis. The fever is usually low-grade, but in a so-called "lupus crisis" may reach 104.9 °F (40.5 °C). The typical skin lesion appears in the facial region, particularly involving the nose and cheeks, producing what is sometimes called a "butterfly rash." Alopecia (spotty loss of hair) also may occur. There also may be ulcerations of the mouth and lips. It is believed that the skin conditions arise from a superabundance of keratin, which plugs the hair follicles and sweat and sebaceous glands. The arthritis most often involves the hands, wrists, elbows, knees, and ankles. Cartilage or bone degradation is not usually found. Tendonitis is not uncommon.

Further examination may show involvement of SLE in other organs. causing, for example, acute hemolytic anemia, thrombocytopenic purpura, or pericarditis. Most frequently, after a flare-up, there will be characteristic remissions, which may extend from months to years. The risk of an acute attack depends to a large degree upon the number of organs that have been affected. Prognosis of recovery and remission diminishes in cases where the kidneys and central nervous system are involved. Situations which appear to precipitate the occurrence of SLE and which aggravate symptoms appear to include infections, stress (emotional and physical), surgery, pregnancy, some drugs, and undue exposure to sunlight.

Moderate involvement of the kidneys may occur in nearly all cases. Less commonly, renal malfunction may be serious and pose a life-threatening situation. Nervous system involvements occur in about half the cases, these varying considerably in magnitude. These may be manifested in psychoses and, in particular, organic psychoses, which include deterioration of intellectual capacity, memory, and disorientation. These manifestations are usually of a transient nature, but they may occur any time during the course of the disease. Cardiac involvement is usually confined to pericarditis, but endocarditis occurs in some cases. Involvement of the respiratory system may cause pleuritic chest pain. Pleural fluid, in such cases, will almost always show high concentrations of protein. In some cases, bacterial pneumonia, pulmonary infarcts, uremic pneumonitis, and congestive heart failure may develop.

The treatment of SLE, as of the early 1990's remains somewhat controversial and consequently nonuniform. This will change with time as both fundamental scientific information, better clinical statistical data, and empirical observations are collected. Treatment is complicated by the variety of symptoms presented by SLE in various patients. Generally, therapy is directed to greater periods of rest to reduce the effects of emotional and physical stress. Aspirin is commonly suggested as an anti-inflammatory drug. When skin rashes are difficult to control, antimalarials, such as chloroquine and hydroxychloroquine, have been used.

Glucocorticoids will demonstrate marked suppression of SLE manifestations in many patients, but these drugs are usually reserved for patients with serious life-threatening conditions.

Currently, there is much research directed toward a better understanding of the origin and course of SLE. This research is motivated not only in the interest of developing improved therapy for SLE patients, but also as a probable rewarding avenue to a better understanding of many autoimmune phenomena. Histocompatibility antigens located on cell surfaces are antigens that elicit rejection of transplanted organs by the immune system. Researchers are interested in these antigens as regards SLE to determine if they are directly involved in provoking autoimmunity or that they may be indirectly involved because of their genetic association with immune response genes. Faulty control of immune responses has been strongly implicated in the etiology of lupus.

SYSTEMS ENGINEERING. A term widely used in engineering and industrial planning, defined somewhat differently in various organizations. Probably there is general agreement that it is the application of the scientific method to a communications system, a data processing system, or an aircraft, a ship or an entire business. Moreover, most of its practitioners would extend the definition to groups of businesses, that is, to industries or even entire societies.

SYZYGY. 1. The astronomical condition of alignment of the earth, moon, and sun at new and full moon, the time of maximum spring tidal forcing. At these times the range of tide is greater than average.

2. A west wind on the seas between New Guinea and Australia preceding the summer (northwest) monsoon.

SZENT-GYÖRGYI VON NAGYRAPOLD, ALBERT (1893–1986). Albert Szent-Györgyi von Nagyrapolt was born in Budapest, Hungary, on 16 September 1893. His father was a member of the aristocracy and his mother's family included a number of eminent Hungarian scientists. He began his advanced studies at Budapest Medical School, but his schooling was interrupted by service in World War I. He was awarded the Silver Medal for Valour, but became disenchanted and was discharged after he purposely wounded himself. He graduated in 1917 as a medical doctor.

In 1919 Szent-Györgyi joined the exodus of intellectuals fleeing from war-torn Hungary. He traveled first to Prague, then to The Netherlands. In the 1920s, he wrote an important paper uniting two competing schools of thought on cellular respiration by stressing the role of both hydrogen and oxygen: he suggested that active oxygen oxidized active hydrogen and that there were intermediate electron carriers (in particular, succinic acid) between the dehydrogenases and the cytochromes.

Noticing a similarity between the browning (i.e. oxidation) of certain fruits and the brown pigmentation of patients with malfunctioning adrenal glands (Addison disease), Szent-Györgyi began studying the adrenal cortex. To continue his research, Szent-Györgyi traveled to England to work with Henry Dale, but his experiments were not fruitful and he returned to The Netherlands. In 1926, perhaps the greatest living biochemist of the time, Sir Frederick Gowland Hopkins, noticed his work on respiration in the potato and invited him to Cambridge with a Rockefeller Foundation Fellowship. He was awarded a PhD in 1927 for isolating less than a gram of a carbohydrate, which was named hexuronic acid (later found to be vitamin C), from orange juice and cabbage water. He later isolated grams of hexuronic acid from adrenal glands at the Mayo Clinic, Rochester, Minnesota, and even more from Hungarian paprika. See also **Adrenal Glands**; **Dale, Henry Hallett (1875–1968)**; and **Hopkins, Frederick Gowland (1861–1947)**.

In the 1930s, with Rockefeller Foundation money, Szent-Györgyi began a research laboratory in Szeged, Hungary. With the help of Joseph Svirbely, Szent-Györgyi discovered that small amounts of hexuronic acid could cure the scurvy of guinea-pigs who were given vitamin C deficient diets, i.e. that hexuronic acid was vitamin C. Svirbely was a former student of Charles Glen King of the University of Pittsburgh, who also claimed priority for the discovery. Despite controversy at the time, the receipt of the Nobel Prize for Physiology or Medicine in 1937 cemented Szent-Gyorgyi's priority. See also **Krebs, Hans Adolf (1900–1981)**.

During the early 1940s, Szent-Györgyi worked on cellular respiration, conducting experiments that proved instrumental in Hans Krebs' discovery of the citric acid cycle. He also worked on actin and myosin, the constituents of muscle, and showed that muscle fibers can be made to contract with the addition of adenosine triphosphate (ATP). He spoke against Hitler and consequently was forced into hiding in 1944. See also **Krebs, Hans Adolf (1900–1981)**.

Szent-Györgyi became disillusioned with the communist rule in Hungary and immigrated to the USA in 1947, eventually becoming a US citizen. He established the Szent-Györgyi Foundation and a muscle research group at Woods Hole, Massachusetts. Later, he opposed the Vietnam War and founded the National Foundation for Cancer Research (NFCR). The insightful, outspoken, charismatic biochemist died of kidney failure on 22 October 1986 at the age of 93.

T

TABER ICE. A seam, lens, or layer of ground ice, usually pure, formed by the drawing in of water to a growing ice crystal as the ground becomes frozen. Sometimes referred to as *segretation ice* or *sirlin-type ice*.

TABES. (1) A progressive wasting of the body or part of it. (2) *Tabes dorsalis* or locomotor ataxia is a syphilitic infection of the spinal cord. This form of syphilis occurs in about 5% of untreated syphilitics around the ages of 25 to 40 years, that is from 8 to 15 years after the original syphilitic infection. Cure is extremely difficult and often impossible. The longer the infection has been present the less chance there is of a cure or even of arresting the disease. See also **Syphilis**.

The symptoms of spinal cord syphilis are numerous and do not make their appearance in any set order. The first group of symptoms usually noticed are: lightning pains, that is, severe shooting pains of a few seconds' duration, usually of the leg (or prolonged pains resembling "rheumatism"; (2) Absence of knee jerks; (3) Fixed and irregular pupils; (4) Difficulty in urination.

The second stage symptoms merge gradually with the first so that in addition to the foregoing symptom difficulty in walking and in-coordination of all forms of muscular movement gradually increase. The walk is often characteristic. The foot is raised high, thrown forward forcibly, and slapped to the ground.

In the last or third stage paralysis often occurs. There is increased mobility about the joints producing a "flail" joint. Eye symptoms sometimes lead to blindness. Impotence is usual. Paroxysms of acute pain simulating surgical lesions occur in various abdominal organs. These may last several days and may be accompanied by vomiting. Perforating ulcers appear on the feet, muscular wasting, weakness, and loss of control of muscle, progresses and death occurs finally from some terminal infection such as pneumonia.

The diagnosis is made from the symptoms, physical signs, and serologic tests of the blood and spinal fluid.

Treatment is carried out in courses lasting several years. The various anti-syphilitic drugs are used intramuscularly, intravenously and intraspinally. In cases not responding to this form of treatment, the patient is inoculated with malaria. The high fever produced by this disease sometimes checks the syphilis of the nervous system. It is more often used with paresis, which may also be present with *tabes dorsalis*. The malaria is then cured with quinine. Other forms of fever therapy may also be used.

TABLELAND. (a) A general term for a broad, elevated region of land with a nearly level or undulating surface of considerable extent, as found in much of South Africa. Sometimes referred to as a *continental plateau*. (b) A plateau bordered by abrupt cliff-like edges rising sharply from the surrounding lowland, sometimes called a *mesa*.

TABULAR ICEBERG. An iceberg that has broken off from an ice shelf. Also called *table iceberg*; formerly called *barrier iceberg*. Newly formed tabular icebergs have nearly vertical sides and flat tops. In the Antarctic, they may be tens of kilometers wide, up to 160 km (100 miles) long, and as much as 300 m (1000 ft) thick, with about 30 m (100 ft) exposed above the sea surface. In the Arctic, large icebergs of this type are called *ice islands*, but they are considerably smaller than the largest of the Antarctic variety. See also **Iceberg**; **Polar Research**; and **Water Resources**.

TACHYCARDIAS. Tachycardia means "fast heart rate" and refers to heart rates greater than 100 beats per minute. Tachycardias can be an appropriate response to exercise or other physiologic causes such fever. Other tachycardias can be inappropriate manifestations due to heart disease or problems with the intrinsic electrical system of the heart. Three mechanisms are thought to explain how tachycardias occur; *abnormal automaticity*, *reentry*, and *triggered activity*.

Automaticity refers to the spontaneous generation of impulses within a tissue. Automaticity is a property of all the heart tissues and is responsible for the normal pacemaker function of the heart. Metabolic abnormalities of cells in the atria, AV junction, or ventricles may cause an increase in the rate of spontaneous impulse formation. When this occurs, tachycardia occurs. A variety of illnesses and drugs can affect automaticity, but abnormal automaticity is thought to account for less than 10% of tachycardias. The most common automatic tachycardias are seen in acutely ill patients with underlying metabolic disease.

Reentry refers to the repetitive cycling of an impulse over a fixed circuit. In reentry, two roughly parallel conducting pathways with common origins connect to form a potential electrical circuit. Normally, impulses travel down the pathways side by side and therefore do not interfere with the rhythm. When a premature beat enters the circuit, however, the difference in conduction properties between the two pathways allows the impulse to travel down only one of the pathways. When the impulse reaches the intersection with the second pathway at the opposite end of the circuit where the pathways again intersect, the impulse travels backward up the second pathway to the intersection with the first pathway. The impulse then "reenters" the first pathway and travels back down it to restart the cycle. The continuously circulating impulse spins around and around the reentrant loop and overtakes the heart's rhythm when it exits the circuit during each lap. Reentrant circuits occur rather frequently both in normal and abnormal hearts, and some may be present at birth. Reentrant circuits may also be acquired as a result of cardiac damage, as is thought to be the case in many patients when ventricular tachycardia appears following a myocardial infarction. See also **Arrhythmias (Cardiac)**.

TACHYLYTE (or Tachylite). Pure tachylite is a natural, basic black glass, which may form along the chilled contacts of dikes or sills. It also occurs as a rind on basic pillow lavas that have been suddenly chilled by plunging into water. Occasionally it forms entire flows from certain Hawaiian volcanoes.

TACONITE. Term for the ferruginous cherts associated with the iron ores of Lake Superior district.

TACTICITY. The regularity of symmetry in the molecular arrangement of structure of a polymer molecule. Contrasts with random positioning of substituent groups along the polymer backbone, or random position with respect to one another of successive atoms in the backbone chain of a polymer molecule.

TACTILE ORGANS. Organs of touch. Sensory organs located at the surface of the body that are stimulated by pressure. The chief tactile organs of the human body are known as tactile corpuscles. They consist of an elliptical bulb about $\frac{1}{300}$ inch (0.008 centimeter) or less in length, enclosed in a connective tissue sheath and divided incompletely by plates of the same tissue. From one to several coarse nerve fibers enter the corpuscle and follow a winding course inside, ending between or on the connective tissue cells. These corpuscles are especially abundant in the skin of the finger tips and in other parts where the sense of touch is

highly developed, hence there can be no reasonable doubt that they serve this sense. They are related to other corpuscles of more limited occurrence which may also be tactile, and are supplemented in the skin by free nerve endings, some of them expanded into disk-like nets, which are regarded as tactile.

In many invertebrates hairlike projections at the surface of the body serve for ready reception of tactile stimuli and in the vertebrates true hairs, often bristlelike, transmit such stimuli to the nerve endings at their bases. From the sensitiveness of the human scalp to light contacts transmitted through erect hairs, it is easy to judge the value of these tactile hairs. They are well-illustrated by the whiskers or vibrissae of the cat and other mammals. See also **Sensory Organs**.

Tactile Feedback. It is common practice in electronic equipment today for designers to rely on coding and switching devices that provide the operator no tactile confirmation that a switch, for example, has been actuated. Shielded, surface-type switches are widely used in cash registers, microwave ranges, and industrial controls, where a switching action is not "felt" by the operator. For maximum assurance to the operator and thus to safety, many designers prefer to use mechanical-type switches that "click" or in some other tactile manner confirm the operation to the operator. Several types of switches offering tactile feedback are shown in Fig. 1.

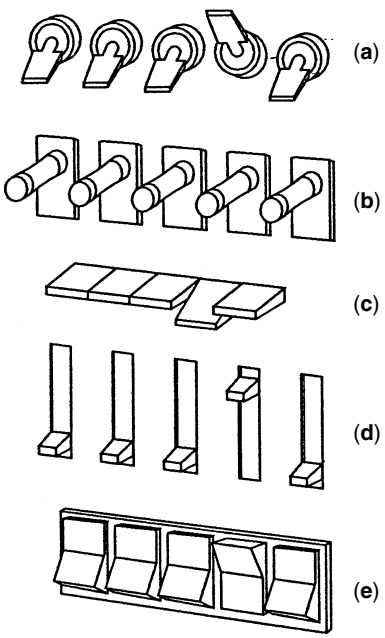

Fig. 1. Types of industrial switches that provide tactile feedback to the operator: (**a**) toggle, (**b**) push-pull, (**c**) paddle, (**d**) slide, and (**e**) rocker switches. (*Microswitch.*)

TALBOT LAW. The apparent brightness of an object viewed through a slotted-disk, rotating above a critical frequency, is proportional to the ratio, of the angular aperture of the opening to the opaque sectors.

TALC. [CAS: 14807-96-6] The mineral talc is a magnesium silicate corresponding to the formula $Mg_3Si_4O_{10}(OH)_2$ which occurs as foliated to fibrous masses, its monoclinic crystals being so rare as to be almost unknown. It has a perfect basal cleavage, the folia nonelastic although slightly flexible; it is sectile and very soft; hardness, 1; specific gravity, 2.5–2.8; luster, waxlike or pearly; color, white to gray or green; translucent to opaque. It has a distinctly greasy feel. Talc, soapstone, and steatite have been used by humans as raw materials since prehistoric times. Molds carved from soapstone were used in the Bronze Age and early Iron Age for casting weapons and tools. In the Mediterranean cultures of the classical period, stone carvings were made from soapstone, and talc was used for treating wounds and in the production of cosmetic powder. In ancient Rome, women used large amounts of powder and rouge. The properties of talc, especially its characteristic greasy feel, were described by Pliny the Elder. The old Arabic word *talq*, which indicates its greasy nature, gave its name to the mineral. In 1550, Catherin de Medici made it once again fashionable to use facial makeup in the form of powdered talc colored by the addition of pigments, a fashion that found innumerable imitators and has continued without interruption until today.

Talc is formed under hydrothermal conditions and is a typical mineral of weaker regional metamorphism (regional dynamo-thermometamorphism). It often occurs in association with chlorite, serpentine, or magnesite.

The main parent rocks that undergo metamorphic mineral reactions leading to talc formation are either (± magnesite-bearing) siliceous dolomites, or olivine- and/or pyroxene- containing ultrabasics. In ultrabasic rocks, talc is often a product of hydrothermal alteration (autometasomatism).

In commercially important deposits, talc occurs in association with tremolite, calcite, quartz, and dolomite, as the product of a more intense regional metamorphism of siliceous dolomites, and with forsterite and anthophyllite due to intense regional metamorphic overprint of ultrabasics. However, talc can also be observed as an authigenic new formation, e.g., in sandy sediments and salt deposits.

Other minerals that occur in association with talc include chlorites, mica, actinolite, feldspars, rutile, pyrrhotite, pyrite, magnetite, and hematite. Limonite, a product of the weathering of iron- containing minerals, especially iron- containing ore minerals, can often be found interspersed with talc.

Deposits

Deposits of talc are widely distributed and mined worldwide in regional metamorphic complexes. The important deposits in Europe are:

• Germany	• Göpfersgrün–Thierstein/Upper Palatinate, Schwarzenbach on the Saale
• Finland	• Central Finland (Lahnaslampi) near Sotkamo, Polvijärvi and Luikonlahti near Sola), Karelia
• France	• Pyrenees: Département Ariége (Trimouns near Luzenac)
• United Kingdom	• Shetland Isles (Baltasound, Unst), Cornwall (Polyphant)
• Italy	• Fontane/Region Pinerolo, Val Malenco/Region Sondrio, Sardinia (Orani and Nuoro District)
• Norway	• Nordland (Altermark), Sognefjord (Framfjord), Oppland (Lalm, Sel, Kvam)
• Austria	• Eastern Styria (Rabenwald, Lassing (closed in 1998), Weisskirchen, Kleinfeistritz, Oberfeistritz, Stubenberg, Anger)
• Sweden	• Handöls, Garpenberg
• Spain	• Provinces of Leon (Puebla de Lillo), Gerona (Pyrenees: Respina), Málaga (Fuengirola), Almeria (Purchena)

Important deposits occur in Canada (Madoc/Ontario and Van Reet/Quebec, which are mined in underground operations, and Penhorwood/Timmins, which is exploited by open-pit mining), the United States [deposits in 11 states; >80% of production from Texas: Allamore Talc District with Van Horn/Hudspeth County; also Montana: Yellowstone, Beaverhead, Treasure Chert; Vermont: Hammondville, Rainboro; California (trains carry talc from deposits in the south east to Nevada); New York State], Uruguay, Brazil (Paraná, Sao Paulo; Bahia: Serra das Eguas), Argentina, Australia (Three Springs, Mt. Seabrook/Western Australia; Mt. Fitton/South Australia), Japan (Hokkaido, Kyushu), the People's Republic of China (Haicheng), Taiwan, South Korea (Dongyang/Chungju region, other deposits in the Geangju, Yesan, Muju/Jinan regions), India (Rajasthan, Andhra Pradesh, Madhja Pradesh, Tamil Nadu, Bihar), and the former Soviet Union.

Processing and Quality Specifications

Depending on the geology and mineability of the deposits, talc is extracted either by open-pit mining after removal of the overburden rock layers or by underground mining. Explosives and pick axes are still used in some places, but today mining is mainly carried out mechanically with mobile cutters able to follow the talc body and produce a raw material that is already size reduced.

The processing of talc depends on the type of deposit. Commonly, the first step is selective mining, followed by flotation to separate the talc from other minerals (e.g., silicates and carbonates such as magnesite). Finally, the higher grades of talc are subjected to highly developed beneficiation processes (e.g., fine grinding, air classification).

Many common grades of talc powder are sold without grinding or sieving the mixture of minerals produced by the mine. The talc content then corresponds to the rock composition and is subject to quality variations arising both from the deposit itself and from the method of extraction (contamination with refuse rocks).

Finnish producers use flotation to treat their talc ore, which contains ca. 60% talc and ca. 40% associated minerals (mainly magnesite with some dolomite, and, in one deposit, a nickel ore containing ca. 0.2% Ni). The talc concentrate contains ca. 95% talc and 3–4% carbonate, the remainder consisting of other mineral impurities.

In the mine, talc or talc-containing mineral mixtures obtained in lump form are crushed with jaw crushers. If necessary, the talc ore is further size reduced with impact or hammer crushers. Grinding is carried out with high-speed impact mills, centrifugal swing-hammer mills, roller mills, tube mills with cylinder charging (cylindrical pebbles), and jet mills.

The following characteristics are typical of pure talc or of talc grades low in accompanying minerals:

- Hydrophobic, organophilic boundary layers parallel to the silicate layers
- Polar and chemosorptive boundary layers (surfaces) at the edges of the platelets
- and on the fracture surfaces (grinding process), with unsaturated valencies
- A corrosion-inhibiting pH of ca. 8.5
- A platelet-like, lamelliform structure with correspondingly large boundary layer (surface boundary; ratio of the area of the flat surfaces of sheet silicate layers to that of the edges is 200:1)
- Barrier action against diffusion of gases and capillary water
- Morphology-dependent pseudoplasticity
- High electrical surface resistance and bulk resistance
- Low dielectric loss angle
- UV absorption
- Resistance to strong acids and alkalis

The increase in boundary layer (boundary surface) that accompanies increasing fineness of grinding accentuates the typical properties of talc. Mineral impurities lower the quality of talc or talc products, as these impurities do not generally exhibit the properties typical of talc. If the mixture of minerals has a talc content of $\leq$50%, it is no longer regarded as talc according to DIN and ISO definitions. If the talc mixture contains $\geq$50% chlorite, it is known as "chlorite, talc-containing" according to DIN 55 629. A product containing <70% talc was at one time known as asbestine

Uses

The users of talc in the order of consumption volume are the paper industry, ceramics, plastics, paints, roofing and sealants, cosmetics and pharmaceuticals, and agrochemicals, followed by several other smaller consumers.

Some of talc's distinguishing attributes permit its wide use as a filler: smoothness, opacity, porosity, high sheet retention, low abrasion, low yellow index score.

Paper. In the manufacturing of paper talc is utilized as a filler, for deposit control, and for coating. Paper coatings profit from talc's naturally high brightness, platy structure and its beneficial properties concerning reduced friction, superior printability, gloss and smoothness. In resin control, the hydrophobic talc particles adhere to the resin and render it harmless. In the paper industry talc has lost some of the market share to cheaper competitors, largely to precipitated and ground calcium carbonate and, to a lesser extent, to kaolin.

Paints and Coatings. Talc is added to paints and coatings in order to produce the following effects:

- Control of the pseudoplasticity (important for processing)
- Ease of redispersion of sediments (important for coatings dispersed in water or other media)
- Improved adhesion to substrates
- Reduced diffusion through coating films (capillary water, gases)
- Synergy with inhibitor pigments (anticorrosion)
- Improved light scattering (especially in emulsion paints)
- Resistance to weathering and atmospheric influences
- Good dielectric properties

By combining platelet-like, flaky talc with needle-like silicates, such as amphiboles, wollastonite, xonotlite, sillimanite, and sintered mullite, interesting effects with regard to thixotrophy, close packing of particles, and elastic strengthening of the matrix can be produced.

The most important uses for talc as a filler in paints and coatings are in:

- Primer paints (based on polyvinyl butyral resin)
- Anticorrosion primer paints
- Undercoats and intermediate fillers
- Coil coatings and powder coatings
- Coatings for plastics
- Emulsion paints (especially one-coat paints), synthetic plasters, and fillers
- Epoxide–tar and polyurethane–tar coatings
- Bitumen coatings

Talc is used as a filler in a wide range of paints for domestic, industrial and protective coatings, because its particles reinforce paint, reduce sagging and give rise to a flattened coat and a smooth film. The amount of talc in paints ranges up to 30 wt%. Talc is the most common extender mineral in heavy duty applications (e.g., marine and protective coatings).

Plastics. Thermoplastics strengthened by the addition of talc to give improved tensile and transverse strength, modulus of elasticity, refractory properties, and dimensional stability are widely used as construction materials. The addition of talc has a very favorable effect on the mechanical properties and hence the serviceability of polypropylene and polyurethane.

As a filler in polypropylene it improves surface properties (e.g., scratch resistance). The filler content can be up to 40%. In the automotive industry polypropylene is used for dashboards, interior trim, bumpers, etc. Talc is also used to produce engineering thermoplastic resins (e.g., nylon compounds to replace aluminum parts in inlet manifolds).

Ceramics. Talc is used in traditional ceramics (e.g., 30–60% in tiles, hobbyware bodies) and in technical ceramics (e.g., main silicate mineral instead of clays and feldspar in lower grade alumina products: steatite and low-expansion cordierite ceramics). In traditional ceramics, the bodies are fired for over 12 h below 1179 °C (2154 °F) (below cone 2), and the porous bodies are then glazed and refired. For this application the talc should contain tremolite and carbonate because these minerals provide for enhanced pressing and permeability characteristics. Otherwise wollastonite must be added to purer talc to improve these properties.

Talc in the massive form known as steatite can be processed and formed directly by cutting and sawing, and in block form it can be used for thermal insulating and electroceramic products. Here, the important properties of talc are its low hardness (enabling it to be easily cut and shaped), the stability of cut products towards firing, and the very low degree of shrinkage, which means that the shaped raw material can be fired directly to porcelain.

Steatite ceramics are used in electrical insulating applications. Steatite must be extremely pure to obtain consistency and to exclude shrinkage. For producing these low-loss bodies, ca. 10% kaolin and 10% barium carbonate are added to this type of talc, which is fired at 1349–1355 °C (2460–2471 °F) (cone 12–13).

Cordierite ceramic bodies can be produced from a mixture containing pure talc (44%), kaolin (41%) and alumina (15%) or from a 1:1 mixture of kaolin and chlorite (chloritic talc). The manufacturing of these ceramics, utilized for automotive catalyst supports, is more expensive because of the higher firing temperatures.

Other Uses. For many other uses, talc is first ground. Powdered talc is used as a lubricant or polishing agent, in pastels, as a filler in the pigment industry, in cosmetics (face powder), as an additive for soaps, in paper production, as a finishing agent in the textile industry, as a filler and glazing agent in a wide range of industries, as a filler in the plastics and rubber industries, as coating for rubber products to avoid sticking and in asphalt processing.

Talc is used as an *antiblocking agent* for plastic films, for example to facilitate the opening of plastic bags such as those used for fruits and vegetables in supermarkets. For these applications a pure white talc, which is used in amounts of up to 2 kg/t, with an ultrafine size of 4 μm, is required to maintain the film color and transparency. Here talc is in competition with two cheaper rivals, namely, diatomaceous earth and synthetic silica. Sophisticated processing is required to obtain ultrafine (<10 μm) grades of talc, and only a few producers are able to supply these.

A limited amount of talc (<2% of world mine production) is utilized in the *cosmetic industry*, mostly for body talcs (its pH and surface area permit it to act as a perfume carrier) but also as a filler in solid antiperspirant sticks, giving good skin slip, and in color cosmetics. Talc provides cosmetics with stability, texture, skin adhesion, slip, and water resistance. Micronized material with a grain size of <5 μm is used in compressed products to prevent trapped air from impairing the quality. In some applications talc is treated with hydrophobic coatings.

The amount of pure high-value talc which is consumed by the *pharmaceutical industry* is very limited. Furthermore, this talc quality requires sophisticated processing to remove all impurities (e.g., accessory minerals, carbon, iron oxide, base metal traces) and special treatments (e.g., cleaning with dilute hydrochloric acid, washing, drying, sterilization by heating to 160 °C (320 °F) or exposure to gamma radiation or ethylene oxide). The main applications of talc are dusting (90–99% talc) and in tablets (1–10% talc as a glidant or lubricant, 5–30% talc as a diluent). Talc must not be used to dust surgical gloves because it can contaminate wounds.

In *agriculture*, talc satisfies all criteria (inertness, compatibility with the active ingredient, fineness, and low abrasiveness to equipment) required of a dry carrier for pesticides, fertilizers, herbicides, fungicides, and insecticides. It is used in granules and wettable powders but not in liquid formulations. In these applications, talc competes with other materials, such as fuller's earth, kaolin, diatomite, perlite, gypsum and sepiolite. The largest consumer of talc (commonly of low grade with 95% <325 mesh) is for pesticides.

In *animal feeds*, talc is used as an anticaking coating in feed bins and as a coating on the feed itself. Since talc is nontoxic, it is harmless and poses no danger to livestock. Its hydrophobicity prevents water loss and absorption. Furthermore, it protects the products and enables free flowing through the production and packaging plant. The amount of talc in animal feed is up to 1–2% in meal and up to 0.3–0.5% in pellets.

Roofing applications exploit talc (commonly <80 mesh, passing 180 μm) as a stabilizer for the asphalt of tar paper, asphalt shingles, and roll roofing; it improves weathering and fire resistance.

A mixture of talc and chlorite with a specific size distribution, developed by Talc de Luzenac, improves the separation of waste from the water in biological *wastewater treatment* plants.

In the *rubber industry*, talc in fine grades and free of impurities is utilized mostly to lubricate molds, to prevent surfaces from sticking together, and as a mold release agent since it maintains its lubricating properties at high temperatures. As a rubber filler, talc is in carpet backing, valves, and cable insulation but is not suitable for tire manufacturing because of its low hardness and platy cleavage.

Some *minor applications* of talc are the sealant industry (e.g., joint compounds, dry wall compounds, butyl caulks, polyurethane sealants), sculpturing (e.g., steatite and soapstone for producing decorative articles), food (e.g., preparation, mostly polishing, of foodstuffs including cereals and rice, coating of chewing gum to avoid sheets sticking together) and polishing (when good color and limited abrasion is required, such as shoe, floor, and car polishing).

Health and Safety

Pure talc is toxicologically harmless. However, where there are high concentrations of dust in the air, face masks should be worn. If the talc contains detectable amounts of asbestos or asbestos minerals, an MAK value of 2.0 mg/m^3 applies. Talc is a nontoxic, inert substance or raw material, but it can contaminate wounds and if inhaled it can cause lung irritations.

TALL OIL. [CAS: 8002-26-4]. *Tall* is the Swedish word for pine, and the term tall oil is an American adaptation of *tallolja,* a Swedish product name associated with the kraft pulping process and with products from the fractional distillation of crude tall oil.

Pine wood contains an extractable fraction, ≈3%, consisting of free and combined fatty and rosin acids and nonacidic compounds (tall oil components). In the alkaline pulping process the tall oil components are saponified into a soapy material that, when acidulated, gives a mixture of free rosin and fatty acids and neutral components — crude tall oil (CTO). CTO is refined mainly by vacuum distillation processes to separate the various compounds almost completely into rosin and fatty acid fractions.

The *rosin* part of CTO is a complex mixture of rosin acids, a three-ring fused system with the empirical formula $C_{20}H_{30}O_2$. The tall oil *fatty acids*, primarily C_{18} types, are similar in composition to those derived from soybean oil. The *neutral constituents* of tall oil — predominantly esters, sterols, and hydrocarbons — are generally regarded as troublesome "impurities" that impair its utilization and distillation.

Abbreviations of basic tall oil names and common analyses often used in publications and reports are: Crude tall oil (CTO); Tall oil fatty acids (TOFA) [CAS: 61790-12-3]; Tall oil rosin (TOR) [CAS: 8052-10-6]; Distilled tall oil (DTO) [CAS: 8002-26-4]; Tall oil pitch (TOP) [CAS: 8016-81-7]; and Heads, light ends (H) [CAS: 65997-03-7].

CTO as Byproduct and Raw Material

The kraft pulping process was developed late in the 19th century. Some years later it was discovered in Sweden that a product similar to oil or wood tar could be obtained when the soapy material was acidulated with sulfuric acid. The recovery of byproducts from the kraft pulping process is shown in Figure 1.

Tall Oil Precursor in Pine Wood. Exploitation of the original tall oil materials in pine wood in the form of products such as tar and pitch dates from centuries B.C. Gum and wood rosin are still produced, and compete with the rosin fraction, tall oil resin (TOR), derived from CTO.

Products such as gum rosin, and turpentine oil fractions (distillates) obtained by distillation of exuded oleoresin from wounded living trees are still of high volume and importance. However, gum rosin production in the United States has declined to almost zero today owing to the lack of affordable labor. Extraction of products such as wood rosin and turpentine fractions from stumps rich in rosin and liquid gum has declined because of the shortage of stumps.

Replacement of Original Products by Tall Oil. The production of CTO as a byproduct of the kraft pulping process and the subsequent refining of CTO have supplied important and renewable resources such as

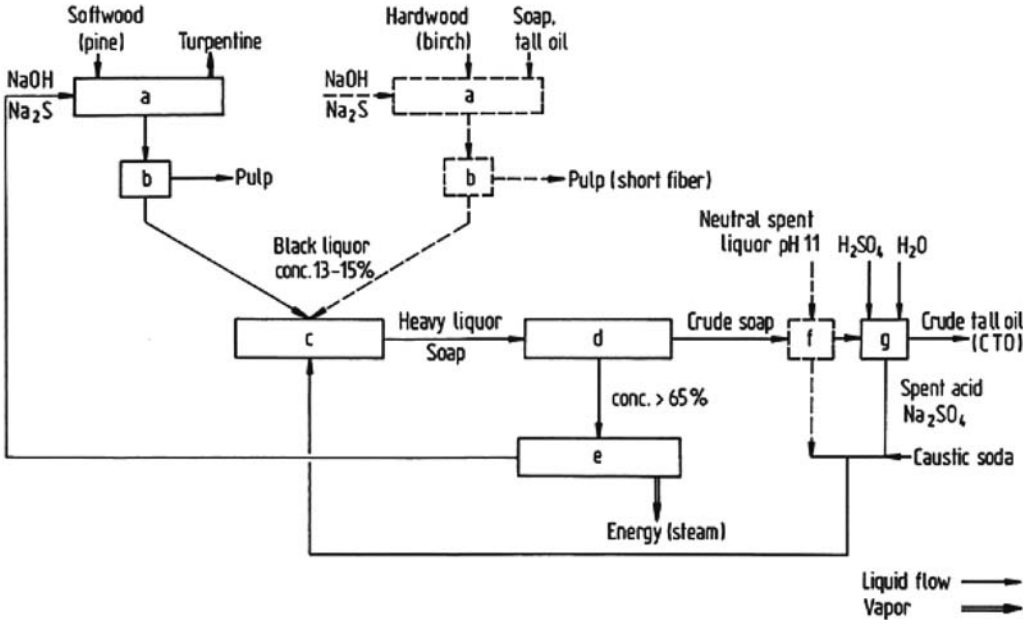

Fig. 1. Recovery of byproducts from the kraft pulping process a) Digester; b) Filter; c) Evaporator; d) Settling tank; e) Chemical recovery, energy production; f) Washing; g) Reactor.

tall oil rosins and tall oil fatty acids as two basic chemical raw materials. The decreasing supply of wood and gum rosin in the United States is well compensated by the TOR production, which has increased proportionally to pulp production.

Tall Oil in Wood. The extractable portion of wood differs chemically, in part, from the compounds found in the CTO product. The chemical changes occurring during various processing steps are shown in Figure 2. Examples of composition of the extract from different wood species are listed in Table 1.

TABLE 1. COMPOSITION OF THE EXTRACT FROM DIFFERENT WOOD SPECIES

Compounds	Pine	Spruce	Birch
Esters,%	40	43	58
Free fatty acids,%	18	10	6
Free rosin acids,%	34	25	0
Total,%	92	78	64

Composition and Properties of CTO. The wide range of compositions and properties of crude tall oil on the market can be explained and understood from the chemistry of tall oil. Many tall oil components are sensitive to chemical reactions and changes in properties and composition. The use of wood species other than pine [e.g., spruce and hard wood (birch)] in the kraft pulping process lowers the yield of CTO and the selection of available fatty and rosin acids. It also changes the composition and properties of the CTO. The quality and yield of CTO from the kraft pulping process consequently depend on many variables such as type and length of wood storage, season of the year, amount of wood residue used, hardwood usage, and type of pulping employed.

Crude tall oil is a dark brown, tarlike product; its odor, influenced by sulfur components from pulp processing and soap skimming/acidulation, is unpleasant and penetrating. The three main constituent groups — fatty acids, rosin acids, and neutral materials (unsaps) — vary widely in composition, depending on the wood's origin. See Table 2. The saponification number (SN) of CTO is always higher than the acid number (AN) because of the unsplit esters in the crude oil. The difference increases for lower qualities, indicating less available rosin and fatty acids.

TABLE 2. PRIMARY CONSTITUENTS OF TALL OIL IN DIFFERENT WOOD SPECIES

Extractives, %	Fatty acids, kg/t wood	Rosin acids, kg/t wood	Unsap*, kg/t wood
Pine ≫ 3	15–20	5–10	2–5
Spruce ≫ 1	4–8	1–2	1–3
Birch ≫ 2	12–18		5–10

[a] Unsaponifiables.

The crude is normally transported and stored at 50–80 °C (122–176 °F) to avoid crystallization and settling of rosin acids. The viscosity of the

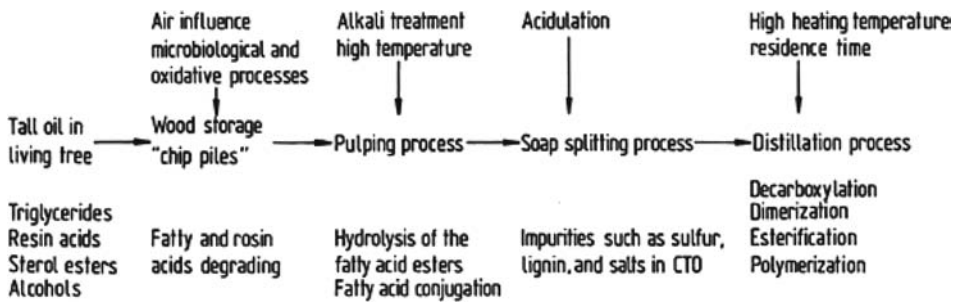

Fig. 2. Chemical changes in tall oil during processing.

crude is variable; it is mainly a function of the rosin content. Viscosity must be measured on a clear, noncrystallized product. Impurities such as lignin, soap residue, water–oil emulsions, sodium salts, and sulfuric acid occur in the product. The amount of these undesirable materials depends on the efficiency of the soap washing and splitting process. Sour components such as sulfuric acid in the separated brine and degassed sour vapors from heated CTO in storage tanks impart the crude corrosive properties. The physical properties of tall oil (empirical values) are; boil-up temperature (at 1.33 kPa) 180–270 °C (356–518 °F), heat of vaporization 290–330 kJ/kg, specific heat 2.1–2.9 J/g, heat of combustion,–(33 000–38 000) kJ/kg, density (at 20 °C (68 °F)) 950–1020 kg/m^3, liquid viscosity (at 70 °C (158 °F)).

Typical data and composition of crude tall oil are presented in Table 3.

During the kraft pulping process, CTO precursors are hydrolyzed to soluble sodium soaps in the cooking liquor. The soap and spent cooking liquor (black liquor) are washed and filtered from the pulp and concentrated in multipleeffect evaporators from 13–15% to >65% solids. Evaporation increases the solids content so much that the soap — contaminated with black liquor to a greater or lesser extent — precipitates and rises continuously to the surface of the upgraded liquors in skimming tanks connected to the evaporation process. When the soap is skimmed from the top of the black liquor tanks, contamination of the soap with some black liquor is unavoidable. The major part of this black liquor containing about 10% lignin should be removed. Otherwise, precipitation of the lignin and gypsum (gypsum is formed because of the presence of calcium in the black liquor) will occur during subsequent acidulation. Good decantation or separation of the soap is thus important. A low black liquor content of the soap decreases acid consumption and the amount of toxic hydrogen sulfide and carbon dioxide released during acidulation. In addition, soap present in black liquor and in the heavy black liquor (i.e., concentrated black liquor) decreases the capacity of both the evaporator system and the recovery boiler.

The *splitting* or *acidulation process* is a chemical reaction between the sodium soaps and sulfuric acid. The tall oil soap is converted into free fatty and rosin acids by reaction with dilute sulfuric acid (ca. 30%) at elevated temperature (ca. 98 °C). The reaction can be summarized as follows:

$$2\mathrm{RCOONa} + \mathrm{H_2SO_4} \rightarrow \mathrm{Na_2SO_4} + 2\mathrm{RCOOH}$$

where R denotes a rosin or fatty acid alkyl group.

Three phases are formed during the reaction: liberated tall oil, a lignin–fiber phase, and the spent acid phase (Na_2SO_4, free H_2SO_4). The phases can be separated because of their different densities. The splitting process is performed either batchwise or continuously. In both cases the equipment must be made of acid-proof material, able to resist dilute sulfuric acid (spent acid or brine) at 90–100 °C. A pH of 2.5–3.5 is normal for complete reaction with a minimum of equipment corrosion. The Hedemora–Celleco continuous tall oil system is shown in Figure 3.

Upgrading of Soap Extraction (Crude Soap Refining Process). On a limited scale, crude birch–pine soap is upgraded by extraction of neutrals before acidulation. The crude soap refining (CSR) process developed by Holmbom and Avela in Finland yields not only a cleaner CTO but also commercial compounds such as sitosterols, terpenes, and aliphatic alcohols from the extracted neutrals. This upgrading process has been in operation since 1977 (Kaukas, Finland).

Uses
